DEVELOPMENT OF METHODS OF TEST
FOR QUALITY CONTROL OF PORCELAIN ENAMELS

U.S. DEPARTMENT OF COMMERCE
NATIONAL BUREAU OF STANDARDS

NATIONAL BUREAU OF STANDARDS

The National Bureau of Standards¹ was established by an act of Congress March 3, 1901. Today, in addition to serving as the Nation's central measurement laboratory, the Bureau is a principal focal point in the Federal Government for assuring maximum application of the physical and engineering sciences to the advancement of technology in industry and commerce. To this end the Bureau conducts research and provides central national services in four broad program areas. These are: (1) basic measurements and standards, (2) materials measurements and standards, (3) technological measurements and standards, and (4) transfer of technology.

The Bureau comprises the Institute for Basic Standards, the Institute for Materials Research, the Institute for Applied Technology, the Center for Radiation Research, the Center for Computer Sciences and Technology, and the Office for Information Programs.

THE INSTITUTE FOR BASIC STANDARDS provides the central basis within the United States of a complete and consistent system of physical measurement; coordinates that system with measurement systems of other nations; and furnishes essential services leading to accurate and uniform physical measurements throughout the Nation's scientific community, industry, and commerce. The Institute consists of an Office of Measurement Services and the following technical divisions:

Applied Mathematics—Electricity—Metrology—Mechanics—Heat—Atomic and Molecular Physics—Radio Physics²—Radio Engineering²—Time and Frequency²—Astrophysics²—Cryogenics.²

THE INSTITUTE FOR MATERIALS RESEARCH conducts materials research leading to improved methods of measurement standards, and data on the properties of well-characterized materials needed by industry, commerce, educational institutions, and Government; develops, produces, and distributes standard reference materials; relates the physical and chemical properties of materials to their behavior and their interaction with their environments; and provides advisory and research services to other Government agencies. The Institute consists of an Office of Standard Reference Materials and the following divisions:

Analytical Chemistry—Polymers—Metallurgy—Inorganic Materials—Physical Chemistry.

THE INSTITUTE FOR APPLIED TECHNOLOGY provides technical services to promote the use of available technology and to facilitate technological innovation in industry and Government; cooperates with public and private organizations in the development of technological standards, and test methodologies; and provides advisory and research services for Federal, state, and local government agencies. The Institute consists of the following technical divisions and offices:

Engineering Standards—Weights and Measures—Invention and Innovation—Vehicle Systems Research—Product Evaluation—Building Research—Instrument Shops—Measurement Engineering—Electronic Technology—Technical Analysis.

THE CENTER FOR RADIATION RESEARCH engages in research, measurement, and application of radiation to the solution of Bureau mission problems and the problems of other agencies and institutions. The Center consists of the following divisions:

Reactor Radiation—Linac Radiation—Nuclear Radiation—Applied Radiation.

THE CENTER FOR COMPUTER SCIENCES AND TECHNOLOGY conducts research and provides technical services designed to aid Government agencies in the selection, acquisition, and effective use of automatic data processing equipment; and serves as the principal focus for the development of Federal standards for automatic data processing equipment, techniques, and computer languages. The Center consists of the following offices and divisions:

Information Processing Standards—Computer Information—Computer Services—Systems Development—Information Processing Technology.

THE OFFICE FOR INFORMATION PROGRAMS promotes optimum dissemination and accessibility of scientific information generated within NBS and other agencies of the Federal government; promotes the development of the National Standard Reference Data System and a system of information analysis centers dealing with the broader aspects of the National Measurement System, and provides appropriate services to ensure that the NBS staff has optimum accessibility to the scientific information of the world. The Office consists of the following organizational units:

Office of Standard Reference Data—Clearinghouse for Federal Scientific and Technical Information³—Office of Technical Information and Publications—Library—Office of Public Information—Office of International Relations.

¹ Headquarters and Laboratories at Gaithersburg, Maryland, unless otherwise noted; mailing address Washington, D.C. 20234.

