# Fire Environment In Counterflow Ventilation <br> (The In-flight Aircraft Cabin Fire Problem) 

B.J. McCaffrey and W.J. Rinkinen

## Abstract

Using propane gas burning in a diffusive mode, fire sources up to the equivalent heat release rate of a fully involved seat were simulated in an approximately $1 / 2$-scale closed section of a ventilated wide-body aircraft cabin. The ventilation flow direction was as in commercial practice-counter to that of the buoyancy driven fire gases, i.e., fresh air was forced in at the top of the enclosure and drawn out at the bottom. Results for the $1 / 2$. scale system indicate that for nominal ventilation rates, significant enthalpy exchange through ventilation in times corresponding to a few airchanges is limited. That is, only a small proportion of the energy release rate of the fire is getting exhausted. These results will depend on time, it may not be a general conclusion. Also the time response of the aircraft cabin material may be different than this experimental facility, and a complete dimensionless variable analysis might suggest different time scales, full to $1 / 2$ scale. Correlations of thermal conditions in the enclosure as a function of time, heat release rate of the fire, and position in the cabin are presented. Semiinfinite transient conduction models appear adequate in capturing the essential features of the fire plume-ceiling thermal interaction. Reduced
data for the entire test series will be made available for future cabin modelling purposes. Data from one typical experiment is included in the appendix of the present report. The others will be made available through NTIS and for the near term on the CFR Electronic Bulletin Board. (CFRBBS: 24 hrs/day, 7 days/wk, 301-921-6302)

### 1.0 Introduction

The effects of normal aircraft ventilation on the growth of an incipient inflight fire as well as on the spread of smoke and toxic products in the cabin are at present not known to any reliable, empirically-based degree. Because of the lack of good information no guidelines are available to a flight crew concerning possible mitigative actions to be initiated regarding cabin ventilation when they are confronted with an on-board fire incident. In an effort to establish the necessary data base the Federal Aviation Administration has recently begun studies both at their laboratories and through contracts with various fire research organizations aimed at elucidating the phenomena and gaining the required scientific understanding. Not only will these studies offer near-term benefit, for example, insight for recommendations and guidelines for crew action in the event of fire, but they should in addition offer the rational basis for estimating the possible benefits of proposed future design changes, for example, emergency venting of smoke.

One such study, the subject of this report, is taking place at the Center for Fire Research (CFR), National Bureau of Standards. This study involves an experimental program in a $1 / 2$-scale section of a wide body simulated aircraft, exactly addressing the effects of ventilation on the fire environment. (Aircraft cabins are generally ventilated from top to bottom. Fresh air is forced in at the ceiling of the fuselage and exhausted near the floor. Fires create hot gases with buoyant forces which are in the opposite direction from that of the ventilation flow. The inability to analytically characterize the resulting large scale eddy mixing process is responsible for the uncertainty surrounding the fire question.)

This report looks at the major thermal effects and addresses the following tasks:
i) the design and instrumentation of a test article simulating the interior and ventilation pattern present in commercial aircraft;
ii) the collecting of the necessary data required to thoroughly determine the effects of "counterflow" ventilation on fire growth and spread;
iii) heat transfer to the ceiling of the test article. It became apparent soon after the initiation of the study that a major portion of the energy release rate of the fire was not getting exhausted through the floor vents. Rather, the energy was
being transferred to the ceiling, and hence it was necessary to study carefully the implications of that heat transfer.

A description of the test article will be presented along with the results of a systematic study of the thermal environment resulting from a constant heat release rate fire in a closed chamber ventilated in a counterflow direction, i.e., from top to bottom, at air exchange rates equivalent to those encountered in a commercial aircraft. (Throughout this study it must be kept in mind that only trends and phenomena are being investigated. Caution must be exercised in interpreting the small scale measurements. For example in the case of exchange rates, Froude number scaling analysis would yield differences of $\sqrt{ } 2$ in event times between model and full scale. See Quintiere (1978) for a full discussion of this point.)

Surprisingly in the past there have been few studies which have attempted to predict the fire enviroment in a moderately sealed enclosure for any sort of forced ventilation. For aircraft specifically, Sarkos and Hill (1985) noted substantial differences in hazard histories at different points throughout the cabin between a controlled ventilation, in-flight fire scenario case (the present configuration) compared with the postcrash tests where the cabin was ventilated naturally through fuselage openings. Apparently because of mixing the former tended to distribute the seat fire hazards throughout the airplane, i.e. hazard conditions existed at a station as much as 12 m ( 40 ft ) from the source at an elevation as low as 1.7 m (5 ft 6 in ) prior to flashover. In contrast hazardous conditions were limited to the ceiling layer in the naturally ventilated, post crash test up until the point of flashover.

Up until very recently calculations involving numerical solutions of the conservation equations with radiation and elaborate turbulence models, quite successful in reasonably high velocity, forced convective flows, have not yielded the same kinds of successes for highly buoyant, low speed flows. The large scale structure responsible for the major share of the mixing has not been properly modelled. DeSouza, Yang and Lloyd (1985) in a two-dimensional calculation show that flows with velocities equal to $0.1 \mathrm{~m} / \mathrm{s}$ have little effect and flows at $1 \mathrm{~m} / \mathrm{s}$ have drastic effects on the stability of the hot upper layer. Unfortunately, there are non-negligible three-dimensional effects associated with the flow field and the actual aircraft flow velocities fall precisely between these two extremes. Mitler (1984) has attempted forced ventilation calculations using zone models and indicates clearly the weaknesses of that approach because of the lack of a good mixing algorithm for the incoming stream. Finally, using a well-stirred reactor analysis Eklund (1984 a,b) has shown the importance of ventilation with regard to fire hazard development including visibility.

One experimental study of fire growth in a sealed container with ventilation, worth noting, is that of a nuclear containment vessel at the Lawrance Livermore National Laboratory, the resulting correlations presented by Foote, Pagni, and Alvares (1986). In that study the representative upper level gas temperature rise varied with the ventilation flow rate to a not immodest -0.36 power. Cox, Kumar, and Markatos (1986) were able to do a reasonable job in reproducing some of these results using more modern three-dimensional field modelling techniques. Unfortunately however, their ventilation flow direction
was in the same direction as the buoyant flow, i.e., in at the bottom and out at the top, the same direction as the normally generated flows due to the fire - the hot gases simply get pushed along by the vent flow.

