LIVE LOAD STUDIES OF CONVEYOR SYSTEMS AND POSTAL FACILITIES

Final Report

Prepared for

Post Office Department

## NATIONAL BUREAU OF STANDARDS

The National Bureau of Standards ${ }^{1}$ was established by an act of Congress March 3, 1901. The Bureau's overall goal is to strengthen and advance the Nation's science and technology and facilitate their effective application for public benefit. To this end, the Bureau conducts research and provides: (1) a basis for the Nation's physical measurement system, (2) scientific and technological services for industry and government, (3) a technical basis for equity in trade, and (4) technical services to promote public safety. The Bureau consists of the Institute for Basic Standards, the Institute for Materials Research, the Institute for Applied Technology, the Center for Computer Sciences and Technology, and the Office for Information Programs.
THE INSTITUTE FOR BASIC STANDARDS provides the central basis within the United States of a complete and consistent system of physical measurement; coordinates that system with measurement systems of other nations; and furnishes essential services leading to accurate and uniform physical measurements throughout the Nation's scientific community, industry, and commerce. The Institute consists of a Center for Radiation Research, an Office of Measurement Services and the following divisions:

Applied Mathematics-Electricity-Heat-Mechanics-Optical Physics-Linac Radiation ${ }^{2}$-Nuclear Radiation ${ }^{2}$-Applied Radiation ${ }^{2}$-Quantum Electronics ${ }^{3}$ Electromagnetics ${ }^{3}$-Time and Frequency ${ }^{3}$-Laboratory Astrophysics ${ }^{3}$-Cryogenics ${ }^{3}$.

THE INSTITUTE FOR MATERIALS RESEARCH conducts materials research leading to improved methods of measurement, standards, and data on the properties of well-characterized materials needed by industry, commerce, educational institutions, and Government; provides advisory and research services to other Government agencies; and develops, produces, and distributes standard reference materials. The Institute consists of the Office of Standard Reference Materials and the following divisions:

Analytical Chemistry-Polymers-Metallurgy-Inorganic Materials-Reactor Radiation-Physical Chemistry.
THE INSTITUTE FOR APPLIED TECHNOLOGY provides technical services to promote the use of available technology and to facilitate technological innovation in industry and Government; cooperates with public and private organizations leading to the development of technological standards (including mandatory safety standards), codes and methods of test; and provides technical advice and services to Government agencies upon request. The Institute also monitors NBS engineering standards activities and provides liaison between NBS and national and international engineering standards bodies. The Institute consists of the following technical divisions and offices:

Engineering Standards Services-Weights and Measures-Flammable FabricsInvention and Innovation-Vehicle Systems Research-Product Evaluation Technology-Building Research-Electronic Technology-Technical AnalysisMeasurement Engineering.
THE CENTER FOR COMPUTER SCIENCES AND TECHNOLOGY conducts research and provides technical services designed to aid Government agencies in improving cost effectiveness in the conduct of their programs through the selection, acquisition, and effective utilization of automatic data processing equipment; and serves as the principal focus within the executive branch for the development of Federal standards for automatic data processing equipment, techniques, and computer languages. The Center consists of the following offices and divisions:

Information Processing Standards-Computer Information-Computer Services -Systems Development-Information Processing Technology.
THE OFFICE FOR INFORMATION PROGRAMS promotes optimum dissemination and accessibility of scientific information generated within NBS and other agencies of the Federal Government; promotes the development of the National Standard Reference Data System and a system of information analysis centers dealing with the broader aspects of the National Measurement System; provides appropriate services to ensure that the NBS staff has optimum accessibility to the scientific information of the world, and directs the public information activities of the Bureau. The Office consists of the following organizational units:

Office of Standard Reference Data-Office of Technical Information and Publications-Library-Office of Public Information-Office of International Relations.

## IMPORTANT NOTICE

NATIONAL BUREAU OF STAN for use within the Government. Be and review. For this reason, the pl whole or in part, is not authorizer Bureau of Standards, Washington, the Report has been specitically pri

Approved for public release by the director of the National Institute of Standards and Technology (NIST) on October 9, 2015
accounting documents intended bjected to additional evaluation sting of this Report, either in )ffice of the Director, National he Government agency for which es for its own use.

## Abstract

A total of approximately $1,040,000 \mathrm{sq}$. ft. of floor space in postal mail handing facilities has been surveyed for occupancy loads in this study. Seven major postal facilities located in different regions across the country were surveyed over their entire work floor area. These seven facilities ranged in height from 1 to 3 stories. The information on loading recorded during the surveys is presented in this report in great detail in arithmetic averages and summaries and in basic statistical parameters. This is done so that basic data on actual loadings will be available for assessment of the loading that could result from a change in the fundamental mail handling processes that are being used presently. Observations of current loading conditions (exclusive of Christmas season peaks) show that 1. Ceiling loads, which incorporate bulk mail on conveyors, did not exceed 100 psf in areas greater than $200 \mathrm{sq} . \mathrm{ft}$; 2. Floor loads on areas of structural slab size did not exceed 60 psf.