² Located at Boulder, Colorado 80302.

³ Located at 5285 Port Royal Road, Springfield, Virginia 22151.

Government agency for which
is for its own use.

U.S. DEPARTMENT OF COMMERCE
NATIONAL BUREAU OF STANDARDS

INTRODUCTION

The general subject of our current work is to provide a technique to measure the quality of adherence of cover coat porcelain enamels applied direct-to-steel. The long-range goal is to develop a non-destructive method to estimate the quality of adherence in these systems. A more easily attainable goal is to find a test method to give a better estimate of enamel adherence than is obtained with the PEI adherence test even though it may involve specimen damage. Results obtained with one possible device to assist in direct-on adherence measurement, a commercially available adhesion tester, are described in this report.

A round-robin test on carefully prepared specimens covering a wide range of adherence values is described. The suggested modification of current practice is immediately available and is shown to result in more reliable and repeatable estimates of adherence in production than those obtained from trained observers.

RESULTS AND DISCUSSION

A. Preparation of a Series of Cover Coats Direct-to-Steel with a Wide Range of Adherence

Direct-on specimens previously used were prepared by the several frit companies using various decarburized steels, various pickling and cleaning procedures and porcelain enamels in white, coppertone and avocado. For a more careful and extensive study of direct-on adherence the Direct-on Adherence Advisory Committee (DOAAC) recommended that a new series of specimens be obtained. Companies represented on the advisory committee volunteered a single uniform steel supply, and the preparation of a series of specimens in which the adherence quality was controlled by various amounts of nickel deposition, with the same porcelain enamel on all specimens.

Preliminary tests with this new specimen series showed a good inverse correlation between bare metal exposed after drop weight deformation and the amount of nickel added before enamel application.

The widely accepted concept of adherence measurement is that when adherence to the metal is good, much enamel will be retained within a deformed area, but when poorer adherence is attained, little or no enamel will be retained after a similar deformation. Assuming that this is a valid criteria of adherence quality, it will be noted from Table 1 and Figure 1 that the new specimen series covered a wide range

of quite uniform adherence grades.

B. Direct-on Adherence Round Robin Phase II

A series of tests was described in the previous report to determine industry agreement on adherence evaluation by visual rating of drop-weight deformed specimens.

The comparative tests described in the previous report were repeated with the controlled nickel deposit, DOAAC specimens.

Two specimens of each of the five DOAAC grades were deformed in a drop-weight device using a one-half inch ball indenter and a five pound weight dropped through a distance of 16 inches. Two indentations were made on each specimen. One was over a 3/4-inch bottomless die while the other was over a 5/8-inch die. Each observer made his visual rating, according to his laboratory practice, before sending the specimens to the next cooperating laboratory. The number of meter counts for each indentation was measured both before and after circulation among the industry observers. The specimens were identified by code letters so that the observers did not know the grade numbers.

Comparison of the results given in Table 2 with similar results described in the previous report, shows that a much improved agreement was obtained among the various observers in Phase II. The better agreement may be attributed to the observers rating the same test-pieces, rather than companion specimens, or to the use of only one deforming device, or to both of these. A plot of the visual ratings as a function of PEI meter counts is shown in Figure 2. The equations of the least squares lines through the points of Figure 2 are:

$$\text{For the } 3/4\text{-inch die: } y = 1.625 + 0.056 x$$

$$\text{For the } 5/8\text{-inch die: } y = 1.058 + 0.063 x$$

where y = the visual ratings of experienced industry observers, and
 x = PEI Adherence Meter counts.

Figure 3 allows a comparison of the visual adherence ratings of the various observers with an instrumental rating based on an industry consensus. Perfect correlation lines are shown on these plots. Observer B appears to assign ratings that agree well with the industry average. The ratings assigned to Observer D appear to be more severe than the instrumental ratings. The bias of Observer A appears to be toward less severe ratings than either Observer D or the industry consensus.