There appears to be no systematic study in the literature of the desired configuration. Evidence suggests that mixing of the upper layer is significant (Sarkos and Hill 1985) and for the reversely ventilated (in at the bottom-out at the top) case the thermal environment is medium to strongly dependent on the ventilation rate. For the counterflow situation, the direction of interest here, little guidelines exist - the present experimental program was carried out to fill this void.

### 2.0 Experimental

A view of one-half of the test article is shown schematically in Fig. 1. It is constructed of two symmetrical chambers built on a raised frame with wheels so that the interior could be accessed easily, and with the two halves clamped together forms a reasonably sealed enclosure. Each chamber is approximately 2.4 m long by 2.4 m wide by 1.2 m high ( $8 \times 8 \times 4 \mathrm{ft}$ ) thus simulating to approximately $1 / 2$-scale a closed section of aircraft $9.8 \mathrm{~m}(32 \mathrm{ft})$ long by 4.9 m (16 ft) wide by $2.4 \mathrm{~m}(8 \mathrm{ft})$ high. The skin is of 24 gauge ( 0.7 mm thick) galvanized sheet and the frame was constructed of $38 \times 38 \mathrm{~mm}$ and $51 \times 51 \mathrm{~mm}$ angle and channel members 3.2 mm thick of hot rolled, AISI C-1020 metal. The skin was riveted to the frame, and the joints, generally overlapped sheet, were sealed with high temperature silicone adhesives. High temperature gasket material was used in the clamped butted joint where the two chambers were
connected. The reproducibility of the seal after movement of the chambers could be determined by checking the pressure transducer reading at a given ventilation flow rate. Windows in the walls provided visual observation of the fire behavior.

The floor and ceiling were composed of sheets of calcium silicate board ("marinite") which, positioned approximately 10 cm off the skin, formed a plenum with slit openings to provide for the airflow, as shown in figure 1. Fresh air is pumped from the laboratory into a top center aperture in both halves of the box. It fills the plenum and flows out more or less uniformly, since the slit area is a small fraction of the plenum cross section. The air flows out of the two slits in the marinite for either of the two configurations 'wall' or 'central' into the cabin proper. At the floor the air flows out through the slits into the lower plenum and is collected through two apertures in the bottom skin and continues out of the building through ducting. The two apertures in the bottom skin are exact replicas of those in the top skin. Fans located upstream of the top aperture provide flow and positive pressure in the box. The building exhaust system provides slight negative pressure near the outlet of the ducts leading from the bottom apertures.

The table in the Appendix provides the complete list of instruments and the correspondence with locations and instrument type can be determined from Figure 1. Not shown on the figura are the inlet airflow velocity measurements, cabin pressure relative to the laboratory, gas sampling instruments and smoke meters.

For the work reported here both fire size (a steady flow of $\mathrm{C}_{3} \mathrm{H}_{8}$ through a 0.15 m diameter glass bead burner located at the floor. Fig l) and ventilation were steady in time. The procedure was quite straightforward. The ventilation fans were started and flow rates selected and several minutes were allotted before steady conditions were assured. At that point the computer was started, instructing the data scanner to begin reading the various channels and writing the data to memory. After about one minute of data taking the ignition system was activated and the propane flow rate was set to the desired constant heat release rate value. The remainder of the experimental procedure consisted in simply waiting for the desired run duration time to elapse.

Most of the initial study consisted of experiments performed in an empty enclosure. In order to evaluate the effect of additional thermal energy storage capacity in the cabin simulated seats were constructed and placed symmetrically in the cabin since it turned out that a large fraction of the fire heat release was not being exhausted. In addition the effects on the environment of any large scale fluid motion could possibly be evaluated since blockage due to the presence of the seats would provide a different cabin flow pattern. They were 32 in number and consisted of bent sheets of aluminum with the seat and back composed of 13 mm thick sheets of marinite (Fig. 2). If required, material with different thermal capacitance could be accommodated.

### 3.0 Results

Table 1 presents the set of experiments for the thermal environment portion of the study and gives condition of ventilation in terms of time for one air exchange, i.e., $4.9 \times 2.4 \times 1.2 \mathrm{~m}^{3}$; ceiling ventilation position, either at the wall or at positions 0.6 m in from the wall (see Fig. l); heat release rate and seating configuration.

The complete set of reduced data for one run, F1202 is shown in the Appendix. Data in the same form i.e. 2-D arrays of time in seconds, and instrument output, reduced to appropriate engineering units, is available for the entire test series. Since the experimental set-up regarding ventilation direction in a closed space is rather unique this data ought to be valuable regarding future modelling efforts, especially in validating three dimensional turbulent mixing schemes that are designed for handing large coherent eddy structures.

The results will show first the effect of ventilation rate on the environment in the cabin for a fixed fire size and vent location. The vent position will then be changed and the effect noted. The next section contains the work relating to the effect of the fire size for a fixed ventilation rate and contains considerable analysis of ceiling heat transfer rates in order that the results may be generalized to different materials and scale. Finally a section on stratification completes the thermal portion of the study.

Ventilation rates varied from 2 to $41 / 2$ minutes as the time for one volume airchange. Keep in mind any scale factor when interpreting these rates for
full scale. These are consistent with specification values for the commercial fleet. It was not necessary to vary the rate (nor the inlet position) beyond these limits because of the nature of the results - the buoyancy forces of the fire were dominating over ventilation as regards exhausting enthalpy. The extent of mixing however may depend on the venting rate and position.

Heat release rates varied from 6 to 60 kW in the experiments or if Froude number scaling is assumed, 30 to 350 kW . This would correspond to full scale heat release rates of 2 raised to the $5 / 2$ power. The 350 kW fire is representative of about a fully involved seat fire.

