This paper is devoted to an analysis of the data from the Livermore loops benchmark. We will show that in a general predictive sense the dimension of this data is rather samll; perhaps between two and five. Two techniques are used to reduce the 72 loops timings for each machine to a few scores which characterize the machine. The first is based on a principal component analysis, the second on a cluster analysis of the loops. The validity of the reduction of the data to a lesser dimension is checked by various methods.

Key words: benchmarks; computers; performance; Livermore loops; principal components; clusters.

[^0]
## 1 Introduction

This paper is concerned with the analysis of the benchmark data obtained from the Livermore Fortran Kernels (LFK). Our objective is to summarize this data and present it in a simple, clear manner with minimal loss of information. A related objective is to estimate the information content of the LFK loop timings.

The LFK code consists of 24 short Fortran code segments along with a driver to execute and time the segments and present the data in a standard format (McMahon[1986]). The timing results are given in megaflops (million floating point operations per second). The segments are all compute bound, no attempt is made to measure I/O rates. The segments consist primarily of short DO loops which are designed to cover a very wide range of execution rates. Therefore, the set contains a loop which will vectorize very well and may run at 1000 megaflops on a certain system, as well as another loop which may run at 4 megaflops on the same system. The loops in the 24 segments are each run with three different lengths, thus giving a total of 72 different test segments. We have selected 48 different machine/compiler systems from the data given in the report by McMahon and used this set to test our data analysis techniques. There is extensive experience with these segments on serial and vector machines, but very few results have been reported for parallel machines. We will refer to the 24 code segments as the "loops", and the 72 numbers obtained from timing the loops as the "loop runs".

The LFK benchmark data set describes each system by 72 numbers. Our objective is to describe each system by far fewer numbers, perhaps two to four. We will refer to these numbers as the "scores" for each system. McMahon's report reduces this data to two scores, the harmonic and geometric means of the megaflops rates. In addition, he sometimes adds tre arithmetic mean to give three numbers to characterize the systems. It is certainly desirable that these numbers have an easily understood meaning; for example, one number might be a mean megaflops rate for loops which vectorize well, and another the rate for loops which do not vectorize. One way to do this is to divide the loops into two or three
groups and characterize the systems by the geometric mean megaflops rates over these groups. One group might contain the "fast" loops which vectorize easily, another those which vectorize poorly or not at all. Another method is to include all the loops in each group, but weight the loops differently in each group. McMahon's paper gives megaflops rates for 49 different weightings of the loops. The problem with this approach is that the choice of the groups and/or the weights is rather arbitrary.

The method used to reduce the dimension of the data must preserve the information in the data. In order to develop a systematic reduction of the dimension of the data, we must define the information that we are attempting to retain and preferably provide some way to quantify this information. We will do this by using the reduced data (i.e. three or four scores for each system ) to reconstruct an approximation to the original 72 loop runs. The quality of the reduction can then be measured by the discrepancy between the original and reconstructed data. Also, we can determine how well the reconstructed data retain the ranking of the systems on the segments; that is, if one system is faster than another in the original data it should also be faster in the approximation.

The reduction of the dimension of the data can be obtained from a principal component analysis of the data matrix $\mathbf{A}$, that is the $m \times 72$ matrix of megaflops rates, where $m$ is the number of systems. In principal component analysis, the data matrix $\mathbf{A}$ is approximated by the product $\mathrm{BC}^{t}$ where B has dimension $m \times q$ and C has dimension $72 \times q$. The B matrix contains $q$ scores for each of the $m$ systems. The $q$ columns of $C$ are the eigenvectors of $\mathbf{A}^{t} \mathbf{A}$ corresponding to the $q$ largest eigenvalues of $\mathbf{A}^{t} \mathbf{A}$. These $q$ eigenvalues are the squares of the singular values of $A$. The $q$ elements $b_{i j}$ of $\mathbf{B}$ for $1 \leq j \leq q$ then characterize the $i^{\text {th }}$ system. The quality of this characterization is determined by how well the $\mathbf{A}$ matrix is approximated by the product $\mathrm{BC}^{t}$.

The dimension of the reduced data, that is $q$, can be related to the predictive capability of the LFK data. If this data, for a collection of $m$ systems, adequately describes these systems, then any given computer code could be modeled as a combination of the 72
segments weighted in some way. That is, the running time of the given code could be well estimated by computing the weighted sum of the running times of the segments. If there are $m$ systems and $n$ of these codes, then the running times of these codes form an $m \times n$ matrix which we denote by $\mathbf{F}$. Our problem is to find a $72 \times n$ matrix $W$ of weights which will predict the running time of these codes from that of the LFK loops. The matrix $\mathbf{W}$ can be defined as the least squares solution of the equation $\mathbf{A W}=\mathbf{F}$. As we will see, the singular values of the LFK data matrix $\mathbf{A}$ drop off very rapidly. This means that the least squares solution is not well determined. Only the first three or four weights for any given system are well determined. In this sense the dimensionality of the LFK data is quite small, certainly far less than 24 . We will devote considerable attention to the selection of a reasonable value for the dimension $q$. However, we are unable to give a precise value for this dimension - it seems to lie between 3 and 5.

This reduction by means of the principal component analysis has the disadvantage that the scores in the matrix $\mathbf{B}$, for a given system are not determined solely by the benchmark times for that system. If a new system is added to the set, then the characterizations for all the systems may change. Therefore, we will discuss a second technique to define the scores for the systems.