C. The Instrumental Rating of Direct-on Adherence

Phase II of the Round Robin adherence test suggests the following instrumental method for the rating of cover coats direct-to-steel.

1) Specimen deformation - A drop-weight device using a) a one-half inch diameter hemispherical indenter (or tup), b) an 80 inch-pound impact energy (such as 5 pounds from 16 inches), and c) a 5/8-inch diameter bottomless die, should be used to deform the specimen with a single blow.

2) Estimation of the area of bare metal - The PEI Adherence Meter may be used to obtain the number of counts on the deformed specimen or part.

3) Enter Table with the number of counts (not the adherence index) and read directly the instrumental rating of a basis of 1 to 5 in which 1 represents the best and 5 the poorest adherence.

D. Tensile Tests with Adhesion Tester

1) One rather obvious and straightforward way to measure adherence of a cover coat to its substrate is by tensile testing. Through the use of high strength adhesives tensile fixtures can be attached to the top surface of the steel sheet. The stress required to strip the enamel layer from the substrate should be a measure of the adherence quality. Experiments with a commercially available adhesion tester have been made in an attempt to evaluate the adherence of cover coats porcelain enamel direct-to-steel. The device used is illustrated in Figure 4. An aluminum alloy spool (or button), in the foreground of the horizontal specimen is attached to the glass layer by an epoxy adhesive. The jaw of the device, engaged under the top flange of the button, pulls vertically when the hand wheel at the top is turned and the stress required to cause failure is indicated on the vertical barrel scale. One type of failure is shown by the specimen on the left where failure occurred near the interface between the glass and the black oxide-rich layer.

2) A device similar to that shown in Figure 4, but with a 2000 psi capacity, was adapted to operate with a constant speed motor so that load could be applied continuously and at a uniform rate. The stress scale marked at 250 psi intervals was difficult to read with much precision. Additional scale marks were scribed onto the barrel, under a microscope, assuming linearity between the 250 psi marks. The stress-time curve shown in Figure 5 allowed failure stress to be estimated rather precisely by measuring loading time to failure.

3) A summary of average failure stresses obtained in multiple specimen tests is given in Table 4 together with nickel flash data and average PEI meter counts in the button holes. It can be seen that the amount of metal bared at failure is proportional to the nickel deposited during specimen preparation. The individual values for the 16 grade 5 specimens given in the lower part of Table 4 illustrate the scatter of failure stresses (from 550 to 834 psi) and also show that, within this group of specimens, the amounts of bare metal reflected by the meter counts in the button holes occur randomly over the scattered failure stresses.

The results in Table 4 reflect elements of both encouragement and discouragement. The amount of bare metal by meter counting in the button holes places the six DOAAC grades in the same order as measurements on drop-weight deformed specimens. The failure stresses, on the other hand, fail to place the different grades with the possible exception of grades 1, 2, 3 in the order which we have assumed is valid.

Two hypotheses are suggested to explain the lack of significance of the failure stresses in the button tests:

HYP I. Two things occur, either in rapid sequence or simultaneously when failure occurs: a) a disc of enamel is sheared out and b) the enamel disc is parted at the vertical location of failure in the enamel system. This hypothesis suggests that both the stress required to shear out the disc and the stress required to remove the sheared disc from the substrate are combined in the total stress at failure. If the stress component required to shear the disc could be separated from the adherence stress the latter might serve to evaluate adherence. Experiments to test this hypothesis are described in a later paragraph.

HYP II. During the removal of buttons by tensile stress, a critical strain within the metal initiates micro-cracking at the button circumference. Additional stress causes crack growth resulting in catastrophic failure.

Experiments with an altered hold-down plate to avoid circumferential micro-cracking are underway. Enamelled specimens on heavier gage metal will be used to test the micro-cracking theory. Other changes in the button geometry may be helpful in testing the validity of this hypothesis.

4) Sand Blast Series. Two possible approaches are visualized to eliminate or avoid the shear stress referred to in hypothesis I of the previous paragraph.

a) remove the enamel layer except under the button by sand-blasting. This should avoid the restraint of the continuous enamel layer and the failure stress might consist only of that required to

overcome adherence.