Table 1: Experiment Parameters

|  | Ventilation <br> Exchange <br> Time (min.) | Ventilation <br> Inlet <br> Location | Heat Release <br> Rate <br> (kW) | Seating <br> Configura <br> tion |
| :--- | :--- | :--- | :--- | :--- |

| F1903 | 2.4 | CENTRAL | 40 | None |
| F2603 | 2.4 | CENTRAL | 60 | None |
| F0206 | 2.4 |  | 30 | 32 Seats |

The set of graphs of the data, contained in the appendix, is typical for all the tests. They are for F 1202 , an intermediate fire size and ventilation level, flow being through the "wall" and there are no seats. The first four
figures Fig. 3 - 6, are for the thermocouple trees or gas temperature around the cabin. They rise rapidly as the fire is turned on, somewhere near the 60 s point, and except for their level the behavior in time of all the trees is nearly identical - no transit delay time could be ascertained. (The TC's are visually protected from any flame radiation by their angular location relative to the support rod.) The front of the thermal wave is moving at meters per second and hence only if the TC's were being sampled at a rate such that the time between scans is less than one second could transit times be picked up. Obviously in a real situation where the aspect ratio could involve the entire length of the aircraft, spatial variation will become a factor. Phenomenologically however this should not create a problem - the same things will be happening at later times downstream.

The actual level of temperatures in different parts of the cabin will be discussed in the section on the effect of fire size. Not surprisingly the TC closest to the ceiling reaches the highest temperature and the furthest away or lowest reaches the lowest temperature with the remainders ranked accordingly. The glaring exception, TC $1 \& 2$ on tree $A$, can be explained by structural blockage (see section on upper level gas temperatures). This is an important point. In spite of the external ventilation which will cause mixing and stirring, the upper layer is perfectly stratified; $d T / d z$ is everywhere positive. From the figures $3-6$ it can be seen that as the fire is turned off the high to low ranking remains in spite of the fact that the ventilation is running. The ventilation can not overcome the residual buoyancy in the gases - the cabin is still stratified. One however can argue that the difference between high and low in that case may not be very significant.

The point of all this speculation about stirring has to do with the ability of the ventilation system to flush out adequately smoke and hot gases from the cabin during a fire situation. Recall the exhaust is going out at the floor level. If the buoyancy of the fire gases is such that only relatively cool and clean air is remaining near the floor then the system cannot be expected to perform adequately. What size of buoyant forces, or fire condition can overcome the plane's ventilation system will need to be addressed. A small smoldering fire (like a whole group of smokers) can obviously be handled by the present system, however it is not clear whether or not toxic products associated with the fire-cabin scenario seen on Figs. 3- 6 could be adequately flushed from the cabin in a reasonable amount of time using the same ventilation system.

Fig. 7 shows the temperature of the thermocouples located in the two ventilation exhaust lines and confirms the contention made above that only cool gas is being removed in times of interest for this case. The level has hardly reached $50^{\circ} \mathrm{C}$ at 450 seconds, when the fire has been turned off. (Fig. 7 and the previous figures indicate significant thermal stratification, in themselves however they cannot indicate the level of mixing of conserved species.) The much more gradual rise in time vs the gas temperature behavior in Fig. 7 indicates the delay in "filling" the entire cabin from the top down before any warm gas appears in the exhaust.

Next, on Fig. 8, are the time history of the ceiling TC's which like the gas temperature show a rapid rise in temperature. These are TC's peened into the
marinite ceiling and offer a reasonable measure of surface temperature rise with time. The level of temperature attained will vary inversely with distance from the fire. They are exposed to the full brunt of the fire plume gases and will be critical in determining heat transfer rates later in the analysis.

Fig. 9 contains the traces of the output of four TC's mounted on the inside walls at various positions around the cabin. The time histories are notably different from the gas and ceiling time history in regards rapid temperature rise and exhibit more the characteristic of the exhaust gases but at higher temperature levels. These TC's are fastened to the metal walls with screws and their slower response vs the ceiling ought to be attributed to the lower convective coefficient due to lower gas velocities on the sidewalls, a finite filling time to bring hot gases to the lower position on the walls and finally the high thermal conductivity of the wall material. Additionally, for the "wall" ventilation configuration the flow field is rather complex with the cold jet running down the side along with a portion of the ceiling jet which due to sufficient momentum has made the turn and starts heading downward adjacent to the measuring station. The last effect can be checked with the results of a "central" ventilation run which ought to present a different local flow velocity to the probe. Comparison of Fig. 9 with its counterpart for run F0403, identical to F1202 except for location of the vent inlet, shows little difference in temperature signal.

Wall temperature and heat transfer from exterior measurements can be seen on Figs. $10 \& 11$ which show on the same scale, gauge heat flux in $\mathrm{kW} / \mathrm{m}^{2}$ and
temperature rise above ambient. There is a pair of signals for each of the four stations, the smoother of the two is the thermopile temperature output. Note before the fire is turned on there are some non-zero signals. Prior to this run, an experiment took place and even after the period of time allowed for cooling, the box still retained some small differential energy. For single runs in a day these transducers registered negligible initial signal. The time histories seen on Figs. $10 \& 11$ are similar to those seen on the interior thermocouples, Fig. 9. The data seen on Figs. $10 \& 11$ can be used for validating heat transfer model calculation for these wall flows.

Fig. 12 shows the output of the velocity measuring transducers in the inlet ventilation ducts converted to volumetric flowrate and the static differential pressure measurement, cabin to laboratory. The velocity profile across the duct has been measured and documented and the use of a single centerline measurement corrected accordingly. The non-uniformity of the flow signals represent asymmetry between the two halves of the enclosure as do the two exhaust temperature measurements on Fig. 7.

The behavior of the enclosure regarding pressure is interesting. As the fire is turned on the spike in pressure signal due to expansion is clearly evident. As heat is added continually at a constant rate it takes quite a while for the cabin to equilibrate back to the initial, prior to fire, value. During other tests with smaller fires and hence longer running times that equilibration was assured to a high degree of accuracy. There is no doubt as to when the fire is turned off as a mirror image of the process occurs. There are analyses available which predict pressure rise in closed vessels due to the onset of a
fire using simple First Law Thermodynamic concepts. Fig. 12 may be used to validate those with "small leaks" for pressure equilibration.

The above offers a sampling of the kinds of data that have been obtained and is available for modelers interested in this configuration. The remainder of the report presents detailed analyses appropriate to the problem at hand, namely the effect of aircraft ventilation on the fire environment.