The technique is cluster analysis. The 72 loop runs are decomposed into a few nonoverlapping clusters. We have experimented with values of $q$ (the number of clusters) between two and five. The cluster procedure seems to divide the loop runs in accordance with the degree of their vectorization on the vector systems. Given the clusters, then the geometric mean (or other means, see Smith[1988]) of the megaflops rates of a given system over each cluster is used to define the scores for that system. Thus, given $q$ clusters, there are $q$ scores for each system. Once the matrix $\mathbf{B}$ of scores is defined, an approximation of the original data matrix is constructed from the score matrix. The quality of this approximation can then be evaluated.

The paper is organized as follows. Section 2 describes the summary statistics for both
systems and loops. Section 3 gives a mathematical description of the data reduction technique used. In sections 4 and 5 we discuss the results of our data reduction based on the principal component and cluster analyses respectively. The final section summarizes our findings and identifies directions for further work.

## 2 The Data and Descriptive Statistics

The data we use consist of 72 loop rates (megaflops) for 48 machine/compiler systems. We identify each loop run by a three-digit number; the first digit is the ID for the loop length and the next two-digits the loop segment number. For example, 214 designates loop 14 using the second loop length. The summary statistics for loops are listed in Table 1. It indicates that most of the loop distributions are skewed to the left (mean larger than the median). The range statistic (difference between maximum and minimum rates) can be used to identify loops that deliver high megaflops rates. The 72 loop runs are all positively correlated. The correlation coefficients for the loop runs at the first set of loop length range from 0.2309 (between loops 4 and 22) to 0.9910 (between loops 8 and 18). The correlation matrix is displayed in Table 2.

The summary statistics for different machine/compiler systems are listed in Table 3, which includes the three different means, performance ranges, and standard deviations.

## 3 The Principal Components Technique for Data Reduction

In this section we describe the use of principal components as a general data reduction technique. Given a data matrix $\mathbf{A}$ of dimension $m \times n$, our goal is to find a matrix $\mathbf{C}$ of size $n \times q(q \ll n)$, such that $\mathbf{B}=\mathbf{A C}$ preserves most of the information in $\mathbf{A}$. In our case $n=72$. More precisely, $\mathbf{C}$ is chosen so that the matrix $\mathbf{B}=\mathbf{A C}$ is the best linear
predictor of $\mathbf{A}$ on the basis of $q$ linear functions. If $\mathbf{B}$ can replace $\mathbf{A}$ without much loss of information, then only a small number ( $q$ ) of derived variables is needed to retain most of the variation present in all of the original variables. This dimension-reducing process may aid in the interpretation of the data.

The criterion for determining the matrix $\mathbf{C}$ is based on how well matrix $\mathbf{B}$ can predict matrix $\mathbf{A}$. To reproduce $\mathbf{A}$ from $\mathbf{B}$, we attempt to find a matrix $\mathbf{R}$ of size $q \times n$ such that

$$
\hat{\mathbf{A}}=\mathbf{B R}
$$

is a good approximation of $\mathbf{A}$. Then we will have

$$
\mathbf{A}=\mathbf{B} \mathbf{R}+\epsilon=\hat{\mathbf{A}}+\epsilon
$$

The usual least squares estimator for $\mathbf{R}$ is $\left(\mathbf{B}^{t} \mathbf{B}\right)^{-1} \mathbf{B}^{t} \mathbf{A}$, or

$$
\hat{\mathbf{A}}=\mathbf{A C}\left(\mathbf{C}^{t} \mathbf{A}^{t} \mathbf{A} \mathbf{C}\right)^{-1} \mathbf{C}^{t} \mathbf{A}^{t} \mathbf{A}
$$

Thus, our goal is to find a matrix $\mathbf{C}$ such that

$$
\begin{equation*}
\|\mathbf{A}-\hat{\mathbf{A}}\|=\left\|\mathbf{A}-\mathbf{A C}\left(\mathbf{C}^{t} \mathbf{A}^{t} \mathbf{A} \mathbf{C}\right)^{-1} \mathbf{C}^{t} \mathbf{A}^{t} \mathbf{A}\right\| \tag{4.1}
\end{equation*}
$$

is a minimum.
There may not be a unique matrix $C$ which yields a minimum norm in equation 4.1. We will show that one solution for the matrix C is an $n \times q$ matrix whose columns are the first $q$ principal components of $\mathbf{A}$; that is, if $\lambda_{1} \geq \lambda_{2} \geq \cdots \geq \lambda_{q}$ are the $q$ largest eigenvalues of $\mathbf{A}^{t} \mathbf{A}$ and $\mathbf{p}_{1}, \ldots, \mathbf{p}_{q}$ are the eigenvectors of unit norm corresponding to $\lambda_{1}, \cdots, \lambda_{q}$ respectively, then $C=\left(\begin{array}{llll}\mathbf{p}_{1} & \mathbf{p}_{2} & \cdots & \mathbf{p}_{q}\end{array}\right)$.

