NIST STEP Working Form Programmer’s Reference
Stephen Nowland Clark

1 Introduction

The NIST STEP physical file parser [Clark90c], and its associated STEP parser, STEPparse, are Public Domain tools for manipulating product models stored in the STEP physical file format [Altemueller88]. These tools are a part of the NIST PDES Toolkit [Clark90a], and are geared particularly toward building STEP translators. This reference manual discusses the internals of the STEP Working Form, including STEPparse. The reader is assumed to be familiar with the design of the Toolkit ([Clark90a], [Clark90b], [Clark90c]). In some cases, technical knowledge of the Express Working Form [Clark90e] is also required.

The STEP Working Form relies on the NIST Express Working Form [Clark90b] as an in-core data dictionary, which provides a context in which STEP models can be interpreted. The tight dependency of the STEP Working Form abstractions on those of the Express Working Form is due to the schema-independent nature of the former. The STEP Working Form, and, in particular, STEPparse, contain no knowledge of any particular information model. Applications built on these tools can thus manipulate STEP product models in the context of any number of Express information models without requiring recompilation.

1.1 Context

The PDES (Product Data Exchange using STEP) activity is the United States’ effort in support of the Standard for the Exchange of Product Model Data (STEP), an emerging international standard for the interchange of product data between various vendors’ CAD/CAM systems and other manufacturing-related software [Smith88]. A National PDES Testbed has been established at the National Institute of Standards and Technology to provide testing and validation facilities for the emerging standard. The Testbed is funded by the CALS (Computer-aided Acquisition and Logistic Support) program of the Office of the Secretary of Defense. As part of the testing effort, NIST is charged with providing a software toolkit for manipulating PDES data. This NIST PDES Toolkit is an evolving, research-oriented set of software tools. This document is one of a set of reports which describe various aspects of the Toolkit. An overview of the Toolkit is provided in [Clark90a], along with references to the other documents in the set.

For further information on the STEP Working Form or other components of the Toolkit, or to obtain a copy of the software, use the attached order form.
2 STEPparse Control Flow

A STEPparse translator consists of two separate passes: parsing and output generation. The first pass builds an instantiated Product representing the product model specified in the STEP input file. This Product can then be traversed by an output module in the second pass, producing whatever report is desired. It is anticipated that users will need output formats other than those provided with the NIST Toolkit. The process of writing a report generator for a new output format is discussed in detail in section 4.

2.1 First Pass: Parsing

The first pass of a STEPparse translator is a very simple parser. The STEPparse grammar itself is independent of any conceptual schema. The lexical analyzer recognizes any entity class name simply as an identifier; the actions associated with rules in the grammar then interpret this name as referring to a particular Express entity, and construct appropriate objects. As each construct is parsed, it is added to the Working Form. Because the STEP physical file format does not allow forward references to as-yet-undefined entity instances, all symbol references can be (and are) resolved during this parsing pass, so that no symbol resolution pass is required.

The STEP parse parser is written using the standard UNIX™ parser generation languages, Yacc and Lex. The grammar is processed by Bison, the Free Software Foundation’s¹ implementation of Yacc. The lexical analyzer is produced by Flex², a fast, Public Domain implementation of Lex.

2.2 Second Pass: Output Generation

The report or output generation pass manages the production of the various output files. In the dynamically linked version of STEPparse, this pass loads successive output modules dynamically, calling each to traverse the Working Form. The dynamic linking mechanism is discussed briefly in [Clark90d]. It is also possible to build a statically linked translator, with a particular output module loaded in at build time; this is, in fact, the only mechanism available in an environment which is not derived from BSD 4.2 UNIX.

A report generator is an object module, most likely written in C, which has been compiled as a component module for a larger program (i.e., with the -c option to a Unix C compiler). In the dynamically linked version, the object module is linked into the running parser, and its entry point (by convention a function called print_file()) is

---

¹ The Free Software Foundation (FSF) of Cambridge, Massachusetts is responsible for the GNU Project, whose ultimate goal is to provide a free implementation of the UNIX operating system and environment. These tools are not in the Public Domain: FSF retains ownership and copyright privileges, but grants free distribution rights under certain terms. At this writing, further information is available by electronic mail on the Internet from gnu@prep.ai.mit.edu.