### 3.1 Effect of Ventilation Rate and Position on Gas <br> Ceiling, and Wall Temperature

At a fixed fire size ( 30 kW ) there results little change in either gas temperature (Figs. $13 \& 14$ ) or in ceiling or wall temperature (Figs. $15,16 \&$ 17) due to changes in the air exchange rate from $4 \frac{1}{2}$ min to 2 min per airchange. (Note that unlike Figs. 3 through 12, for the remaining graphs the identification numbers on the right hand side of the curves do not necessarily correspond to the channel numbers). In fact the wall heat transfer rates (Fig. 16, 17) are just slightly higher in the higher exchange rate case perhaps due to better contact of the hot gases with the wall surface. The bulk gas temperatures (Fig. 13, 14) themselves however, appear to follow the more intuitive direction, i.e. higher level temperature for lower flow rates.

Fig. 18 shows the exhaust flow thermocouple readings for the high and low flow rates. There are two exhaust positions and hence two traces per experiment. One can easily do a quick calculation of the enthalpy leaving in the exhaust gases. The enclosure volume is $4 \times 8 \times 16 \mathrm{ft}^{3},\left(14.5 \mathrm{~m}^{3}\right)$ or for the 2 min .
exchange rate, the volume flow rate is $14.5 / 2 / 60=0.12 \mathrm{~m}^{3} / \mathrm{s}$. At about 540 s , as the fire is turned off, the maximum temperature rise for the 2 min. case is about 25 K . Hence

$$
\mathrm{Q}=\dot{\mathrm{V}} \rho \mathrm{C}_{\mathrm{p}} \Delta \mathrm{~T}=0.12 \mathrm{x} 1.2 \times 1 \times 1 \times 25=3.6 \mathrm{~kW}
$$

(using properties of room air, $\rho=1.2 \mathrm{~kg} / \mathrm{m}^{3} ; \mathrm{C}_{\mathrm{p}}=1 \mathrm{~kJ} / \mathrm{kg} \cdot \mathrm{K}$ ). For the 4.5 min. case, the flow is $0.054 \mathrm{~m}^{3} / \mathrm{s}$, the temperature rise is about 18 K and hence the enthalpy leaving at about 500 s is $.054 \times 1.2 \times 1 \mathrm{x} 18=1.2 \mathrm{~kW}$. Note the falloff of the temperature signal compared to the gas or ceiling temperatures when the fire is extinguished. In the latter cases the temperature drops immediately. For the exhaust flow temperature only slight decreases are noted as the gases containing stored energy in the enclosure continues to flow out. Note also in the rising portion of the traces the much more slowly rising signal than, for example, the gas or ceiling traces. That is, the 3.6 and 1.2 kW figures, representing $12 \%$ and $4 \%$ respectively, of the energy source, will continue to rise with time much more so than the more asymptotically looking gas temperature traces.

Instead of comparing the two cases at approximately the same absolute time perhaps it would be more appropriate to compare the signals at comparable characteristic flow times. For example 540 s for the 4.5 min . case is about 1.8 flow times $[(540-60) /(4.5 \times 60), 60 \mathrm{~s}$ before fire is ignited] or equal to somewhere around 280 s for the 2 min . case $(1.8 \times 2 \times 60+60)$. That $\Delta T$ would be closer to 15 K or about 2.2 kW or $7 \%$ of heat release rate. At times corresponding to a few airchanges, only a small amount of energy is being carried down and out through the ventilation.

The amount of energy through the metal side walls can be estimated using the measurements of wall heat flux seen on Figs. $16 \& 17$. Heat flux values from Fig. $16 \& 17$, and here no difference between the two cases will be assumed, bunch around 0.2 to $0.3 \mathrm{~kW} / \mathrm{m}^{2}$ for three of the sensors and for the remaining one, 0.7 to $0.8 \mathrm{~kW} / \mathrm{m}^{2}$. Assume that the wall area can be divided into a hot upper central region ( $3 \mathrm{~m}^{2}$ ) to go with the high flux and the remainder of the area ( $15 \mathrm{~m}^{2}$ ) for the lower values. The total flux through the walls at the time the fire is turned off is

$$
Q=q^{\prime \prime} \times A=0.75 \times 3+0.25 \times 15=6 \mathrm{~kW}
$$

or about $20 \%$ of the total heat release rate of the fire. Like the ventilation thermocouples, the signals on Figs. 16 \& 17 fall gradually after the fire is turned off. This indicates significant dissipation of a lot of stored energy.

The above indicates that approximately $30 \%$ of the total energy created by the fire leaves through the walls and ventilation flow in times equal to several airchanges. Therefore, $70 \%$ must remain. In the configuration without seats only the floor and ceiling have the capability to store energy. These internal components are separated by plenums from the actual metal floor and ceiling skin. Over these times, the external metal floor and ceiling skin do not get very warm. Therefore, their energy transfer paths have been ignored. (The metal skin above the marinite ceiling is exposed to the incoming cool
air. The rise of the metal floor interior temperature will be reflected in Fig. 18.)

Considering then that the floor and ceiling are the primary absorbers, the thermal capacity is equal to

$$
\mathrm{mC}_{\mathrm{p}}=(8 \times 16 / 12) /(3.281)^{3} \times 700 \times 1.1=233 \mathrm{~kJ} / \mathrm{K}
$$

(where $700 \mathrm{~kg} / \mathrm{m}^{3}$ and $1.1 \mathrm{~kJ} / \mathrm{kg} \mathrm{K}$ are representative of the density and specific heat of the material). If the heat transfer rate was assumed constant over the 540-60 $=480$ s time that the fire was turned on and assuming $70 \%$ of the 30 kW was being stored then an average temperature rise of the interior would be $21 /(233 / 480)=43 \mathrm{~K}$.

Observation of the ceiling surface temperature as the fire is turned off on Fig. 15 indicates that a 40 K rise in ceiling temperature is not an unreasonable number. To transfer all the energy the $12 \mathrm{~m}^{2}$ ceiling would require an average heat flux of $21 / 12=1.8 \mathrm{~kW} / \mathrm{m}^{2}$. Derived heat transfer coefficients (see Ceiling Temperature section) are in the range . 02 to .07 $\mathrm{kW} / \mathrm{m}^{2} \mathrm{~K}$ making the average temperature difference between gas and ceiling 25 to 90 K - a reasonable number, not unlike the more detailed calculation result. Obviously a more accurate partitioning of energy around the interior requires the more detailed result, suffice it to say here that since a large fraction of the energy does not get removed in the present configuration knowledge of the thermal characteristic of the enclosure will be very important.