By the spectral decomposition of $\mathbf{A}$, we can write

$$
\begin{aligned}
\mathbf{C}^{t} \mathbf{A}^{t} \mathbf{A C} & =\left(\begin{array}{c}
\mathbf{p}_{1}^{t} \\
\vdots \\
\mathbf{p}_{q}^{t}
\end{array}\right)\left(\lambda_{1} \mathbf{p}_{1} \mathbf{p}_{1}^{t}+\cdots+\lambda_{n} \mathbf{p}_{n} \mathbf{p}_{n}^{t}\right)\left(\begin{array}{lll}
\mathbf{p}_{1} & \cdots & \mathbf{p}_{q}
\end{array}\right) \\
& =\operatorname{diag}\left(\lambda_{1}, \ldots, \lambda_{q}\right)
\end{aligned}
$$

since

$$
\begin{aligned}
\mathbf{p}_{i}^{t} \mathbf{p}_{j} & =0, \text { if } i \neq j \\
& =1, \text { if } i=j
\end{aligned}
$$

We have

$$
\begin{aligned}
\hat{\mathbf{A}} & =\mathbf{A C} \operatorname{diag}\left(\lambda_{1}^{-1}, \cdots, \lambda_{q}^{-1}\right) \mathbf{C}^{t} \mathbf{A}^{t} \mathbf{A} \\
& =\mathbf{A}\left(\begin{array}{lll}
\mathbf{p}_{1} & \cdots & \mathbf{p}_{q}
\end{array}\right) \operatorname{diag}\left(\lambda_{1}^{-1}, \cdots, \lambda_{q}^{-1}\right)\left(\begin{array}{c}
\mathbf{p}_{1}^{t} \\
\vdots \\
\mathbf{p}_{q}^{t}
\end{array}\right)\left(\lambda_{1} \mathbf{p}_{1} \mathbf{p}_{1}^{t}+\cdots+\lambda_{n} \mathbf{p}_{n} \mathbf{p}_{n}^{t}\right) \\
& =\mathbf{A}\left(\mathbf{p}_{1} \mathbf{p}_{1}^{t}+\cdots+\mathbf{p}_{q} \mathbf{p}_{q}^{t}\right)
\end{aligned}
$$

A matrix result (see Rao[1973] p.70) states that the matrix $\hat{\mathbf{A}}$ of size $m \times n$ of rank $q$, for which $\|\mathbf{A}-\hat{\mathbf{A}}\|$ is minimum, is given by $\mathbf{A}\left(\mathbf{p}_{1} \mathbf{p}_{1}^{t}+\cdots+\mathbf{p}_{q} \mathbf{p}_{q}^{t}\right)$; where $\mathbf{p}_{1}, \ldots, \mathbf{p}_{q}$ are the first $q$ eigenvectors of matrix $\mathbf{A}^{t} \mathbf{A}$, corresponding to the $q$ largest eigenvalues of $\mathbf{A}^{t} \mathbf{A}$. Thus, the matrix $\mathbf{C}$ whose columns are the first $q$ principal components yields the minimum of $\|\mathbf{A}-\hat{\mathbf{A}}\|$.

There are other optimal properties regarding principal components besides minimizing $\|\mathbf{A}-\hat{\mathbf{A}}\|$. For more detailed discussions, see Jolliffe[1986]. The goodness of the data reduction is measured by $\|\mathbf{A}-\hat{\mathbf{A}}\|$. Since there is a large variability of the megaflops rates between and within systems, it makes more sense to look at the relative change; that is, $\left(a_{i j}-\hat{a}_{i j}\right) / a_{i j}$, not $a_{i j}-\hat{a}_{i j}$. This motivates the need of a logarithmic transformation for the original data. Several other reasons also call for the log transformation. The transformation helps to correct the skewness of the loop distributions. The transformation results in data being described by geometric rather than arithmetic means which is more appropriate (Tleming and Wallace[1986]) for data which have such a wide range. In addition, it also resolves the dilemma of whether to use the megaflops rate or the time/megaflop as the unit of the measurement in the analysis (Smith[1988]).

## 4 Principal Component Analysis of Benchmark Data

The first 7 eigenvalues of matrix $\mathbf{A}^{t} \mathbf{A}$ (after $\log$ transformation) are given below.

|  | 1 | 2 | 3 | 4 | 5 | 6 | 7 |
| :--- | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| Eigenvalue | 318.714 | 17.4104 | 4.72784 | 1.67885 | 1.39222 | 0.82538 | 0.60049 |
| Proportion | 0.9163 | 0.0501 | 0.0136 | 0.0048 | 0.0040 | 0.0024 | 0.0017 |
| Cumulative | 0.9163 | 0.9663 | 0.9799 | 0.9848 | 0.9888 | 0.9911 | 0.9929 |

Here the $k^{t h}$ "Proportion" entry is the ratio of the $k^{t h}$ eigenvalue to the trace of $\mathbf{A}^{t} \mathbf{A}$, and the "Cumulative" entry the ratio of the sum of the first $k$ eigenvalues to the trace. Since the sum of eigenvalues is the trace of $\mathbf{A}^{t} \mathbf{A}$, i.e. the total sum of squares of $\mathbf{A}$, the ratio of each eigenvalue to the sum can be viewed as the proportion of the total sum of squares accounted for by the corresponding component.