² Vern Paxson’s Fast Lex is usually distributed with GNU software, although, being in the Public Domain, it is not an FSF product and does not come under the FSF licensing restrictions.
called. The code of this module consists of calls to STEP Working Form access functions and to standard output routines. Chapter 4 provides a detailed description of the creation of a new output module.

3 Working Form Implementation

As in the Express Working Form [Clark90d], the Object abstraction is implemented as a Symbol header block with a pointer to a private struct Object. This C structure contains the real definition of the abstraction, but is never manipulated directly outside of the Object module. Product is implemented as a pointer to a private structure, struct Product.

Most stylistic and other conventions from the Express Working Form are equally valid for STEP; they are reiterated here for emphasis.

3.1 Primitive Types

The STEP Working Form makes use of several modules from the Toolkit general libraries, including the Error and Linked_List modules. These are described in [Clark90d].

3.2 STEP Working Form Manager Module

In addition to the abstractions discussed in [Clark90c], libstep.a contains one more (conceptual) module, the package manager. Defined in step.c and step.h, this module includes calls to initialize the entire STEP (and Express) Working Form package, and to run each of the passes of a STEPParse translator.

3.3 Code Organization and Conventions

Each abstraction is implemented as a separate module. Modules share only their interface specifications with other modules. A module Foo is composed of two C source files, foo.c and foo.h. The former contains the body of the module, including all non-inlined functions. The latter contains function prototypes for the module, as well as all type and macro definitions. In addition, global variables are defined here, using a mechanism which allows the same declarations to be used both for extern declarations in other modules and the actual storage definition in the declaring module. These globals can also be given constant initializers. Finally, foo.h contains inline function definitions. In a compiler which supports inline functions, these are declared static inline in every module which includes foo.h, including foo.c itself. In other compilers, they are undefined except when included in foo.c, when they are compiled as ordinary functions. foo.c resides in ~/pdes/src/step/; foo.h in ~/pdes/include/.

The type defined by module Foo is named Foo, and its private structure is struct Foo. Access functions are named as FOOfunction(); this function prefix is abbreviated for longer abstraction names, so that access functions for type Foolhardy_Bartender might be of the form FOO_BARfunction(). Some
functions may be implemented as macros; these macros are not distinguished typographically from other functions, and are guaranteed not to have unpleasant side effects like evaluating arguments more than once. These macros are thus virtually indistinguishable from functions. Functions which are intended for internal use only are named FOO_function(), and are usually static as well, unless this is not possible. Global variables are often named FOO_variable; most enumeration identifiers and constants are named FOO_CONSTANT (although these latter two rules are by no means universal).

Every abstraction defines a constant FOO_NULL, which represents an empty or missing value of the type. In addition, there are several operations which are defined for every type; these are primarily general management operations. Each abstraction defines at least one creation function, e.g. FOOcreate(). The parameters to this creation function vary, depending on the abstraction. A permanent copy of an object (as opposed to a temporary copy which will immediately be read and discarded) can be obtained by calling FOOcopy(foo). This helps the system keep track of references to an object, ensuring that it is not prematurely garbage-collected. Similarly, when an object or a copy is no longer needed, it should be released by calling FOOfree(foo), allowing it to be garbage-collected if appropriate.

For each abstraction, there is a function FOOis_foo(obj) which returns true if and only if its argument is a foo. This is useful when dealing with a heterogeneous list, for example.

3.4 Memory Management and Garbage Collection

In reading various portions of the STEP Working Form documentation, one may get the impression that the Working Form does some reasonably intelligent memory management. This is not true. The NIST PDES Toolkit is primarily a research tool. This is especially true of the Express and STEP Working Forms. The Working forms allocate huge chunks of memory without batting an eye, and this memory often is not released until an application exits. Hooks for doing memory management do exist (e.g., XXXfree() and reference counts), but currently are largely ignored.

3.5 Object

The Object abstraction is the basic building block of the STEP Working Form. An Object is created for each unit of value in a PDES/STEP product model: each entity instance, aggregate, integer, string, etc. On the surface, this would seem to be a reasonably straightforward module to implement: each Object has an optional name, a Type, and a value. The value may be simple or structured; in either case, it basically comes down to a pointer - either to an array of Objects, or to an integer, real, string, etc.