The conclusions reached above appear to be independent of the position of the inlet "slit" at least as regards the "wall" and "central" configurations. Experiment F1202, the "wall" ventilation case discussed earlier can be compared to $F 0403$ which is an identical run except for position - this is a "central" case. To first approximation the results are identical - the graphs of all the variables can be superimposed within the noise or normal fluctuation of the signal. Some very minor differences are perceptible, e.g. the ceiling temperature "T2" on Fig. 1 is on the order of ten degrees higher for the wall ventilated case, as are the upper TC's on trees D\&B slightly higher. One might postulate a cooling curtain effect in the central case. Again however these are very small changes and it would take considerably more analysis of the data to quantify the precision of these differences. The data is available to do precisely that if later models were dictating such differences. For purposes here however, and to reasonably high confidence the position of the vent had little effect on the measurements recorded.

### 3.2 Effect of Seats

The effect of seats is to exacerbate the problem of trying to exhaust hot gases by the normal ventilation, i.e. out the bottom. Either through additional energy transfer to the seats or by the blockage of large scale flows the gas temperature in the lower regions is cooler and more stratified, i.e. the gradient of temperature is larger. And this is reflected in the level of exhaust gas temperature. For a given case, FO206 with seats vs F0403 without seats, everything else identical, there is about a factor of two decrease in the differential temperature of the exhaust gases between the
configuration with seats opposed to that without seats at comparable flow times. The remaining transducers are not greatly affected with some minor differences e.g. exterior wall heat transfer in the lower regions is somewhat less in the with-seat configuration. Upper level gas \& ceiling temperatures are similar in the two cases.

### 3.3 Effect of Fire Size

Gas, wall and ceiling as well as exhaust gas temperatures all vary significantly with heat release rate. The generalization, details, etc. of these findings are contained in the following.
i) Ceiling Temperatures (T1-T4)

An excellent fit of the temperature rise - time data of the ceiling thermocouple signal is:

$$
\begin{equation*}
\frac{\Delta T}{\Delta T_{\max }}=1-\exp \left[h^{2} \frac{t}{\rho c k}\right] \cdot \operatorname{erfc}\left[h ل \frac{t}{\rho c k}\right] \tag{1}
\end{equation*}
$$

which is the solution for the surface temperature history for one-dimensional heat conduction through a semi-infinite slab exposed at $t=0$ to a large mass of fluid of temperature $\mathrm{T}_{\mathrm{max}}$. Surface resistance is indicated through the, assumed constant, film coefficient, $h$. The governing differential equation is the familiar diffusion equation with the given initial and boundary conditions:

$$
\begin{align*}
& \frac{\partial T}{\partial t}=\alpha \frac{\partial^{2} T}{\partial x^{2}}  \tag{2}\\
& t \leq 0 \quad T=T_{0}  \tag{3}\\
& t>0, \quad x=0 \quad-k \frac{\partial T}{\partial x}=h\left(T_{\text {max }}-T\right) \tag{4}
\end{align*}
$$

The adequacy of Eq. (1) as a fit to a typical data set can be judged by observation of Figs. 19 through 22. They show temperature rise-time data for the four ceiling positions with the best least squares fit determined by Eq. (1) shown by the smooth curves. Note the data set includes only that portion with the fire "on". The point here is to generalize the data and perhaps garner something of the physics of the fire-ceiling interactions. Eq. (I) is essentially a two parameter data-fit expression. The parameters are $\Delta T_{m a x}$ and $h \bullet(\rho c k)^{-\frac{1}{2}}$. We do a least squares fit of the data to the Eq. (1) form and derive the best constants. Using the simple semi-infinite transient conduction model, Eqs. (1)-(4), one can associate or relate the derived $\Delta T_{\text {max }}$ with the measured fluid or gas temperatures determined independently by the thermocouple trees; the $\rho c k$ portion with the thermal properties of the given "inert" ceiling material; and finally, the derived or best $h$, an effective heat transfer coefficient, with the thermo-fluid mechanical environment experienced by the ceiling.

It is an "effective" coefficient because of the simplicity of the thermal model, i.e. no reradiation through the hot layer to the colder floor, the loss of the semi-infinite approximation at longer times (small fires) due to the finite thickness of the ceiling material and also the transient nature of the gas temperature rise, to name just a few restrictions.

Having now a reasonable "model" for fire-ceiling inceraction or at least a reasonable analytical fit to the data, one is able to see how these parameters change as a function of fire size. The results of least squares fitting of all the ceiling temperature data for a fixed configuration in the form of Eq. (1) led to several observations. For a fixed fire size, $Q, \Delta T_{\text {max }}$ and $h$ varied considerably with position or location relative to the fire. At a fixed position $\Delta T_{\text {max }}$ varied almost linearly with fire size and $h$ varied much more weakly with Q .

In order to systematize the data analysis more easily a functional form of the $h$ variation with $Q$ was chosen. Because of the nature of Eq. (1) and the data sets, a range of $\Delta T_{\text {max }}$ and $h$ values could yield similarly accurate least squares fits. On a plot of the sum of the squares of the differences between calculated values and actual data values vs $h$, the minimum of the curve (which will be the best value for the fit) was rather broad. A very sharp minimum would have dictated a unique pair. Therefore a range of $h$ and corresponding $\Delta T_{\text {max }}$ values would all give statistically similar results. Visual examination of the plots could not differentiate which pair within the range yielded better results.

The effective film coefficient $h$, was chosen to vary with Reynolds number to the $1 / 2$ power. This dependence is characteristic of an extremely wide range of geometries from convective heat transfer studies. Velocities from buoyant plumes and real fires vary with heat release to the $1 / 3$ power, and hence $h$ will be allowed to vary with $Q$ to the $1 / 6$ power, a result totally consistent within the experimental data scatter. (A larger Reynolds number exponent
could have been chosen if the lower portion of the flame zones where the dependence on fire size becomes weaker, i.e. $1 / 5$ in the intermittent and 0 in the continuous flame, were controlling the phenomena. Irrespective of what model is chosen the data dictates a weak $h$ dependence on $Q$, which must be satisfied.)

The efficacy of choosing a fixed power for the $h-Q$ variation can be demonstrated by considering the $\Delta T_{\text {max }}$ vs $Q$ data before and after fixing the $1 / 6$ power for $h$ vs. $Q$. The correlation coefficients for the power fits of $\Delta T_{m a x}$ vs $Q$ in four ceiling positions ranged from 0.89 to 0.98 in the arbitrary situation. By letting $h$ vary with $Q^{1 / 6}$, going back to the fitting routines and obtaining the new $\Delta T_{\text {max }}$ it turns out that those $\Delta T_{\text {max }}$ vs $Q$ fits now have all four correlation coefficients greater than 0.99 !