The values of $\|\mathbf{A}-\hat{\mathbf{A}}\|$ resulting from using one to seven components are given below, which indicates that the values of $\|\mathbf{A}-\hat{\mathbf{A}}\|$ begin to level off after 3 or 4 components have been extracted.

| No. of Components | 1 | 2 | 3 | 4 | 5 | 6 | 7 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $\\|\mathbf{A}-\hat{\mathbf{A}}\\|$ | 37.38 | 23.70 | 18.30 | 15.95 | 13.69 | 12.16 | 10.91 |

If we consider only the reduction in the size of the eigenvalues of $\mathbf{A}^{t} \mathbf{A}$ and the difference $\|\mathbf{A}-\hat{\mathbf{A}}\|$, then it is difficult to decide how many components should be used to approximate the data matrix A. However, an inspection of the elements of the $C$ matrix shows a correlation with the nature of the code segments. The $j^{\text {th }}$ component, shown below, is simply the $j^{\text {th }}$ column of the C matrix. The first component clearly measures overall performance of systems as would be expected since all the correlations between the 72 loop runs are positive and this component accounts for $91.63 \%$ of the total variation.

| 121 | 0.12303 | 221 | 0.13286 | 321 | 0.13659 |
| 122 | 0.11467 | 222 | 0.12890 | 322 | 0.12892 |
| 123 | 0.10885 | 223 | 0.11174 | 323 | 0.11171 |
| 124 | 0.06075 | 224 | 0.06937 | 324 | 0.07914 |

We observe that the faster loops tend to have a negative second component. That is, the second component, given in the table below, contrasts loops that deliver high megaflops
rates (negative coefficients) with the rest (positive coefficients). Also, we observe that the degree of the loop vectorization is correlated with the magnitude of the second component. For example, the sign of the coefficients of runs 107, 207 and 307 indicates that the loop 7 is a vectorized loop; and the magnitude of the coefficients reveals that the loop performance increases as the loop length increases. Similarly, the loop 9 is also a vectorized loop, however, the megaflops rate tops out at the second segment of loop length and further increase of loop length will not increase the performance as indicated by the magnitude of the coefficients of runs 209 and 309. Thus, after overall performance has been accounted for, the next source of variation is between systems with vectorization capability and systems without that capability.

The third component, given below, identifies the loop length effect for each vectorized loop. The smaller the coefficient, the larger the impact of the loop lengths to the loop
performance. For example, the performance of the loop 1 is an increasing function of all the 3 loop lengths, while for loop 2 , it's an increasing function only for the first 2 loop lengths. The large and almost identical coefficients in loop 20 indicate that the loop is scalar and therefore there is no loop length effect. Overall, the first 3 components account for a substantial proportion of the total variation ( $97.99 \%$ ).

### 4.1 Goodness of Reduction

Although the principal components were derived solely based on the minimization of $\| \mathbf{A}-$ $\hat{\mathbf{A}} \|$, other criteria can also be used to assess the adequacy of the dimension reduction. Our objective is the simplification of the benchmark data. This requires a reduction in its dimension. However, looking only at the norm $\|\mathbf{A}-\hat{\mathbf{A}}\|$ and the eigenvalues of $\mathbf{A}^{t} \mathbf{A}$ does not provide a clear indication of the number of components which should be used to reconstruct $\hat{\mathbf{A}}$. We will use three extra measures of the quality of the approximation of $\mathbf{A}$ by $\hat{\mathbf{A}}$. The first is a comparison of the geometric means of the megaflops rates for each system obtained from the original data $\mathbf{A}$ with the means obtained from the approximate data of $\hat{\mathbf{A}}$. The second is the performance range, the difference between the maximum and minimum megaflops rates, for each system. The third is the Spearman rank correlation coefficient (Noether[1967]) for the 72 loop runs for each system. The Spearman correlation indicates how well the rank ordering of the loop rates is preserved. Specifically, for each system, the Spearman correlation coefficient between the ranks of the 72 megaflops rates of $\mathbf{A}$ and $\hat{\mathbf{A}}$ is calculated. A large Spearman correlation indicates a good preservation of the ranking. Table 4 lists the results for one to four components (used in the data reduction). This table shows the ratio of the geometric mean of the reconstructed data to the geometric mean of the original data, and also gives a similar ratio for the range of the data for each system.

Table 4 shows that the Spearman coefficient tends to be smaller for the scalar systems because there is much less variation of the loop rates compared to that for a vector system. Therefore the rank order is not as well defined for the scalar systems so that the data in the $\hat{\mathbf{A}}$ must be more accurate in order to preserve the rank order.

Note that the geometric mean is already quite accurate when only one component is used to construct $\hat{\mathbf{A}}$. Also, in Table 4, there is little change in the geometric means obtained from $\hat{\mathbf{A}}$ in going from one to four components.

However, to preserve the rank ordering of the loop rates for each system, as measured
by the Spearman correlation, requires three components. There is considerable change in the Spearman correlations in going from one to two components, and some change from two to three components. Table 4 is concerned with the ranking of the loops for each system; thus there are 72 elements in the ranking with the fastest loop at the head of the ranking. Perhaps a ranking of the systems for each loop is of greater significance to benchmarking. Here there are 48 systems in the ranking for each loop with the fastest system at the head of the ranking. For such a ranking of the systems on each loop, the Spearman correlations are sufficiently large (i.e. generally greater than 0.9 ) when only two components are used to generate $\hat{\mathbf{A}}$.

It is very difficult to accurately reproduce the range using only a few components to construct the $\hat{\mathbf{A}}$. The actual range for the ETA205-V is 167 and the approximate range using four components is only 56 . For other vector systems the error was not this large, but was still in the $20 \%$ region. Approximating extreme values is very difficult. It is difficult to determine how important these extreme values are in the evaluation of the system. Nevertheless, it seems that three components are the minimum number required to adequately preserve the central tendency, the spread, and the rank ordering of the original data.