As with most abstractions in the Express Working Form, Object is implemented as a Symbol header whose definition field points at a struct Object, which is defined thus:

    struct Object {

Type type;
Generic user_data;
union {
    Constant enumeration;
    Integer integer;
    Logical logical;
    Real real;
    String string;
    Object* entity;
    Aggregate aggregate;
    value;
};

The first two fields are pretty straightforward. Note that user_data is a generic pointer field. In strict ANSI C, only a pointer can be safely stored into this field and later retrieved; it is safest to only store pointers in this field. In particular, the age-old trick of casting pointers and integers back and forth, never completely portable, is now officially frowned upon.

The value union is where things get tricky. This field contains the actual value of the object represented. Unstructured types (numbers, logicals, and strings) are represented directly; e.g., object.value.integer contains an integer, and object.value.string, a character pointer. The value of an enumeration object is represented as a Constant, which will be an element of the appropriate enumeration. The integer representation of this enumeration element can be retrieved by calling (int)CSTget_value(object.value.enumeration).

An entity instance's value field, value.entity, is a pointer to the base of an array of objects. Each element of this array corresponds to an attribute of the entity; attributes appear in the same order as in a PDES/STEP physical file, with empty attributes explicitly represented by OBJECT_NULL. The offset to a particular attribute value is retrieved from the Express data dictionary by calling ENTITYget_attribute_offset(entity, attribute), where entity is the entity class of the object in question and attribute is the Variable representing the attribute to be located.

The most convoluted object value representation is that for aggregates. An aggregate value is represented as a pointer to a struct Aggregate, defined as

    struct Aggregate {
        int low;
        int high;
        Expression max;
        Object* contents;
    };

The last field, contents, holds the actual contents of the aggregate, as an array of Objects. The low field provides a lower bound on allowable indices into this array, and doubles as a logical offset to the first element of the array. This value is 1 for any
non-array aggregate. Thus, when low is 1, some_aggregate[1] is found at contents[0]. Similarly, in an array whose low is 10, the some_array[12] is found at contents[12-10 = 2]. low remains constant in any particular aggregate object. The high field gives an upper bound on the indices of currently filled slots in an aggregate object. Every index into the aggregate beyond high which is in bounds is guaranteed to return OBJECT_NULL. The end result is that a loop of the form for (i = low; i <= high; ++i) <use contents[i-low]> will always hit all of the elements of an aggregate. This function of offsetting by the lower bound is bundled into the various aggregate indexing functions of the working form (OBJaggr_at(), OBJlist_insert(), etc.), so that the indices which a user sees will be the ones which would be expected based on the Express model. In the current implementation, high in an aggregate whose type (from Express) gives a finite upper bound always remains constant at this bound. In the case of an aggregate with no specified upper bound, however, high may vary with the number of elements actually in the aggregate. The expression (from Express) giving the absolute upper bound on an aggregate is cached in aggregate->max. high is never allowed to be greater than the value of this expression.

The two calls OBJaggr_at() and OBJaggr_at_put() can be used with any kind of aggregate, although they are intended to be used primarily for building general aggregates which will later be OBJtype_cast() into specific types of aggregates. This is how STEP parse builds aggregates, since it is considerably easier than figuring out at parse time what type of aggregate should be built. The various class-specific manipulations (list concatenation, set intersection, etc.) are provided by calls requiring aggregates of a particular class: OBJlist_concat(), OBJset_intersect(), etc. It should be noted that the calls for combining aggregates are destructive: each modifies its first argument to hold its computed result. In general, the two arguments may safely be set equal. Exceptions are noted in the individual function specifications.

Finally, a word about type conversion (also known as casting, as in C). Type conversions of existing Objects are handled by OBJtype_cast(Object, Type, Error*). Only certain conversions are allowed; other attempted casts leave the Object unchanged and return an error code. Clearly, any Object can trivially be cast into its own type. The different numeric types can be cast about at will. A general aggregate can be cast into any specific aggregate class; otherwise, an aggregate can only be cast into another aggregate type of the same class: an array cannot be cast into a set, etc. Each element of the aggregate being cast must, of course, be recursively cast into the appropriate base type; each of these conversions is subject to the same rules as any other cast. Finally, an entity Object can be converted into an instance of a supertype of its class, or into an instance of a SELECT type containing some type to which it can be cast. These casts of entity instances in fact do not modify the Object being cast.