# LIVE LOAD STUDIES OF CONVEYORS <br> AND POSTAL FACILITIES 

FINAL REPORT<br>By<br>J. O. Bryson and L. E. Cattaneo

## 1. Introduction

A study has been conducted on actual loadings imposed on postal mail handling facilities resulting from mail handiing processes. The main objective of this study was to survey the existing loads in a representative sample of mail handling facilities to develop comprehensive information on the magnitudes and distributions of actual loads imposed on the facilities. Also, loads and forces related to conveyor systems were measured and evaluated. This information would then serve as the basis for engineering recommendations concerning the appropriate structural live loads to be used in the design of future postal facilities.

The program was planned to develop a sufficiently large sample of comprehensive data that could be handled by statistical procedures and calculations to determine the proper loads that major mail handing facilities should be
designed for in consideration of safety and economy. The nature of postal activities in this country is such that the peak volume of mail for processing comes each year for several weeks just before Christmas time and consequently the mail load on a facility is assumed to be highest during this period. Nevertheless, the NBS survey team was restricted from visiting postal facilities during the "Christmas rush" period. As a result of this restriction, an important characteristic element of loading history is missing and, at best, can only be arrived at by conjecture. This means that a statistical treatment of the data will need to be reinforced with engineering judgment on upper limit values for determination of proper design loads.

### 1.1 Scope

The investigation covered a sample consisting of 7 "major postal facilities" ranging in height from 1 to 3 story levels. The principle criteria for selecting a facility were: (1) amount of mechanization equipment; (2) age of structure; and (3) location of facility. The aim was to study the loads in highly mechanized facilities of modern construction and where possible, in those representing different regions of the country.

Selection of the sample of facilities was influenced to a great extent by a conclusion drawn from the preliminary studies that the number of stories in a mail handling facility is an important factor for live load evaluation. Consequently, facilities that were surveyed were chosen to represent categories of one, two, and multi-story structures. The facilities were surveyed in groups according to their number of stories in order to accommodate the data reduction and evaluation, and reporting.

In original planning of the sample, three multi-story mail handing facilities were scheduled for surveying. However, as the work progressed, the conclusion was reached that the data from one of the three multi-story facilities could be considered redundant. In this regard, one facility in this group was eliminated. More recently a second facility was eliminated for reasons of funding (reference: letter from J. N. Wiernicki, POD to J. R. Wright, BRD, NBS, dated June 2, 1970, REPT: C. C. Arnolts: par 68257). This left the data from only one multi-story facility, Omaha, Nebraska, to be used to determine characteristic loadings for this category of facilities.

The facilities that were surveyed for loads are listed below.

| Group | Facility | Number of <br> Stories |
| :---: | :--- | :---: |
|  | Greensboro, North Carolina | 1 |
|  | Chicago (AMF), I11inois | 1 |
| II | Buffalo, New York | 1 |
|  | Houston, Texas | 2 |
|  | New Orleans, Louisiana | 2 |
| III | Los Angeles (AMF), California | 2 |
|  | Omaha, Nebraska | 3 |

The preliminary data from the surveys of the facilities were submitted to the Post Office Department in 4 separate interim reports [1, 2, 3, 4] /․ These interim reports served to show the type of data and its preliminary handling techniques along with an indication of the status of the project.

This is the final report in which it is intended to summarize the results from the 7 facilities surveyed and to present an analysis of the data with design load recommendations in consideration of the information collected.

IN Numbers in bracket indicate the references in Section 5.

## 2. General

The survey techniques and data evaluation procedures as well as all definitions of loads and floor areas were presented in the earlier interim reports [1, 2]. However, because of their importance to the understanding of the rationale for the data analysis, the definitions for building occupancy loads and areas on the work room floor are presented here for convenience of reference.

### 2.1 Building Facilities

The buildings that were surveyed for loads in this investigation are classed by the POD as 'Major Postal Facilities. A major postal facility is one that has a work floor area greater than $50,000 \mathrm{sq}$. ft. [5]. The space provided in these facilities is divided generally into four major areas:

1. Workroom area
2. Mail handling support services areas
3. Platform or docking areas
4. Administration, personnel, and public services areas The workroom is a large open bay floor in which the mail processing activities are centered. The floor area is lined with regularly spaced structural columns which superficially divide the floor space into "grid squares" [1]. The other
areas serve to support, in different ways, the activities on the workroom floor.