Another common practice of assessing the goodness-of-fit is to examine the residuals. Plots of elements of $\mathbf{A}-\hat{\mathbf{A}}$ are displayed in Figures 1a, 1b and 1c. They shows that, among 72 runs, loop 24's have the most extreme outlying points. Detailed examination reveals that most of the outliers are from the same group of machines. For example, the top 3 outliers of runs 224 and 324 are Amdahl (1400VP-V, 1200VP-V, and $1500 \mathrm{VP}-\mathrm{V}$ ); the top outlier of loop 23 is Apollo300-32; the top 2 outliers of runs 121, 219, and 319 are Convex (V-32 and V-64); the top outlier of loop 15 is Alliant-V-64-P. In general, most of the residuals lie within the band of $(-0.5,0.5)$ indicating that 3 principal components are probably sufficient in summarizing the data.

### 4.2 Component Scores

The matrix $\mathbf{B}=\mathbf{A C}$ is the matrix of summary scores obtained from the reduction. We also point out here that the matrix $\mathbf{C}$ (and consequently $\mathbf{B}$ ) is not uniquely determined and that any other matrix $\tilde{\mathbf{C}}$ of size $n \times q$ whose columns span the same space as the columns of $\mathbf{C}$ will also solve the data reduction problem, i.e. $\tilde{\mathbf{C}}=\mathbf{C P}$ where $\mathbf{P}$ is any $q \times q$ nonsingular matrix is also an optimal solution. It is easily shown that there exists a $3 \times 3$ nonsingular matrix $\mathbf{P}$ such that the first column of the matrix $\tilde{\mathbf{C}}=\mathbf{C P}$ will sum to 1 , and the negative and the positive coefficients of the second and the third columns of $\tilde{\mathbf{C}}$ will sum to -1 and 1 respectively. This transformation will allow us to interpret the scores as geometric means. Let $\mathbf{A}$ and $\mathbf{B}$ be the data and score matrices in $\log$ scale and $\overline{\mathbf{A}}$ the original data matrix, i.e. $\mathbf{A}=\log (\tilde{\mathbf{A}})$, then $\tilde{\mathbf{B}}=\mathbf{A} \tilde{\mathbf{C}}$. The rows of $\tilde{\mathbf{B}}$ now represent the summary scores corresponding to each of the 48 systems.

For score 1, we have

$$
\begin{aligned}
\tilde{b}_{i 1} & =\sum_{k=1}^{72} a_{i k} \tilde{c}_{k 1} \\
& =\sum_{k=1}^{72} \tilde{c}_{k 1} \log \ddot{a}_{i k} \\
& =\log \left(\prod_{k=1}^{72} \bar{a}_{i k}^{\tilde{c}_{k 1}}\right)
\end{aligned}
$$

If we let $\tilde{b}_{i j}=\log \tilde{b}_{i j}$, which is the $j^{\text {th }}$ summary score for system $i$ in the original scale, we have

$$
\check{b}_{i 1}=\prod_{k=1}^{72} \tilde{a}_{i k}^{\overline{c k}_{k 1}}
$$

which is a weighted geometric mean of the 72 loop rates with weights $\tilde{c}_{k 1}, k=1,2, \cdots, 72$.
For scores 2 and 3 (i.e. $j=2$ and 3 ), we have

$$
\begin{aligned}
\tilde{b}_{i j} & =\sum_{\left\{\tilde{c}_{k j}>0\right\}} a_{i k} \tilde{c}_{k j}+\sum_{\left\{\tilde{c}_{k j}<0\right\}} a_{i k} \tilde{c}_{k j} \\
& =\log \left(\prod_{\left\{\bar{c}_{k j}>0\right\}} \tilde{a}_{i k}^{\tilde{c}_{k j}} / \prod_{\left\{\tilde{c}_{k j}<0\right\}} \tilde{a}_{i k}^{\left|\tilde{c}_{k},\right|}\right),
\end{aligned}
$$

or

$$
\ddot{b}_{i j}=\prod_{\left\{\tilde{c}_{k j}>0\right\}} \tilde{a}_{i k}^{\bar{c}_{k j}} / \prod_{\left\{\tilde{c}_{k j}<0\right\}} \tilde{a}_{i k}^{\left|\bar{c}_{k j}\right|}
$$

which is a ratir of 2 weighted geometric means. These scores are tabulated in Table 5.
Score 1 measures the overall performance of each system. For vector systems, score 1 can be significantly larger than the geometric mean, since the weights $\tilde{c}_{k 1}$ have slightly larger value on vectorizable loops. For scalar systems, score 1 and the geometric mean are very close, implying that vectorizable loops play no significant roles here. Score 2 is the ratio of the scalar performance to the vector performance and can be used to easily identify the vector systems and their vectorizability. The smaller the value of score 2 , the more vectorizable the system. Score 3 measures the loop length effect for the vector systems. Again, the small value of score 3 implies the significant length effect.