3.6 Product

A product in STEP contains a large number of interrelated entity instances, and is represented by the Product abstraction. Each Product is named, and includes a pointer to the Express model which provides the scope in which its component Objects are
defined. These component objects can be retrieved from the Product in several ways: a specific (external) entity instance can be retrieved by name; a Linked_List of all of the (external) entity instances in the Product can be requested; or a particular entity class in the Product's conceptual schema can be queried for all of its instances (note that this last method retrieves both internal and external entity instances). Internal (embedded) entity instances and non-entity Objects must appear as attribute values or aggregate elements somewhere in the Product, and are only accessible via ENTITYget_instances() and component retrieval from the containing Objects.

The above three access methods are supported by storing three references to each Object in a Product. When an Object is added to a Product, it is added to the end of the list of external objects. This list preserves the order in which the Objects were added to the Product, and so is appropriate for applications, such as writing a STEP physical file, which require that there be no forward references to as-yet-undefined Objects. Each external Object is also added to a dictionary which the Product maintains, to allow retrieval by name. And when an entity object is first created, it is added to the instance list of its class.

### 4 Writing An Output Module

We now turn to the topic of actually writing a report generator. The end result of this process will be an object module (UNIX .o file) which can be loaded into STEPparse. This module contains a single entry point which traverses a given Product and writes its output to a particular file. The conceptual entry point is conventionally called print_file(), while the physical entry point, which simply dispatches to print_file(), is called entry_point().

In most cases, there will be a one-to-one correspondence between Objects in the instantiated Working Form and records to be written on the output. When this is the case, the meat of the report generator can be made fairly simple. Since a list of all of the Objects in the Working Form is available, it is easy to iterate over this list and output each Object in sequence:

```c
STEPprint(Product product, FILE* file)
{
    Linked_List list;
    list = PRODget_contents(product);
    LISTdo(list, obj, Object)
        OBJprint(obj, file);
    LISTod;
}
```

The only remaining problem is to write a function OBJprint() which emits the output record for a single Object. Given the variety of types of Objects, this function will probably be controlled by a large switch statement, selecting on the Object's type class (numbers, strings, and aggregates all have to be printed differently). Code to deal with multi-dimensional arrays an internal/external entity references can get tricky, and
should be written carefully. An example of a fairly simple report generator is that used by STEPparse-QDES. The source code for this module is in
~pdes/src/STEPparse_qdes/step_output_smalltalk.c.

4.1 Layout of the C Source

The layout of the C source file for a report generator which will be dynamically loaded is of critical importance, due to the primitive level at which the load is carried out. The very first piece of C source in the file must be the entry_point() function, or the loader may find the wrong entry point to the file, resulting in mayhem. Only comments may precede this function; even an #include directive may throw off the loader. An output module is normally layed out as shown:

```c
void
entry_point(void* product, void* file)
{
    extern void print_file();
    print_file(product, file);
}

#include "step.h"

... actual output routines ...

void
print_file(void* product, void* file)
{
    print_file_header((Product)product,
         (FILE*)file);
    STEPprint(product, file);
    print_file_trailer((Product)product,
         (FILE*)file);
}
```

The print_file() function will probably always be quite similar to the one shown, although in many cases, the file header and/or trailer may well be empty, eliminating the need for these calls. In this case, STEPprint() and print_file() will probably become interchangeable.

Having said all of the above about templates, code layout, and so forth, we add the following note: In the final analysis, the output module really is a free-form piece of C code. There is one and only one rule which must be followed: The entry point (according to the .a.out format) to the .o file which is produced when the report generator is compiled must be appropriate to be called with a Product and a FILE*. The simplest (and safest) way of doing this is to adhere strictly to the layout given, and write an entry_point() routine which jumps to the real (conceptual) entry point. But any other convention which guarantees this property may be used.
4.2 Output Module Linkage Mechanisms

One of the powers of STEPParse is the flexibility which it gives a user with regard to generating output. An important component of this flexibility on BSD Unix systems is the dynamic loading of output modules. Both static and dynamic binding of output modules are supported by STEPParse. This is implemented by physically breaking the object code from the Working Form manager (step.c) into three separate .o files: the initialization code and the first pass of STEPParse are compiled into step.o, which is stored in libstep.a. The static linking version of the second pass (without any output module) is compiled into step_static.o; and the dynamic loading version into step_dynamic.o. Sources for all of these components reside in step.c; the various sections are extracted via conditional compilation: When this file is compiled with the preprocessor symbols reports and static_reports defined, step_static.o is produced. With reports and dynamic_reports defined, step_dynamic.o is produced; and with none of these defined, step.o is produced.