The workroom floor is divided into designated work areas to accommodate specific mail processing activities. The work areas are of different sizes, depending on amount and type of activity, and usually cover a number of grid squares. Within the work areas the activities and types of equipment employed for processing the mail toward its destination are the principle factors which affect the characteristics of the occupancy loads.

### 2.2 Building Occupancy Loads

The loads that are imposed on the structure due to the mail handing processes are defined as follows:
(1) Mail load - all types of mail in various containers being processed or stored within the facility.
(2) Fixed mechanization load - load due to the weight of mail processing equipment either anchored to the ceiling or bolted to the floor (i.e., bulk mail-conveyors, parcel and sack sorting machines, letter sorting machines, etc.)
(3) Mobile mail handling and miscellaneous operating equipment - items that are used to contain the
mail that is being processed or stored on the work floor, also different types of maintenance equipment (i.e., baskets, hand trucks, tables, bag racks, motorized sweepers, etc.)
(4) People - the weight of the maximum number of people assigned to a specific area.

The loads are ordered into two groups according to the manner in which they are supported by the structure. They are ceiling supported loads and floor loads as follows:
I. Ceiling Loads

1) Fixed mechanization (e.g., ceiling suspended conveyors)
2) Mail
II. Floor Loads
3) Fixed mechanization (e.g., floor mounted conveyors) and workroom equipment
4) Mobile mail handling and miscellaneous operating equipment
5) Mail
6) People

The ceiling loads and floor loads in a l-story facility are basically independent of each other. However, in a multistory facility consideration must be given to the combined effect of the ceiling loads of one story and the floor loads of the story above it.

### 2.3 Work Areas

It was stated earlier that it is the mail processing activities and consequently the types of equipment employed for processing the mail within the workroom which are the principal factors affecting the characteristics of the occupancy loads. The workroom floor is divided into designated "work areas" for specific mail processing activities. For the purposes of this study the activities were covered by 10 work area categories designated as follows:

Area 1 - "Culling, Facing and Cancelling"'
Area 2 - "Letter Distribution"
Area 3 - "Main Office Carriers"
Area 4 - "Flats Distribution"
Area 5 - "Pouching"
Area 6 - "Sawtooth Platform Area"
Area 7 - "Outgoing Parcel Post"
Area 8 - "Incoming Parcel Post"
Area 9 - "Outgoing Non-preferential"
Area 10 - "Temporary Storage"
Detailed descriptions of the activities and types of equipment found in each of the areas listed above are given in an earlier report [2].

### 3.1 Presentation of Data

Data obtained during the survey are presented together with results in various forms by means of Tables and Figures in Section 5. Table l-a lists some physical data generally describing the facilities which were surveyed. Table l-b is a more detailed listing of the distribution of workroom space into the different work areas at each facility.

### 3.1.1 Mail Loads on Conveyors

Table 2 is a sample of conveyor mail load data. Each value is the mail load, in pounds, on a lo-ft. length of conveyor (here, $31 / 2 \mathrm{ft}$. wide), observed at regular intervals as the conveyor belt carried the mail through the conveyor section being observed. Values were recorded at intervals of 2 ft . of belt travel. Tabular values are in order by rows starting at the top and reading from left to right. Additional details describing this technique of data acquisition are given in an earlier report [1].

Figure 1 is a sample histogram of observed conveyor belt mail loads in lb/sq. ft. based on the data of Table 2. Numerous zero values resulting from empty lo-ft. belt lengths were deleted to avoid clogging the load scale zero
position. Much of this type of data is repetitious and is not included for the sake of brevity.

### 3.1.2 Ceiling Loads

Values of uniformly distributed and concentrated loads caused by selected suspended conveyors and their structural support are not again presented here to conserve space. Since these data, as originally reported, were not considered to require further processing the reader is referred to the interim reports $[1,2,3,4]$ for ceiling data pertaining to the various facilities. However, it is important to repeat the fact that the selected sections of mechanization were purposely chosen because of their apparent heavy loads as evidenced by complex construction. In summary, for the mechanization sections observed, the range of calculated gross uniformly distributed loads (with live load) varied from 19 psf to 340 psf , and the range of concentrated (hanger) loads, from 200 lb to 1640 lb .

Figure 2 is a plot of the uniformly distributed loads of the mechanization sections versus the plan areas of the sections observed in all 7 facilities. The curve was drawn to represent the upper limit boundary load values of the collected data.