Another advantage of reducing the dimensionality of the data is that we are able to plot the data. The original 72 -dimensional data are impossible to visualize. The first 3 components give the best-fitting 3-dimensional subspace and preserve a substantial proportion of the total variation. Figure 2 gives the plot of the machines with respect to the first 2 scores. The size of the markers in the plot is proportional to the reciprocal of the third score. The vector and scalar systems are in separate clusters, with the vector systems at the bottom of the plot. Note that when the Cray systems are run in scalar mode, they appear in the scalar cluster. The markers are: Alliant - " $\square$ ", Amdahl -" $\triangle$ ", Apollo -" $\oplus$ ", Convex -" $\nabla$ ", Cray -" + ", DEC - "*", ETA - " $\bullet$ ", IBM - "o", NEC -"*", SCS - " 0 ", Sperry " $x$ ", and all others - " $\otimes$ ".

## 5 Cluster Analysis on Loop Runs

As we mentioned earlier, although the principal components have some desired optimal properties in data reduction, there is one disadvantage of being data dependent. If a new system is added to the benchmark data set, then the scores for all the systems may change. In order to eliminate this data dependence, the 72 loop runs are divided into $q$ clusters.

The geometric mean of the megaflops rates over each cluster is used to define $q$ scores for each system. Once the clusters are defined, then the scores for each system are completely independent of the scores for the other systems. However, the clusters must be defined so that these scores give a good characterization of the systems.

The decomposition of the loop runs is obtained from a $72 \times q$ matrix $G$ of weights. This matrix is used to generate a score matrix $B$ in the same way that the matrix $C$ of principal components generates a score matrix, that is $\mathbf{B}=\mathbf{A G}$. This matrix $\mathbf{G}$ is restricted to have a single non-zero element in each row. This non-zero element identifies the cluster membership and the weight within the cluster for the loop run. Therefore G can be used to decompose the loop runs into $q$ clusters. The elements of $G$ must be chosen so that the score matrix $\mathbf{B}$ is the best possible predictor of the original data matrix $\mathbf{A}$. In fact, we could formulate the problem by the same technique used in section 3, i.e. our goal would be to find a matrix $G \in \Gamma$, where $\Gamma$ is the collection of all the $72 \times q$ matrices having only a single non-zero element in each row, such that

$$
\begin{equation*}
\left\|\mathbf{A}-\mathbf{A G}\left(\mathbf{G}^{t} \mathbf{A}^{t} \mathbf{A} \mathbf{G}\right)^{-1} \mathbf{G}^{t} \mathbf{A}^{t} \mathbf{A}\right\| \tag{6.1}
\end{equation*}
$$

is a minimum.
The minimization of (6.1) is a difficult (computational) problem. However, in the general case (i.e. no restriction imposed on $G$ ) the problem is equivalent to the minimization of the trace of the residual variance of predicting $\mathbf{A}$ based on the linear predictor $\mathbf{A G}$ (see Rao[1973], p.593). This residual variance can be expressed as the covariance matrix of $\mathbf{A}$ given A G (that is, the covariance conditional on AG), which is

$$
\begin{equation*}
\Sigma-\Sigma \mathrm{G}\left(\mathrm{G}^{t} \Sigma \mathrm{G}\right)^{-1} \mathrm{G}^{t} \Sigma \tag{6.2}
\end{equation*}
$$

where $\Sigma$, of size $72 \times 72$, is the covariance matrix of the loop runs. To minimize the trace of (6.2), we need to maximize $\operatorname{trace}\left(\boldsymbol{\Sigma} \mathbf{G}\left(\mathbf{G}^{t} \boldsymbol{\Sigma} \mathbf{G}\right)^{-1} \mathbf{G}^{t} \boldsymbol{\Sigma}\right)$. If there were no constraint imposed on $G$, the optimum choice of $G$ would be $G=C$, the $q$ largest principal components of
$\Sigma$. Also, since (see Rao[1973] p.592) for any $72 \times q$ matrix $\mathbf{X}$

$$
\begin{aligned}
\max _{\mathbf{X}} \operatorname{trace}\left(\boldsymbol{\Sigma X}\left(\mathbf{X}^{t} \boldsymbol{\Sigma} \mathbf{X}\right)^{-1} \mathbf{X}^{t} \boldsymbol{\Sigma}\right) & =\operatorname{trace}\left(\boldsymbol{\Sigma} \mathbf{C}\left(\mathbf{C}^{t} \boldsymbol{\Sigma} \mathbf{C}\right)^{-1} \mathbf{C}^{t} \boldsymbol{\Sigma}\right) \\
& =\operatorname{trace}\left(\mathbf{C}^{t} \boldsymbol{\Sigma} \mathbf{C}\right)
\end{aligned}
$$

this motivates us to reformulate the problem; instead of finding $G \in \Gamma$ to minimize (6.1), we will find $G \in \Gamma$ such that

$$
\begin{equation*}
\operatorname{trace}\left(\mathrm{G}^{t} \Sigma \mathrm{G}\right)=\mathrm{g}_{1}^{t} \Sigma \mathrm{~g}_{1}+\cdots+\mathrm{g}_{q}^{t} \Sigma \mathrm{~g}_{q} \tag{6.3}
\end{equation*}
$$

is a maximum, where $\mathrm{g}_{i}$ is the $i^{\text {th }}$ column of $\mathbf{G}$. If we denote by $\mathbf{h}_{\boldsymbol{i}}$ the column vector containing the non-zero elements of $\mathrm{g}_{i}$, and $\Sigma_{i}$ the covariance submatrix of $\Sigma$ corresponding to these non-zero elements, then $\mathrm{g}_{i}^{t} \mathrm{\Sigma g}_{i}=\mathrm{h}_{i}^{t} \Sigma_{i} \mathrm{~h}_{i}$. In addition,