Since step_static.o and step_dynamic.o both define the function STEPreport(), only one can be linked into any given executable. This selection is what determines whether a STEPParse translator links in output modules statically or dynamically. Note that a suitable output module (.o file) must appear after step_static.o in the linker’s argument list when a statically linked translator is being built.

5 Working Form Routines

The remainder of this manual consists of specifications and brief descriptions of the access routines and associated error codes for the STEP Working Form. The error codes are manipulated by the Error module [Clark90d]. Each subsection below corresponds to a module in the Working Form library. The Working Form Manager module is listed first, followed by the remaining data abstractions in alphabetical order.

5.1 Working Form Manager

**Procedure:** STEPInitialize
**Parameters:** Error* erc - buffer for error code
**Returns:** void
**Description:** Initialize the STEP Working From package. In a typical STEP translator, this is called by the default main() provided in the Working Form library. Other applications should call this function at initialization time.
**Errors:** none

**Procedure:** STEPparse
**Parameters:** String filename - the name of the file to be parsed
             Express data_model - conceptual schema (as produced by EXPRESSpass_2())
**Returns:** Product - the product model parsed
**Description:** Parse a STEP physical file into the Working Form
Procedure: STEPreport
Parameters: Product product - the product to output
Returns: void
Description: Invoke one or more report generators for a STEP Working Form model.
Description: Invoke one (or more) report generator(s). When this function is compiled with
-Ddynamic_reports, it will repeatedly prompt for report generators and output
files, dynamically loading and executing them. When it is compiled with
-Dstatic_reports, a report generator must also be included at link time, with the
entry point print_file(Express, FILE*).

5.2 Object

Procedure: OBJaggr_at
Parameters: Object object - object to examine
            int index - index of requested element
            Error* errc - buffer for error code
Returns: Object - value at requested position
Description: Retrieves the value at some position in an aggregate. Note that the calls which are
specific to a particular aggregate class are much to be preferred.
Errors: ERROR_index_out_of_range - the index is outside of the bounds of the aggregate

Procedure: OBJaggr_at_put
Parameters: Object object - object to modify
            int index - index at which to put element
            Object value - value to insert
            Error* errc - buffer for error code
Returns: void
Description: Store a value into an aggregate object. Note that the calls which are specific to a
particular aggregate class are much to be preferred.
Errors: ERROR_index_out_of_range - the index is outside of the bounds of the aggregate

Procedure: OBJaggr_lower_bound
Parameters: Object object - object to examine
Returns: int - the lower bound of the object
Description: Retrieves the lower bound of an aggregate object. For an array, this is the index of the
first element of the array. For other aggregates, it is 1.
Errors: none

Procedure: OBJaggr_upper_bound
Parameters: Object object - object to examine
Returns: int - the upper bound of the object
Description: Retrieves the upper bound of an aggregate object. For an aggregate with a constrained
size, this is the value of the upper limit or index. For an aggregate with an infinite
upper bound, the value returned is guaranteed to be larger than the highest index of a
filled slot in the aggregate.
Errors: none
Procedure: OBJarray_at
Parameters: Object array - array to examine
int index - index of requested element
Error* errc - buffer for error code
Returns: Object - value at requested position
Description: Retrieves the value at some position in an array.
Errors: ERROR_index_out_of_range - the index is outside of the bounds of the aggregate

Procedure: OBJarray_at_put
Parameters: Object array - array to modify
int index - index at which to put element
Object value - value to insert
Error* errc - buffer for error code
Returns: void
Description: Store a value into an array object.
Errors: ERROR_index_out_of_range - the index is outside of the bounds of the aggregate

Procedure: OBJbag_add
Parameters: Object bag - bag to modify
Object item - item to add
Error* errc - buffer for error code
Returns: void
Description: Inserts an object into a bag.
Errors: ERROR_bag_full - there is no more room in the bag

Procedure: OBJbag_intersect
Parameters: Object bag - bag to intersect into
Object unitee - bag to intersect with
Error* errc - buffer for error code
Returns: void
Description: Intersects two bags. This operation is destructive: the first bag holds the resulting intersection on return.
Errors: none

Procedure: OBJbag_remove
Parameters: Object bag - bag to remove from
Object item - item to remove
Error* errc - buffer for error code
Returns: void
Description: Remove a single occurrence of some item from a bag, if it appears.
Errors: none

### OBJcreate_ud_entity

**Procedure:**  
OBJcreate_ud_entity  

**Description:**  
Create a user-defined entity. This procedure is not yet implemented.

### OBJfast_get_attribute

**Parameters:**  
Object object - object to examine  
Variable attribute - attribute to retrieve  
Error* errc - buffer for error code  

**Returns:**  
Object - value of attribute  

**Description:**  
Retrieves the value of an attribute from an entity instance. This call is faster than OBJget_attribute() when the caller already has the actual attribute record for the desired attribute, rather than simply having its name (as expected by OBJget_attribute()).