The results of all the curve fittings are contained in Table 2 and illustrated in Fig. 23 which shows how $\Delta T_{m}$ (open symbols) and $C$ or $h$ (filled symbols) vary with position in the cabin. Note that $C / Q^{1 / 6}$, i.e. the film coefficient, ( $C=$ $h / J \rho c k$ ) varies inversely with position from the fire, a not unexpected result given that the fire generated gas flow velocities will be decreasing as one moves further from the fire. The same is true, in general, as regards $\Delta T_{m}$. Except for position $T 1$ which is slightly further from the fire than position T2 and for all the central ventilation data (square symbols) exhibits higher temperatures. With ventilation at the edge or wall position, Tl drops below T2 following the trend of cooler regions being further from the fire (triangle symbols). The curtain of cool air falling between the fire and the positions of $T 4$ and $T 2$ in the former case may provide disturbance to a decreasing
thermal stress with distance from the fire trend, that is, if one can ignore the enclosure asymmetry to begin with. The hash marks on the figure indicate the length and breath of the compartment. Perhaps T3 and T1 ought to be compared separately from T4 and T2 for the central configuration cases.

The lower part of Fig. 23 yields for the present center ventilation configuration a film coefficient $h$ of between about 5 and $80 \mathrm{~W} / \mathrm{m}^{2} \mathrm{~K}$. The lower number is typical for free convection with the higher value ( $r / \mathrm{H} \rightarrow 0$ ) well into the forced convective range for gases. The data also bounds that found by Quintiere (1978) for a ceiling in a corridor just outside a burn room.

To construct figure 23, an average $n$ equal to 0.933 was chosen from Table 2. The $\Delta T_{m}=A Q^{n}$ was recalculated to yield a new $A$ and compared to the temperature levels at each position irrespective of slight changes in Table 2 values of $n$. Note the triangles on the figure, these are for the one data set with wall ventilation and therefore have not gone through the extensive analysis that the central ventilation or squares have, i.e. $h \propto Q^{1 / 5}$. Quite large decreases in $h$ could result in small increases in $\Delta T_{m}$ and still preserve the goodness of the least squares fit. In other words the impression that $h$ for the wall ventilation case is twice that for the central ventilation may not be a correct one. To convert $C$ to $h$ a value of $\rho c k=0.1\left(\mathrm{kw} / \mathrm{m}^{2} / \mathrm{K}\right)^{2} \cdot \mathrm{~s}$ was chosen for the ceiling material. How well the derived bulk "bath" temperatures, $\Delta \mathrm{T}_{\mathrm{m}}$, compare to actual measured gas temperatures will be presented in the next section.

[^0]ii) Upper Level Gas Temperatures (A2, B1, C1, D1)

Time histories of the uppermost thermocouple (TC) temperature rise for the four TC trees are shown in Figs. 24-27. (Note for tree "A" that the second TC is used since, due to blockage by a structural rib on the ceiling, the topmost TC on that pole was somewhat shielded from the hottest gases and consistently recorded a temperature slightly less than the second from the top.) For want of any other particular method the data was correlated using the semi-infinite erfc function analysis used previously. Observation of Fig. 24-27 seems to indicate that it is adequately representing the data. The $\Delta T_{m}$ and $C$ 's shown on the traces are the determined least squares fit of Eq. (1).

Table 3 contains the results of the curve fitting analysis for the other five fire sizes. The results of the variations with fire size or heat release rate, $Q$, were similar to the ceiling analysis. That is, $\Delta T_{m}$ varied, nearly linearly with $Q$; while $C$, scattering considerably, varied very weakly with $Q$. As before, to systematize the data analysis, $C$ was made to vary with $Q^{1 / 6}$, and the analysis fitting was repeated to obtain the best $\Delta T_{m}$ for that new $C$. (Here the similarity to an actual convective film coefficient may be more tenuous since gas or rather the $T C$ 's are being heated, not a semi infinite plate). An example of exactly how things change by this manipulation is to consider Fig. 24-27. The $\Delta T_{m}$ and C's shown on the figures are the "raw" or best values. Those in the table have been "processed", e.g., $\Delta T_{\mathrm{m}}$ for Dl went from 206 to 205 K while $C$ increased from .085 to $.0897 \mathrm{~s}^{-1 / 2}$, etc. Meanwhile the sum of the squares of the deviations does not change appreciably. The big

TABLE 3: UPPER GAS LEVEL TEMPERATURE CORRELATION PARAMETERS ${ }^{2}$

2 Least Squares Fit to $\Delta T / \Delta T_{m}=1-e^{C^{2} t}$ erfc $C ل t$ (No seats, central ventilation, $2.4 \mathrm{~min} \cdot$ )
difference again came about when considering $\Delta T_{m}$ vs $Q$. In all cases the correlation coefficient increases to over 0.99 with the formalized C-Q ${ }^{1 / 6}$ variation.

From Table 3 the mean power for gas variation, 0.836 is measurably lower and the data is less scattered than the ceiling temperature rise variation, i.e. $\mathrm{n}=0.933$. Fig. 28 shows the radial variation of $\Delta \mathrm{T}_{\mathrm{m}} / \mathrm{Q}^{.836}$ with again the numbers reworked using the constant $n$. For comparison the ceiling variation with distance using 0.933 is also shown. Heat transfer to the ceiling as a function of position (as well as with time) can be determined from the plot. Additional information required is contained in figure 28 which shows C/Q ${ }^{1 / 6}$ for the gas as well as the ceiling. Here they are left in the "C" form, a simple data fitting constant, as opposed to conversion of the ceiling value to $h$ as on Fig. 23.

The gas values of $C$ appear to be less dependent on position than those of the ceiling. For the ceiling $C$ increases significantly as one gets closer to the fire indicating a smaller time constant or smaller time to reach $\Delta T_{m}$. Here the analog with a film or heat transfer coefficient makes sense - the plume velocities will be highest in the stagnation - turning region of the ceiling.