$$
\max _{\mathbf{h}_{i}} \mathbf{h}_{i}^{t} \boldsymbol{\Sigma}_{\mathbf{i}} \mathbf{h}_{i}=\mathbf{c}_{i}^{t} \Sigma_{i} \mathbf{c}_{i},
$$

where $\mathbf{c}_{\boldsymbol{i}}$ is the eigenvector corresponding to the largest eigenvalue of $\boldsymbol{\Sigma}_{\boldsymbol{i}}$. Thus, the elements of G which maximize (6.3) can be easily determined if the cluster structure is known.

In this paper, we employ the VARCLUS procedure of the SAS[1986] to find the cluster components $G$. It begins with all loops in one cluster and repeats the following steps until $q$ clusters are obtained.

1. The principal components for each cluster are computed, that is, the eigenvectors of each $\boldsymbol{\Sigma}_{\boldsymbol{i}}$. The cluster having the largest second eigenvalue is chosen for further splitting.
2. The chosen cluster is split into two clusters by finding the first two principal components, performing a rotation (Harman[1976]) and assigning each loop run to the rotated (cluster) component with which it has the higher squared correlation.

Once $q$ clusters are obtained then an iterative procedure is used to reassign loop runs to clusters in order to maximize the trace in (6.3).

Since the principal components were obtained without the constraint, a given number of cluster components does not explain as much variance as the same number of principal components. However, the cluster components are easier to interpret than the principal components.

The cluster results obtained from the VARCLUS procedure are given in the tables below. For the two-cluster case, the elements of the matrix $\mathbf{G}$, multiplied by $10^{6}$, are given in the following table.

| Run | Cluster 1 | Cluster 2 | Run | Cluster 1 | Cluster 2 | Run | Cluster 1 | Cluster 2 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 101 |  | 33061 | 201 |  | 33164 | 301 |  | 32941 |
| 102 | 25069 |  | 202 | 25073 |  | 302 | 25094 |  |
| 103 | 25102 |  | 203 |  | 33011 | 303 |  | 32840 |
| 104 | 24585 |  | 204 | 25272 |  | 304 |  | 32541 |
| 105 | 25440 |  | 205 | 25425 |  | 305 | 25438 |  |
| 106 | 24978 |  | 206 | 25059 |  | 306 | 24753 |  |
| 107 |  | 33129 | 207 |  | 33231 | 307 |  | 33075 |

| 109 |  | 32947 | 209 |  | 33220 | 309 |  | 33222 |
| 110 |  | 32580 | 210 |  | 33001 | 310 |  | 33006 |
| 111 | 25129 |  | 211 | 25014 |  | 311 | 24981 |  |
| 112 |  | 32792 | 212 |  | 32997 | 312 |  | 32829 |
| 113 | 24702 |  | 213 | 24742 |  | 313 | 24741 |  |
| 114 | 25129 |  | 214 | 25083 |  | 314 | 25056 |  |
| 115 | 24804 |  | 215 | 24740 |  | 315 | 24721 |  |
| 116 | 25292 |  | 216 | 25251 |  | 316 | 25262 |  |
| 117 | 25394 |  | 217 | 25377 |  | 317 | 25379 |  |
| 118 |  | 32941 | 218 |  | 33300 | 318 |  | 33298 |
| 119 | 25159 |  | 219 | 24654 |  | 319 | 24652 |  |
| 120 | 25262 |  | 220 | 25255 |  | 320 | 25252 |  |
| 121 |  | 32726 | 221 |  | 33043 | 321 |  | 33009 |
| 122 |  | 32737 | 222 |  | 32753 | 322 |  | 32748 |
| 123 | 25063 |  | 223 | 25090 |  | 323 | 25085 |  |
| 124 | 23645 |  | 224 | 22301 |  | 324 |  | 27334 |

As we can see, the weights within each cluster are nearly constant for the above case. In fact, as the number of clusters increases, the weights tend to be even less variable within
each cluster because the clusters become more homogeneous. Thus, we can treat the loop runs within each cluster equally without loss of much information. The clusters obtained from the VARCLUS procedure for $q=3,4$, and 5 are shown below.

| Cluster 1 |  |  | Cluster 2 |  |  | Cluster 3 |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

The cluster analysis apparently groups the loops according to ease of vectorization and megaflops rate. Consider the situation when the loops are broken into four clusters. The first cluster consists generally of loops that do not vectorize, the second of loops which
vectorize very well and give high megaflops rates, the third cluster is an anomaly which consists of a single loop, and the fourth consists of loops which vectorize only moderately well and do not give high megaflops rates. This can be seen from Table 6. This table lists, for each of the 72 loop runs, the first and third quartiles (Q1 and Q3) of the megaflops rates over the 48 systems. Also listed is a vectorization figure. The report by McMahon gives the extent of vectorization for each of the 24 loops for 6 systems: Cray-1, Fujitsu, Cyber205, Convex C1, NECSX-2, and IBM3090. Table 5 of McMahon's report shows full, partial, or no vectorization for each of these systems. The "vector" column in Table 6 gives this number for each loop. If the vectorization number is 6 , then all systems fully vectorized the loop. If this number is 4 p , then four systems partially vectorized the loop and two systems gave no vectorization. It is clear that most of the loops in cluster 1 did not vectorize on any systems, whereas most loops in cluster 2 vectorized on all systems. The average loop in cluster 4 vectorized on only three systems, thus this cluster is intermediate between 1 and 2. Cluster 3 contains only loop 24 which is an analous case. This loop is the following:

$$
\begin{aligned}
& \mathrm{M}=1 \\
& \text { DO } 24 \mathrm{~K}=2, \mathrm{M} \\
& \quad \mathrm{IF}(\mathrm{X}(\mathrm{~K}) \text {. .TT. } \mathrm{X}(\mathrm{M})) \mathrm{M}=\mathrm{K}
\end{aligned}
$$