**Errors:**  
none

### OBJfast_put_attribute

**Parameters:**  
Object object - object to modify  
Variable attribute - attribute to store into  
Object value - value to store into attribute  
Error* errc - buffer for error code  

**Returns:**  
void  

**Requires:**  
TYPEget_class(OBJget_type(object)) == TYPE_ENTITY  

**Description:**  
Stores a value into an attribute of an entity instance. This call is faster than OBJput_attribute() when the caller already has the actual attribute record for the desired attribute, rather than simply having its name (as expected by OBJput_attribute()).

**Errors:**  
Same as for OBJput_attribute().

### OBJfree

**Parameters:**  
Object object - object to free  
Error* errc - buffer for error code  

**Returns:**  
void  

**Description:**  
Release an Object. Indicates that the object is no longer used by the caller; if there are no other references to the object, all storage associated with it may be released.

**Errors:**  
none

### OBJget_attribute

**Parameters:**  
Object object - object to examine  
String attributeName - name of attribute to retrieve  
Error* errc - buffer for error code  

**Returns:**  
Object - value of the named attribute  

**Description:**  
Retrieves the value of a named attribute from an entity instance. This call is the slower method for retrieving an attribute value. If the actual attribute record is already available, use OBJfast_get_attribute() instead.

**Errors:**  
none

### OBJget_line_number

**Parameters:**  
Object object - object to examine  

**Returns:**  
int - line number of object  

**Errors:**  
none
Procedure: OBJget_name
Parameters: Object object - object to examine
Returns: String - the object's name
Description: Retrieves the name of an object. Unnamed objects, which would normally be embedded entities and non-entities, yield STRING_NULL.
Errors: none

Procedure: OBJget_type
Parameters: Object object - object to examine
Returns: Type - the type of the object
Errors: none

Procedure: OBJget_user_data
Parameters: Object object - object to examine
Error* errc - buffer for error code
Returns: Generic - value of user data field for this object
Errors: none

Procedure: OBJget_value
Parameters: Object object - object to examine
Error* errc - buffer for error code
Returns: Generic - the object's value
Description: Retrieves the value of a single-valued object. The value returned will be a char* for a string object, a Constant for an enumeration object, and a pointer to an int, double, or Boolean for an integer, real, or logical object, respectively. See OBJarray_at(), OBJbag_includes(), OBJlist_at(), and OBJset_at() to read from an aggregate. See OBJget_attribute() to read from an entity instance.
Errors: none

Procedure: OBJinitialize
Parameters: Error* errc - buffer for error code
Returns: void
Description: Initialize the Object module. This is called by STEPinitialize().
Errors: none

Procedure: OBJis_external
Parameters: Object object - object to examine
Returns: Boolean - is this an external object (non-embedded entity)?
Errors: none

Procedure: OBJis_internal
Parameters: Object object - object to examine
Returns: Boolean - is this an internal object (embedded entity)?
Errors: none

</tbody>
</table>
Procedure: OBJput_value
Parameters: Object object - object to modify
Generic value - value for object
Error* errc - buffer for error code
Returns: void
Description: Sets the value of a single-valued object. The value given should be a char* for a string object. For an integer, real, or logical object, it should be an int*, double*, and Boolean*, respectively. For an enumeration object, the value given should be of type Constant. See OBJaggr_at_put(), OBJarray_at_put(), OBJbag_add(), OBJlist_add_first(), OBJlist_add_last(), and OBJset_add() to store into an aggregate. See OBJput_attribute() to store into an entity instance.
Errors: none

Procedure: OBJset_add
Parameters: Object set - set to modify
Object item - item to add
Error* errc - buffer for error code
Returns: void
Description: Inserts an object into a set, if it is not already present.
Errors: ERROR_set_full - there is no more room in the set

Procedure: OBJset_intersects
Parameters: Object set - set to intersect into
Object with - set to intersect with
Error* errc - buffer for error code
Returns: Boolean - does this set contain this item?
Errors: none