### 3.1.3 Floor Loads

Tables 3-a through 3-g and 4-a through 4-g present the basic data used in subsequent interpretations. Tables 3-a through 3-g list the frequency of occurrence of various uniformly distributed load intensities (UDL) for grid squares in each work area in each facility. Similarly, Tables 4-a through 4-g list the frequency of occurrence of various percentages of occupied space for grid squares in each work area in each facility. The tabular value intervals ( 2 psf and 5 percent) were determined with the aid of the empirical practical guide [6]:

$$
\text { Interval }=\frac{\text { Maximum Value }}{1+3.3 \log (\text { No. of values })}
$$

for satisfactory definition of all groups of data used in subsequent histograms. Intermediate values (of psf, and of percent) are counted as occurrences of the tabular value to which they are closest. It is to be noted that certain work activity areas were not encountered at some facilities.

Table 5 summarizes values of work areas, mean grid square UDL and mean grid square occupied space percentages in each of the 7 facilities surveyed. For the facilities having more than one story, Table 6 shows the distribution of work areas between different floors when such a division occurred. In
the case of Omaha, for the purpose of comparing with other facilities in this report, the Ground Floor, lst Floor and 2nd Floor were renamed 1st, 2nd and 3rd floors, respectively.

Table 7 lists the mean values of grid square UDL in combined work areas of the same type for various groups of facilities. In the same manner, Table 8 lists the mean values of grid square occupied space percentages in combined work areas of the same type for various groups of facilities.

Table 9 shows values of grid square UDL and grid square percent occupied space for the total of each facility and for the totals of different groups of facilities.

Table 10 is a summary of maximum uniformly distributed load intensities determined for different size areas in each of the surveyed facilities. Code identifications of grid squares and grid sectors refer to designations and floor plans used in Interim Reports 2, 3, and 4.

Table 11 contains values of grid square uniformly distributed load calculated by applying observed upper limit loads over a grid square area equal to the average percentage of observed occupied space, and dividing the total load by the
grid square area. Table 12 lists values of equivalent uniformly distributed load (EUDL) which would cause the same maximum bending moment in a 1 -way grid square slab subjected to observed upper limit loads applied over a centrally located portion of the grid square equal to the average percentage occupied space. The manner of upper limit loading involved in developing both Tables 11 and 12 is described more fully in Section 3.2.3, Analysis of Data-Floor Loads.

For ease of locating them, the remainder of the figures (i.e., those pertaining to floor loads) are divided into two sets, the first set pertaining to grid square UDL, the second to grid square occupied space percentages. It will be noted that one set of figures parallels the other in the source of the data which are presented graphically.

Figures 3-a through 3-j are histograms of grid square uniformly distributed load intensities (UDL) in each of 10 different work areas for the combined data of the 3 onestory facilities. Figures 4-a through 4-i present the same kind of information for the combined data of the four 2 and 3-story facilities; (no area \#9 was encountered in the survey of these facilities). Figures 5-a through 5-j similarly present the same kind of grid square unL information for the combined data of all 7 facilities.

Figures 6-a through 6-g are histograms of grid square UDL for each of the 7 facilities without distinction between work areas in a facility. The following graphs (Figures 7-a through 7-g) are cumulative frequency distributions for each of the 7 immediately preceding respective histograms.

Figure 8 is a histogram of grid square UDL values without distinction between work areas for combined data from the 3 one-story facilities; Figure 9 is the cumulative frequency distribution for the same data. The next two pairs of figures present similar information for the other groups of the surveyed facilities. Figure 10 is a histogram of lumped grid square UDL values from the four 2 and 3 -story facilities and Figure 11 is the corresponding cumulative frequency distribution. Figure 12 is a histogram of all grid square UDL values from the combined 7 facilities and Figure 13 is the corresponding cumulative frequency distribution.

The following figures were described earlier as being the second of two parallel sets and pertain to grid square occupied space percentages.

Figures 14-a through 14-j are histograms of grid square occupied space percentages in each of 10 different work areas for the combined data of the 3 one-story facilities.

Figures 15-a through 15-j present the same kind of information for the combined data of the four 2 and 3-story facilities; (no area \#9 was encountered in the survey of these facilities). Figures $16-\mathrm{a}$ through $16-\mathrm{j}$ similarly present the same kind of grid square percent occupied space information for the combined data of all 7 facilities.

Figures 17-a through 17-g are histograms of grid square occupied space percentages for each of the 7 facilities without distinction between work areas in a facility. The following graphs (Figures 18-a through 18-g) are cumulative frequency distributions for each of the 7 immediately preceding respective histograms.

Figure 19 is a histogram of grid square occupied space percentages without distinction between work areas for combined data from the 3 one-story facilities; Figure 20 is the cumulative frequency distribution for the sane data. The next two pairs of figures present similar information for other groups of the surveyed facilities. Figure 21 is a histogram for all grid square occupied space percentages from the four 2 and 3 -story facilities and Figure 22 is the corresponding cumulative frequency distribution. Figure 23 is a histogram of all grid square occupied percentages from the combined 7 facilities and Figure 24 the corresponding cumulative frequency distribution.