The Amdahl vector systems ran this loop an order of magnitude, or more, faster than the other systems. Therefore the results for this loop have a different structure than those for the other loops; so much different that this loop forms a cluster by itself. Perhaps the Amdahl system has a hardware instruction to locate the smallest element in an array, and the compiler is clever enough to generate that instruction. At any rate, this loop seems to be an anomaly. It is rather remarkable that this cluster analysis seems to select the loops based on vectorization.

Next we consider a method to define scores for each system based on this decompo-
sition of the loops into clusters. Given a decomposition of the loops into $q$ clusters, the corresponding scores are defined as the geometric mean of the megaflops rates for the given system over the clusters. Thus, if there are $m$ systems, then we have defined an $m \times q$ score matrix B. This matrix is shown in Tables 7 for $q=2$ and $q=4$. For the case of four clusters, the first score is the geometric mean over loops which vectorize poorly, the second over loops which vectorize very well, the third over the single loop which finds the smallest element in an array, and the fourth over loops which are partially vectorized.

From the score matrix $\mathbf{B}$, we construct an approximation $\hat{\mathbf{A}}$ of the original data matrix $\mathbf{A}$. The approximation is obtained by least squares. The values of $\|\mathbf{A}-\hat{\mathbf{A}}\|$ resulting from using two to five clusters are given below.

| No. of Clusters | 2 | 3 | 4 | 5 |
| :---: | :---: | :---: | :---: | :---: |
| $\\|\mathbf{A}-\hat{\mathbf{A}}\\|$ | 24.61 | 20.58 | 17.32 | 16.30 |

For a given value of $q$, the $L_{2}$ norm $\|\mathbf{A}-\hat{\mathbf{A}}\|$ based on the principal components is smaller, as we might expect, since the principal component approximation is optimal. Also, from this approximation $\hat{\mathbf{A}}$ the geometric mean and range of the loop runs for each system can be computed. These are shown in Table 8. The mean and range can be compared with those obtained from the original matrix which are displayed in Table 3. In addition, the mean and range can be compared with those in Table 4 obtained from the approximation based on the principal components. The approximation based on cluster analysis requires four clusters to give roughly the same accuracy for the geometric mean and Spearman rank correlation as three components of the principal component analysis. However, the estimate of the range obtained from the scores based on the cluster analysis is superior to that obtained from the scores based on the principal components.

## 6 Concluding Remarks

In this paper, we have investigated the "dimensionality" of the 24 Livermore loops. In this context, dimension is defined as the number of linear combinations of the loop timings
that can be used as "scores" to characterize a computer hardware/software system. This dimension is based on a singular value decomposition of the loop timings over a set of 48 computer systems. Therefore, the dimension is not well defined, since it is difficult to determine when a small singular value should be set to zero and the rank of the data matrix reduced. However, the dimension is certainly greater than one; a single number, such as the Linpack timing, has too little predictive value. We find that three to five of these scores are required to reconstruct the original Livermore benchmark data fairly accurately.

We also present two methods to define the scores for the systems. The first is optimal in a certain sense and is based on a principal component analysis. It has the disadvantage that the interpretation of the scores in not obvious. The second method uses a grouping of the loops into clusters. The scores for a given system are the geometric means of the megaflops rates taken over each cluster. These clusters are closely related to the vectorization of the loops.

There are other ways to approach the data reduction problem. For instance one could ask if a subset of the 72 loop runs will provide essentially the same information as the full set. This question could be addressed by performing a best subset analysis on the LFK data. Another important issue is the external validation of the scores derived in this paper. In particular, the predictive power of the loops could be tested by running the loops on a set of 10 to 15 systems along with a few small "production" codes. Then the scores obtained from the loops could be used to give a least squares prediction of the running times on the production codes. If the loops and the resulting scores really characterize the systems, the prediction should be fairly good.

Document describes a computer program; SF-185, FIPS Software Summary, is attached.
11. ABSTRACT (A 200-word or less factuol summary of most significant information. If document includes a significant bibliography or literature survey, mention it here)

This paper is devoted to an analysis of the data from the Livermore loops benchmark. We will show that in a general predictive sense the dimension of this data is rather small; perhaps between two and five. Two techniques are used to reduce the 72 loop timings for each machine to a few scores which characterize the machine. The first is based on a principal component analysis, the second on a cluster analysis of the loops. The validity of the reduction of the data to a lesser dimension is checked by various methods.
12. KEY WORDS (Six to twelve entries; alphabetical order; capitalize only proper names; and separate key words by semicolons) benchmarks; computers; performance; Livermore loops; principal components; clusters