We now have the ceiling temperature rise as well as a representative upper level gas temperature rise due to a fire in a cabin ventilated from above. As a function of time,

$$
\begin{equation*}
\Delta T=\Delta T_{\max }\left[1-\exp \left(C^{2} t\right) \cdot \operatorname{erfc}(C ل t)\right] \tag{5}
\end{equation*}
$$

with

$$
\begin{equation*}
\Delta T_{\max }=A_{1}(r / H) Q^{n_{i}} \tag{6}
\end{equation*}
$$

for

$$
\begin{align*}
& i=\text { gas } n_{i}=.836 \\
& i=\text { ceiling } n_{i}=.933 \\
& C=B_{i}(r / H) Q^{1 / 6} \tag{7}
\end{align*}
$$

where $A_{i}(r / H)$ and $B_{i}(r / H)$ are contained on the upper and lower portions of Fig. 28 respectively.

### 3.4 Ceiling Heat Transfer

At any radial position the heat transfer rate, gas to ceiling, is from the simple model

$$
\begin{equation*}
\dot{q}^{\prime \prime}=h_{c}\left(T_{\text {max }}-T_{\text {CEIIING }}\right) \tag{8}
\end{equation*}
$$

For the film coefficient, $h_{c}$, derived using the semi-infinite analysis, $T_{\text {max }}$ was assumed to be the constant bath temperature into which one side of the ceiling was suddenly exposed. In reality the gas temperature itself is rising. Additionally from Fig. 28 the independent experimentally derived $\Delta T_{\text {m }}$ for the gas is somewhat higher. It will be useful to see the effect on heat transfer of using the higher and transient gas temperature.

Using the data representation, Eq. (1), the above becomes

$$
\begin{equation*}
\dot{q}^{\prime \prime} / h_{c}=\Delta T_{m g}-\Delta T_{m c}\left[1-\exp \left(C_{c}^{2} t\right) \cdot \operatorname{erfc}\left(C_{c} \downarrow t\right)\right] \tag{6}
\end{equation*}
$$

where the additional subscripts $g$ and $c$ indicate gas and ceiling respectively. Note that if the ceiling maximum temperature (the semi-infinite approx.) is used for the bath or gas temperature then Eq. (9) reduces to

$$
\begin{equation*}
\left.\dot{q}^{\prime \prime}=h_{c} \Delta T_{m c} \exp \left(C_{c}^{2} t\right) \cdot \operatorname{erfc}\left(C_{c} \downharpoonleft t\right)\right] \tag{10}
\end{equation*}
$$

or at short times, say to 30 seconds for $C_{c}$ of order $0.05 \mathrm{~s}^{-1 / 2}$, we can approximate the erfc expression and obtain the convenient

$$
\begin{equation*}
\dot{q}^{\prime \prime}=h_{c} \Delta T_{\mathrm{mc}}\left(1-C_{c} \downharpoonleft t\right) \tag{11}
\end{equation*}
$$

The complete solution can be expressed as (Abramowitz and Stegun 1965):

$$
\begin{aligned}
& \dot{\mathrm{q}} " / h_{c}=\left(\Delta \mathrm{T}_{\mathrm{mg}}-\Delta \mathrm{T}_{\mathrm{mc}}\right)+\Delta \mathrm{T}_{\mathrm{mc}}\left(\mathrm{a}_{1} \mathrm{t}_{\mathrm{c}}+a_{2} t_{c}{ }^{2}+a_{3} t_{c}{ }^{3}\right) \\
& \text { where } t_{c}=\frac{1}{1+\mathrm{p} C_{c} \sqrt{t}}
\end{aligned}
$$

and $a_{1}=.3480242, a_{2}=-.0958798, a_{3}=.7478556, p=.47047$

Note the first term, a sort of compensation for weaknesses in the semi-infinite model since the experimental gas temperatures always come out higher than the bath temperature of the model, represents a value of order $10 \%$ or less of the second term for times of interest here and hence Eq. (10) (and Eq. (11) for short times) ought to be adequate in predicting heat transfer to the ceiling. That is, even though from Fig. 28 the gas temperatures are
higher than the derived ceiling temperature the effect on ceiling heat transfer is small.

The maximum value, i.e. when $t \rightarrow o$, is from (11):

$$
\begin{equation*}
q^{\prime \prime}=h_{c} \Delta T_{\mathrm{mc}} \tag{13}
\end{equation*}
$$

From Fig. 23 or Table 2 we can find the variation of $q$ " with fire size, i.e. $1 / 6+.93$, not a great deal different from direct proportionality. This is a significant finding. It is of interest to determine the partitioning of energy throughout the various modes independent of fire size since perfect scaling will not have been obtained in simulation. That is, it is important to know that, for example, the enthalpy leaving through the lower vents represents some particular fraction of the heat release over the whole range of possible fire sizes and not, for example, just for small or just for large fires. Proportionality insures that the ceiling heat transfer, representing a large fraction of the energy, does indeed scale with fire size.

From Fig. 23 the variations with position are seen to be, not surprisingly, very significant. If one extrapolates the four central ventilation points for $h$ and the two more-central $\Delta T_{m}$ points ( $T_{3}$ and $T_{1}$ ) to $r / H \rightarrow 0$, the maximum values of ceiling heat transfer may be estimated.

$$
\begin{align*}
& h / Q^{1 / 6}=0.043  \tag{14}\\
& \Delta T_{\square} / Q^{93}=9.5 \tag{15}
\end{align*}
$$

in $\mathrm{kW}, \mathrm{K}$, and m .

For the 30 kW heat release rate example, Eq. (13) will yield $.043 \times 9.5 \times 30^{1.1}=$ $17 \mathrm{~kW} / \mathrm{m}^{2}$. At $\mathrm{r} / \mathrm{H}=1$ this reduces to about $7 \mathrm{~kW} / \mathrm{m}^{2}$ and so on, decreasing strongly with distance from the fire. With heat transfer rates of this order it is quite plausible for the approx. $70 \%$ figure of the energy to be absorbed by the ceiling.

How the heat transfer rate falls in time can be seen on Fig. 29 which shows the above example case, the 30 kW fire, for the two $\mathrm{r} / \mathrm{H}$ positions. Initially there is quite a dramatic reduction. Things begin to level off approximately at times corresponding to when the exhaust TC'S are beginning to sense warm air coming out. (Fig. 18).