### 3.2 Analysis of Data

The information presented in Table l-a gives an indication of the overall coverage of the survey which resulted in the acquisition of the large sample of data for this study. It is also to be noted that there was included in the load data, the weight of personnel based on information obtained from facility officials regarding the maximum number of people assigned to various activities. The weight of individuals was conservatively taken to be 175 lbs. for men and women alike. Although the weight of personnel was included in the floor load data, it was not considered a major contributing factor. The mean value of personnel loads in all of the different work areas of all facilities was 0.8 psf. Even two isolated instances of 3 , and 4 psf in small 'Main Office Carriers" areas (approx. 2000 sq. ft.) were considered to be small compared to anticipated design levels. In these two cases the personnel weight represented $1 / 4$ of the total floor load.

Also of general interest are the values in Table l-b which are percentages of facility workrooms assigned to various mail processing activities. Although no firm pattern is established, if the values of Table l-b are ranked for each of the 7 facilities there appears a tendency for work areas 2 and 4 to have the higher apportionment percentages more
frequently, followed next (and equally) by work areas 1,7, 8 , and 10.

The loads investigated in this study fall into three categories: 1. Bulk mail load on storage conveyors;
2. Suspended mechanization loads; 3. Live floor loads. The three categories of loads, by the very nature of their differences, had to be analyzed in different ways.

### 3.2.1 Mail Loads on Conveyors

The main purpose of the various examinations to which the conveyor mail load data were subjected, was to obtain a realistic value which could be included as part of the total in estimating ceiling-suspended mechanization loads applied to ceilings through hangers. Such data of conveyor mail loads were obtained in quantity and detail as described in the earlier interim reports [1, 2]. For example, the values of Table 1 may be thought of as the successive total live loads (caused by mail) experienced at intervals of 2 ft of belt travel by a given pair of hangers supporting a $10-\mathrm{f} \uparrow$ length of a conveyor. Alternatively, the same values are expressed as the uniformly distributed live load over the belt area of the same $10-\mathrm{ft}$ section of conveyor as presented in Figure 1.

However, an evaluation of the effort and the means employed to acquire this and similar types of conveyor mail information [1], together with a consideration of the percentage of it which was helpful, resulted in curtailment of this detailed approach. Nevertheless, added attempts were made at the last 2 facilities surveyed to detect conveyor mail loads which might exceed what had so far been observed. This was done with a permanently recording, threshold-value type of detector attached to a conveyor hanger rod for a period of about 2 weeks but with negative results. An assessment of the conveyor mail load data which was available from the preceding surveyed facilities, therefore, resulted in the adoption of the observed maximum loading as a basis for estimating total ceiling-suspended conveyor loads. The maximum loading observed over a 10 ft . length of a combination storage-transport conveyor at Chicago AMF was 25 psf. Further examination of the data and records of the mode of conveyor operation confirm that such loading was not an isolated occurrence. The proximity of 25 psf to the presently specified maximum conveyor design live load (30 psf) would indicate the latter to be reasonably suitable. A reconsideration of mail processing methods suggests a modification of an earlier judgment [2] regarding the likelihood of such loading exceeding this level of intensity. Post Office Department limitations on sack and
parcel weights, along with photo-electric cell control of conveyors, would tend to restrict the density of loading along a conveyor belt. The above cited maximum values occurred in a lo-ft observation length under conditions of close storage packing of the conveyor. Peak periods of mail handling would increase the lengths of uninterrupted stretches of closely packed mail passing through a 10 ft observation length but, the likelihood of the belt load density being increased is small because of the above restricting factors.

### 3.2.2 Ceiling Loads

The field data for suspended mechanization loads were recorded in the form of dimensions and types of construction materials for selected sections of conveyors and other processing machinery. The area occupied by a mechanization section and its location within the plan of the building were also recorded. Sections were selected which represented the different types of conveyor units and different combinations of units in a common area. These data were reduced to total weights bearing within specific horizontal areas. Calculations were made to determine values of the total load uniformly distributed over the horizontal area for each mechanization section.