Procedure: OBJset_remove
Parameters: Object set - set to remove from
Object item - item to remove
Error* errc - buffer for error code
Returns: void
Description: Remove an item from a set, if it appears.
Errors: none
Procedure: OBJset_remove_all
Parameters: Object set - set to remove from
Object remove - set of items to remove
Error* errc - buffer for error code
Returns: void
Description: Removes all items in a set from some other set. This is set subtraction. This operation is destructive: the first set holds the result on return.
Errors: none

Procedure: OBJset_subset
Parameters: Object set - set to test as superset
Object subset - set to test as subset
Error* errc - buffer for error code
Returns: Boolean - does the first set contain the second as a subset?
Errors: none

Procedure: OBJset_unite
Parameters: Object set - set to unite onto
Object unitee - set to unite with
Error* errc - buffer for error code
Returns: void
Description: Forms the union of two sets. This operation is destructive: the first set holds the resulting union on return.
Errors: none

Procedure: OBJtype_cast
Parameters: Object object - object to be cast
Type type - type to cast to
Error* errc - buffer for error code
Returns: Object - the object, cast to the requested type
Description: Converts an object to a new type, if possible. If the cast is successful (*errc == ERROR_none), the original object should no longer be used. It is guaranteed to be valid only when an error is reported. This call does not report errors to stderr; it is the callers responsibility to check *errc and to call ERRORreport (*errc, (String)context) if it is not ERROR_none.
Errors: ERROR_aggregate_expected - value given for an aggregate was not an aggregate
ERROR_array_expected - value given for an array was not an array
ERROR_bag_expected - value given for a bag was not a bag
ERROR_entity_expected - value given for an entity was not an entity
ERROR_inappropriate_entity - the entity given as a value was not of an expected class
ERROR_integer_expected - value given for an integer was not an integer
ERROR_list_expected - value given for a list was not a list
ERROR_logical_expected - value given for a logical was not a logical
ERROR_number_expected - value given for a number was not a number
ERROR_set_expected - value given for a set was not a set
ERROR_string_expected - value given for a string was not a string
ERROR_incompatible_types - the value given is not of the expected type, in some way not covered by any of the above messages
5.3 Product

Procedure: PRODadd_object
Parameters: Product product - product to modify
            Object object - entity instance to add
Returns: void
Requires: TYPEget_class(OBJget_type(object)) == TYPE_ENTITY
Description: Adds an entity instance to a product model. The instance is assumed already to have been added to the instance list of its class, since OBJcreate_entity() does this.
Errors: none

Procedure: PRODcreate
Parameters: String name - name for new product
            Express model - conceptual schema in which to create product
Returns: Product - a new, empty product
Description: Creates an empty product within a particular conceptual schema.
Errors: none

Procedure: PRODget_conceptual_schema
Parameters: Product product - product to examine
Returns: Express - conceptual schema in which the product exists
Errors: none

Procedure: PRODget_contents
Parameters: Product product - product to examine
Returns: Linked_List - entity instances which make up the product
Description: Retrieves a list of the objects in a product model, in the order in which they were created.
Errors: none

Procedure: PRODget_name
Parameters: Product product - product to examine
Returns: String - the name of the product
Errors: none

Procedure: PRODget_named_object
Parameters: Product product - product to examine
Returns: String name - name of object to retrieve
Description: Object - the named object
Errors: none

Procedure: PRODinitialize
Parameters: -- none --
Returns: void
Description: Initializes the Product module. This is called by STEPinitialize().
Errors: none
## 6 STEP Working Form Error Codes

The Error module, which is used to manipulate these error codes, is described in [Clark90d]. All STEP Working Form error codes are defined in the Object module.

<table>
<thead>
<tr>

OTHER (PLEASE SPECIFY)

These documents and corresponding software will be available from NTIS in the future. When available, the NTIS ordering information will be forthcoming.
The Product Data Exchange Specification (PDES) is an emerging standard for the exchange of product information among various manufacturing applications. The neutral exchange medium for PDES product models is the STEP physical file format. The National PDES Testbed at NIST has developed software to manipulate and translate STEP models. This software consists of an in-memory working form and an associated physical file parser, STEPparse. The internal operation of the STEPparse parser is described. The implementation of the data abstractions which make up the STEP Working Form is discussed, and specifications are given for the Working Form access functions. The creation of STEP translators using STEPparse is discussed.