The generalized form of the solution of the semi-infinite model Eq. (10) is shown on figure 30 where the non-dimensional heat transfer rate $\dot{q} " /\left(h_{c} \Delta T_{m}\right)$ is plotted vs. dimensionless time, $\mathrm{C} J$. The early times solution Eq. (11) is also shown for convenience. The quantities, $h$ and $C$, are related according to $C=h / \downharpoonleft \rho c k$.

### 3.5 Stratification

Fig. 31 shows eight traces of thermocouple readings, top-to-bottom, for tree $D$ during a 40 kW , central ventilation, 2.4 min rate, no seat test configuration. At arbitrary times one can look at the distribution of temperature with
elevation. Fig. 32 presents six such profiles at times equal to 30 s through 460 s after ignition. Obviously, hotter gases are at the top with the entire profile rising in time.

The question now arises as to how to generalize such a plot. The easiest method is to normalize each trace to some value that is representative of that time. Since all the information has been gathered and correlated for the top or maximum reading thermocouples, the trace of that thermocouple would be the obvious choice. Using the erfc model (Fig. 24-27) and the parameters from Table 3 we can, first subtracting out the initial ambient temperature, divide each of the readings of the profiles by the calculated maximum temperature for that time.

Fig. 33 shows the normalized profiles, the fraction of the maximum temperature at the time, that maximum being calculated via Eq. 1 using $\Delta T_{m}=205 \mathrm{~K}$ and $C=0.0897 \mathrm{~s}^{-1 / 2}$. At long times a somewhat universal profile is achieved. The level of scatter is about $\pm 10 \%$ at the top. However we do clearly see the enclosure "filling" as the 30 s profile falls much lower than the one at 60 s which is lower than that at 120 s . The 120 s profile is beginning to approach the longer time result where temporal non-uniformity tends to disappear, and the whole bulk of gas or each strata moves upward in temperature simultaneously. Before this point is reached, times less than 120 s , the upper gases get hotter quickly and the lower gases slowly - there is definite temporal non-uniformity - the rates of rise are different in the upper and lower ragions.

Regarding safety, how the 30 s and subsequent profiles on Fig. 33 "swing" up to the hotter universal profile will be extremely important. The ventilation effects (rate, position, other characteristics) on the universal profile and the "swing" will be required to be documented. That data are available as are the conserved species measurements including $\mathrm{CO}_{2}, \mathrm{CO}$ and $\mathrm{O}_{2}$ and will be available in a forthcoming publication.

### 4.0 Discussion

As well as further data analysis of the kind just indicated above, certain other tasks, the importance of which have become clearer during this study, ought to be pursued further. The thermal environment as a function of heat release is known and various scaling schemes are available which would give confidence to ones ability to generalize these results. Therefore the question as to what size or lower limit of heat release rate will be handled to some prescribed criteria by present ventilation can be posed and a quantitative answer provided.

### 5.0 Conclusions

The conclusions for the thermal field portion of these studies are as follows: Within times of interest, i.e., a few airchanges, the bulk of the fire produced energy was not being exhausted through the normal floor ventilation. The hot gases were accumulating close to the ceiling and except for some local mixing, were hardly affected by the incoming cold stream. As time progressed and the cabin began to fill from the top downward and heat transfer rates
decreased as the ceiling and walls heated, only then did significant temperature levels begin to appear in the outflow stream.

In the present apparatus most of the energy of the fire is transiently being stored in the "marinite" ceiling. The results have been generalized in terms of a semi-infinite slab model exposed to a high temperature constant bath, a function of fire size, through a constant convective film coefficient, $h$, dependent on position in the cabin and weakly on fire size. Heat transfer to the cabin ceiling was found to scale with fire size through almost direct proportionality thus insuring the generality of the present experiments. The behavior of different ceiling materials ought to be reflected through different $\rho c k$ values. Different geometries ought to be reflected by the variation of $h$ through different Reynolds and Grashoff numbers as well as with the heat release rate variations of plume theory. All these effects have been documented and await further analytical data manipulation and experimental verification.

### 6.0 Acknowledgements

Dan Madrzykowski with some help from Bob Vettori converted a conceptual design into a very durable excellently operating experimental apparatus in the form of the $1 / 2$ scale, simulated wide body aircraft cabin used in the present and proposed future studies. Without their friendly cooperation and hard work this task could not have been completed. Thanks are also due the technical coordinator at FAA, Dr. Thor Eklund, who from the broader view of the entire cabin fire problem was able to guide this work effectively suggesting which and how best to approach each of the problems.

## Location

IC - thermocouple chromel-alumel 0.25 um $D$ wire (on trees - TC's faced away from fire)

HF - foil type heat flow sensors (RdF Corporation 20480-3)
IC ${ }_{\text {HF }}$ - copper constantan thermocouples (integral part of heat flow sensor)
$V$ - linearized, temp. compensated hot film anemometer (Omega FMA 603V) cross section was traversed at various fan settings in order to convert singie, centerline velocity value into a flow rate. (Profile fitted nicely into $1 / 7$ power. $\operatorname{Re} \rightarrow 10^{4}$ for all conditions).

The following sheets contain the reduced data for run F1202. See preceding table in Appendix for detailed descriptions of channel numbers, locations from Figure 1 and Appendix, units from axes on remaining figures.

10. SUPPLEMENTARY NOTES

Document describes a computer program; SF-185, FIPS Software Summary, is attached.
11. ABSTRACT (A 200-word or less factual summary of most significant information. If document includes a significant bibliography or literature survey, mention it here)
Using propane gas burning in a diffusive mode, fire sources up to the equivalent heat release rate of a fully involved seat were simulated in an approx. 1/2-scale closed section of $a$ ventilated-wide-body aircraft cabin. The ventilation flow direction was as in a commercial practice-counter to that of the buoyancy driven fire gases, i.e., fresh air was forced in at the top of the enclosure and drawn out at the bottom. Results indicate that for nominal ventilation rates the potential for significant enthalpy exchange through ventilation in times corresponding to a few airchanges is limited. That is, only a small proportion of the energy release rate of the fire is getting exhausted. Correlations of thermal conditions in the enclosure as a function of time, heat release rate of the fire, and position in the cabin are presented. Semi-infinite transient conduction models appear adequate in capturing the essential features of the fire-ceiling thermal interaction. Reduced data on PC-readable floppy disks for the entire test series will be made available for future cabin modelling purposes.