In addition, the hanger loads for conveyor suspension rods were calculated for two different support arrangements: 1. With suspension rods located at the four corners for small conveyor sections; 2. With suspension rods supporting large conveyor sections every 5 ft in a rectangular coordinate grid system. The four-corner support calculations were made for conveyor sections with areas of 75 sq ft or less (the smallest section examined was 4 ft by $3 \mathrm{ft}=$ $12 \mathrm{sq} \mathrm{ft})$. The $5-\mathrm{ft}$ rectangular grid support points arrangement was chosen since it conforms to the POD specification for arrangement of insert anchor points to support suspended mechanization systems. Values for uniformly distributed loads were computed for dead weights of mechanization sections alone, and for mechanization with mail live load added on the conveyor belt areas where they existed. The mail live loads used were those currently specified by POD for design ( 30 psf ). The computed hanger rod loads for the 5 ft -spaced coordinate grid support points were based on the minimum number of support points in a 5 -ft grid system which were calculated to fall within the plan area of the mechanization.

The range of suspended mechanization loads mentioned in Section 3.1.2 (19 psf to 340 psf, with live load) was for 58 values obtained throughout the 7 facilities. These, of
course, are related (although not respectively) to a wide range of areas of examination: $11,620 \mathrm{sq} . \mathrm{ft}$. to $12 \mathrm{sq} . \mathrm{ft}$. The generally inverse relationship between the areas and loads is brought out by the plot of the 58 cases in Figure 2. Note again that the selected sections of mechanization were purposely chosen because of their apparent heavy loads as evidenced by complex construction. Further definition was obtained by fitting an approximate upper boundary curve to the data. Two inferences can be drawn from this empirical relation. 1. There appears to be a limit to the intensity of loading that can be expected in a mechanizationfilled area of a given size. 2. The rate at which the indicated maximum intensity varies with area size, changes abruptly in the vicinity of 100 to 200 sq . ft. of area (or 90 to 100 psf ). That is, load intensities greater than approximately 100 psf can be expected to occur only in relatively small areas. Of particular interest, in Figure 2, is the boundary region associated with areas of grid square size as represented by those in the surveyed facilities. For this range of grid square areas (about 1900 to 700 sq . ft.) the indicated expected maximum intensity of total ceiling load falls within the narrow range of about 70 to 80 psf. The highest actually encountered was 84 psf for a 700 sq . ft . grid square filled with mechanization. This sample had been examined to include such a possibility even though it was,
in fact, not a case of mechanization which was totally ceiling-supported [3]. The choice of the 100 psf value to represent upper limit loading of this type would be reasonably conservative for grid square areas in this approximate size range.

### 3.2.3 Floor Loads

The occupancy loads on the floor in the workroom area of a facility are in a state of constant change. The total mail load within the facility fluctuates with the input-output movement of the mail; and the specific (discrete) loading within the facility changes as the mail is transported from one point to another in the normal processing operations. The total load fluctuations are significant only in considering seasonal peaks (Christmas mail, etc.) and even then the information is of little or no use for engineering design purposes unless it can be conveniently converted to a distribution within the facility. Significant factors for the analysis of loading on the workroom floor are the characteristic magnitudes and distributions of loads, and the limits that these parameters can be expected to have.

The floor areas on which the loads are applied are divided into two categories: 1. Activity associated areas;
2. Structurally significant areas. The activity associated areas are the work areas. The structurally significant areas are the grid square and grid sector areas. The grid square represents the basic floor and ceiling element that the characteristic loading relates to in terms of first order design loads. Therefore, the loadings within work areas have been evaluated in terms of their effect on grid squares (floor or ceiling structural panels).

The analysis of the floor loads is based on the data in the two Tables 3-and 4-series. These values are the first step in reduction of field data in all facilities pertaining to loading and occupancy of grid squares. In review, this part of the survey involved the recording of the weights, size and approximate locacions of all items (and their contents) on the workroom floor [1]. Personnel weights were added later by assignment. Since it was believed that areas of different mail processing activities might present different floor loads information, floor plans of facilities were used to note the specific work area locations. A further breakdown of the floor area was made by defining the areas bounded by column lines as grid squares. The grid squares were then divided into $1 / 2-s p a n$ mid-strips and 1/4-span column-strips corresponding to the structural strips considered in bending moment design of a two-way
flat slab. The overlappirg of the strips in the two directions formed a pattern of grid area sectors which provided a general location scheme. In cases where the boundary of a work area did not coincide with a column line, the work area then contained partial grid squares.

In pursuing the questions of a possible difference in loading conditions of 1. Different work areas; and 2. Facilities of different numbers of stories, the mean values of grid square uniformly distributed load, and of occupied space percentage were chosen as characterizing values. The results of a first consideration of grid square loading and occupancy conditions in each of the work areas of each surveyed facility is given in Table 5. For general information, Table 6 shows the distribution of work areas by floors when the work areas are split. However, in the following analyses, each single activity work area in a facility is considered as a whole. Since, generally, many single work areas in any one facility did not provide a large enough sample of grid squares to form a well defined histogram, such graphs at this level are not presented. Therefore, data was assembled from like work areas in multiple facilities, grouped by their number of stories. This facility grouping was used in connection with answering question (2.), stated above, of whether there might be a possible loading difference in
facilities of different numbers of stories. The same method of grouping was also used in the consideration which follows. In the 3 (l-story) facilities surveyed, the major concern with floor loads was centered on specific activityrelated movable equipment, mail, etc., which contributed to the load and occupancy of a designated work area. As a result, some sections of permanently floor-mounted mechanization were not included as they were in facilities surveyed later. The facility grouping was also used to investigate the effect of such deletions on the overall results. (Any effect is seen later to be of no practical importance).