Table 5 gives results of the sand blast experiment. Two buttons were attached to each specimen. One was pulled off before and the second was pulled off after sandblasting. The failure stresses after the sandblast treatment were always about 30 percent less than that required before cutting away the enamel surrounding the button. This appears to be evidence that a shear stress is involved in the normal failure mechanism.

One must not overlook the fact that a porcelain enamel coating on a metal substrate tends to give the system more rigidity than bare metal. The greater flexibility after enamel removal may enhance circumferential micro-cracking by allowing greater deflections and thus lead to a lower failure stress.

b) the second approach to avoiding a shear contribution to failure stress is through the testing of button sized discs of enamel fired onto substrates of various thickness. Specimens have been received but have not yet been tested.

5) Relation Between Button Contact Area and Failure Stress. Two series of tests have been made to study the relationship between the contact area of the buttons and the observed failure strengths. In the hollow button series the contact area was reduced in steps by removing the central part of the contact end of the buttons. The outside diameter of these buttons was unchanged. The solid button series was made by successively reducing the diameter of the buttons to achieve smaller contact areas. Both of these series of modified buttons are schematically illustrated at the bottom of Figure 6 together with the reduced contact areas. An understanding of the results obtained in the hollow and solid series (Table 6) has not yet been obtained and will be sought in future work.

E. Tensile Tests with Specimens of Large Contact Area

In 1959 adherence tests of porcelain enamels were made at Battelle ^{1/} and tensile values of about 6000 psi were reported. Values obtained with the adhesion tester in our research have yielded values of the order of 600 psi, where the contact area was about 0.5 square inch.

1/ Nature of Adherence of Porcelain Enamels to Metal, King, Tripp and Duckworth, Jour. Am. Ceram. Soc., 42, 504 (1959).

Preliminary tests have been made using the same specimen size and method used in the older Battelle tests. The specimens were cut in squares 1.25-inches on a side and epoxied between appropriate hardware to pull apart in a conventional testing machine. Values obtained so far are given in Table 7. It can be seen that the two poorest grades, 6 and 1, have values of 2980 and 3620 psi. Failures in the epoxy at between 4000 and 4800 have prevented obtaining tensile stresses for the better grades of DOAAC specimens. The epoxy used at Battelle which limited their values to 6000 psi seems to be superior to that used in these preliminary tests.

PLANS FOR THE NEXT REPORT PERIOD

Work described above failed to show a suitable relationship between adherence quality and the tensile test results obtained with the adhesion tester. It is believed that failure in the button tests result from micro-cracks initiated at some point on the button circumference. This cracking tendency, a forerunner of failure, would be enhanced by bending moments within the pulling device or by deflection of the specimen under stress. Experiments are planned to avoid or minimize specimen deflection through the use of 1) a heavy back-up plate, or 2) specimens prepared on heavier than 20 gage metal. Specimens are also available on which button-sized discs of enamel were fired onto metal of various gages in the usual way. These specimens might avoid shearing stresses and thus pinpoint an inadequacy of the button tests as currently practiced. A suitable hold-down ring will be used with the series of reduced diameters buttons in an attempt to obtain results in better agreement with theory.

WEATHERING STUDIES

In 1966 an exposure test was initiated which consisted solely of nature-tone enamels on steel. The enamels exposed at Kure Beach and South Florida completed three-years' exposure during this report period. These enamels were returned to the laboratory at the National Bureau of Standards for their three-year inspection.