The results of combining the data for like work areas in various groups of facilities is summarized in Tables 7 and 8 and presented graphicaliy in the Figures 3-, 4-, 5-, 14-, 15-, 16-series. Within each facility group, the mean values of grid square $U D L$ and grid square percentage occupied space in Tables 7 and 8 were subjected to statistical tests [7] at the $1 \%$ level of significance to determine if the means of different work areas differed significantly. In all facility groups (1-story, 2 and 3 -story, All) the tests indicated either no difference between means of different work areas, or differences which were statistically significant but were judged to be practically unimportant from an engineering viewpoint.

Recognizing no practical difference between the loading conditions (of weight and of space) of different work areas, the data in each of the facilities were lumped without distinguishing between work areas and replotted as the histograms of the Figure 6-series. Corresponding cumulative frequency distributions may be found for comparison in the Figure 7-series. The characteristic values for each facility are summarized in Table 9.

The lumped data of each facility were then combined into two groups (1-story, 2 and 3 -story) and similarly tested for significant difference between means of grid square UDL and between means of grid square occupied space of the two groups. Again, it was concluded that there were no differences of practical importance. Figures 8 thru 11 and 19 thru 22 illustrate the frequency of grid square loadings and occupancies in these groupings the characteristic values of which are also summarized in Table 9.

In general, with regard to loading and occupancy, the data also showed lack of practical difference between the respective means of seven ist floors, four 2 nd floors and one 3rd floor; and between the means of the lst floors in the two different groups of facilities. It is of interest to note that the slight differences observed between the
lst, 2nd and 3rd floors (i.e., between the respective nominal mean values 9,10 , and 11 psf ; and between 28,31 , and $31 \%$ ) show an increase in loading with floor level (although small) rather than a decrease as had originally been presumed.

Based on a statistical comparison of the means, there is no justification for not pooling the data. It was, therefore, judged admissible to combine all observations of grid square loading, and of grid square occupancy, from all facilities surveyed, in order to obtain the histograms and cumulative frequency distributions of Figures 12, 13 and Figures 23, 24. The characteristic values of these, also, are summarized in Table 9. The mean values which are representative of grid square loading and percentage occupancy for the 1283 determinations obtained in surveying 1.04 million sq. ft. of workroom space are nominally 10 psf and $30 \%$.

Nevertheless, attention is also directed to the possibility of higher levels of floor load occurring. In this regard, consideration is given to cumulative probability levels obtained from the frequency distributions for the data. For
example, observe the $99 \%$ probable loads tabulated in Table 9, (i.e., the load which would probably not be exceeded in 99 out of every 100 grid squares). This is also done for percentage occupancy of grid squares. It is to be noted, however, that the $99 \%$ probable occupancy percentages in the 2 and 3 -story facilities were determined after exclusion of certain grid squares wholly or mostly filled with permanent floor mechanization which were not subject to random occupancy.

Additional records of upper limit observed loads are given in Table 10. These refer to maximum loadings measured on areas of different sizes described in earlier reports [2, 3, 4]. The grid square maximum load values for Table 10 were deliberately chosen for complete (whole) grid squares and in some instances are less than the $99 \%$ level values obtained from the cumulative frequency distributions for all grid square observations which include partial grid squares. As in the case of the ceiling loads analysis, it is also apparent in Table 10 that the intensity of extreme loadings increases with decrease in area of observation.

A further analysis was made to determine possible floor load levels higher than those observed. This was done by computing values of uniformly distributed loads resulting
from maximizing grid square loadings for various conditions. In earlier reports [2, 3, 4] this was done in an overly conservative manner in that the maximized load distributions were obtained from the work area cumulative fraction load curves and applied to a complete grid square area. The equivalent uniformly distributed load values (EUDL) for equal maximum bending moment in a one-way slab obtained in this way made no allowance for maneuvering space. The approach taken in the following determinations employs a more realistic procedure for obtaining a maximum credible loading.