After the enamels arrived at the laboratory, they were cleaned by scouring thirty strokes with a cellulose sponge that had been moistened with a one-percent solution of trisodium phosphate and sprinkled with calcium carbonate followed by successive rinses with tap water, distilled water and alcohol. After cleaning the specimens were measured for changes in gloss is reported as percentage gloss retained. The gloss and color retention values are presented in Table 8 and Figure 7. These data indicate that these enamels have

good color and gloss retention after three years' exposure. After the gloss and color measurements were completed, the enamels were carefully examined for signs of rust. A summary of enamels with either rust spots or iridescent stains (the usual forerunners of obvious rust) is presented in Table 9. These data indicate that almost all the enamels exposed at Kure Beach and half of the enamels exposed at South Florida had signs of rust occurring on them. This was true whether they were tested for continuity of coating before exposure or not. However, these enamels were not tested at high overvoltages so differences between the tested and untested enamels might not be realized. When these enamels were inspected to note only those specimens with obvious rust on them, the results presented in Table 10 were obtained. Thus, it can be seen that while many of the specimens appear to have the beginning of rust, most of the small rust spots are noticeable at this time only by extremely close observation.

The enamels exposed at Gaithersburg, the final site in this test, will complete their three-year exposure during the next report period. A complete report of the three-year inspection of these enamels will be prepared following the completion of this inspection.

| 5 | 6 | 8 | 1 | 1 | 2 | 2 | 2 | 1.4 |

1/ Each specimen had two indentations; one over a 3/4 inch die and the other over a 5/8 inch die.

2/ The same deformed specimens were circulated to the laboratories in sequence. Five trained observers assigned visual ratings on a scale of 1 to 5. (1 is best).

3/ The instrumental rating is based on PEI Adherence Meter counts before circulation, see text and Table 3.

| 699 | 15 | 679 | 14 |
| 564 | 22 | 679 | 20 |
| 672 | 17 | 679 | 19 |
| 591 | 21 | 699 | 15 |
| 564 | 17 | 807 | 13 |
| <u>645</u> | <u>19</u> | <u>834</u> | <u>19</u> |
| mean 642 | 17.2 | 712 | 17.5 |

TABLE 5 SUMMARY OF SAND BLAST SERIES

| <u>Before Sandblasting</u> | | | | <u>After Sandblasting</u> | | | |
|----------------------------|------|----------------|-----------|---------------------------|----------------|-----------|-------------------------------|
| Grade | n | Failure psi | V, % | n | Failure psi | V, % | Shear Stress $\frac{1}{2}$ |
| 6 | 7 | 655±110 | 18 | 8 | 435±110 | 31 | 34 |
| 1 | 12 | 630 70 | 18 | 7 | 495 65 | 14 | 22 |
| 2 | 6 | 670 140 | 20 | 8 | 485 140 | 35 | 28 |
| 3 | 8 | 660 40 | 7 | 8 | 360 74 | 25 | 46 |
| 4 | 6 | 680 120 | 17 | 8 | 545 80 | 18 | 20 |
| 5 | 5 | 765 150 | <u>19</u> | 8 | 465 90 | <u>24</u> | <u>39</u> |
| | Mean | | 16.5 | | | 24.6 | 32 |

1/ Difference between failure stress before and after sandblasting is suggested as the shear stress. It is expressed here as a percentage of the failure stress before sandblasting.

TABLE 6 THE EFFECT OF BUTTON GEOMETRY ON FAILURE STRESS 1/

| | <u>HOLLOW BUTTON SERIES</u> | | | |
|-----------------------------------|-----------------------------|-------|-------|-------|
| Contact area, square inches | 0.172 | 0.289 | 0.424 | |
| Mean failure stress, psi | 1320 | 1015 | 590 | |
| Number of Determinations | 10 | 5 | 6 | |
| Coefficient of Variation, % | 30 | 10 | 19 | |
| 95 Percent Con- fidence limits | 290 | 120 | 115 | |
| | <u>SOLID BUTTON SERIES</u> | | | |
| Contact area, square inches | 0.114 | 0.223 | 0.361 | 0.482 |
| Mean failure stress, psi | 1225 | 680 | 645 | 680 |
| Number of Determinations | 7 | 6 | 6 | 6 |
| Coefficient of Variation, % | 14 | 19 | 21 | 17 |
| 95 Percent Con- fidence limits | 155 | 133 | 142 | 119 |