Information regarding the frequency of discrete load intensities, observed in the various work areas of each facility, was obtained, as before, from the respective cumulative fraction load curves. However, the profile of upper value load intensities was applied not to the complete area of a grid square in a given work area but, rather, to a percentage of the grid square equal to the mean percentage of occupancy in that work area. Further, work areas of the same activity on more than one floor in a facility were not treated as a combined area (as in earlier reports) in order to avoid unrealistic maximization of discrete loads within a given work area. In Table 11 the UDL's are upper limit values determined by considering the loads and occupied
space described above to be placed randomly in the grid square (simulating survey conditions). These upper UDL's are calculated by dividing the sum of the applied maximized loads by the whole grid square area. Note that these upper limit loads, though artificially maximized, are not excessively greater than the $99 \%$ level of observed UDL's in Table 9.

The same method of load maximizing over partial grid square occupancy was used to obtain the values of Table 12. However, Table 12 contains calculated equivalent uniformly distributed loads which develop the same bending moment in a one-way grid square slab as would the maximized loads over a centrally (not randomly) located average percentage of occupied space. Within this central area, the applied discrete loads (which were derived from the respective work area's cumulative fraction load curve), were arranged in order of decreasing intensity from the center to the outer edge of the occupied space. Even such "reduced" values of maximized EUDL appear very conservative when compared with observed $99 \%$ level grid square UDL's in Table 9. Further, regarding observed high load intensities, it is recalled that the very highest grid square UDL recorded in the entire survey of 1283 grids (cf. Table 10) was 58.8 psf for a whole grid square which was $88 \%$ occupied by nutting trucks

The loads information that was collected during the study outside of the "Christmas rush" period showed some interesting results. The data indicates that there is no practical difference between loading conditions (weight and space) of different work areas. Also, there were suprisingly similar values for loadings irrespective of floor level or number of stories in a facility. These results did not support the assumption made at the outset of the loads study that the loading would vary with facility height. It was taken for granted, following preliminary studies of POD documents and general discussions with officials, that as the number of stories changes between facilities so would the arrangements and distributions of work areas which would directly affect the loading by floor level. However, because the loadings did not show any practical difference for different work areas, the assumption that loading varied with the number of stories was based on a false premise. It would appear, therefore, that in considering facility loads, on the basis of the observed data, differentiation between work areas, between story levels, and between facility categories (by number of stories) is not justified.

It was stated earlier that an important characteristic element of the loading on facilities, represented by the data collected in the surveys, is missing. This characteristic
element pertains principally to floor loads, and is assumed to be a product of the peak volume of mail that develops throughout the country during the "Christmas rush" period. This information is needed to eliminate uncertainties regarding the magnitude and extent of peak loadings. Also, since these loadings occur every year for at least two to three weeks, they must be considered working loads under which undesirable structural performance (cracking, etc.) is to be avoided.

In considering the information collected in the study, there were found three principal values of live floor loads pertaining to grid square loadings. They are as follows:

1. The mean value of the frequency
distribution for loadings on
all grid squares in the survey --- 10 psf
2. The value of grid square loading at the 99 percent probability
level for the frequency distri-
bution covering all grid squares
in the survey --- 30 psf
3. The maximum loading found on a grid square for the entire survey of 1283 grids -.. 59 psf

In an effort to obtain a value for "maximum crediblef" loading, various studies were conducted which combined observed data with professional judgment. In the preliminary (interim) reports, EUDL values were computed with a technique that was considered, at the time, very conservative. It is now considered not "credible". In support of this, it was found that the maximum grid square loading of 59 psf covered 88 percent of the grid square area (essentially complete coverage), the type of items being loaded nutting trucks. To illustrate, Figure 25 shows loaded nutting trucks closely spaced on a workroom floor (New Orleans). The loading conditions found for the grid square shown (located behind the man in the photograph) were 36 psf and 48 percent occupied area. Note also from Table 10, that the maximum grid sector UDL, for all facilities, of 137 psf (caused by sacks of mail stacked on the floor) is in a grid square having a UDL of only 24 psf. An example of this type of floor loading is seen in Figure 26 where the

[^1]grid square loading was 19 psf. However, here again, a Christmas season examination might reveal more congested or intensive loading.

Two methods were used to derive, from observed data, credible loadings for postal mail handling facilities. Both methods used the characteristic features of maximum ?oads and average occupied space for a given work area applied to the area of a grid square. These methods are described in Section 3.2.3, of this report in relation to: 1. "Maximized grid square UDL values in Table 11; 2. EUDL values in Table 12. The highest load values computed by these methods were 52 psf (work area 10 in New Orleans) with method \#1; and 159 psf (work area 10 in Omaha) with method \#2.

### 4.2 Recommendations

Design load recommendations are made for the three categories of load investigated in this study. They are: 1. Bulk mail load on storage conveyors; 2. Suspended mechanization loads; 3. Live floor loads. The recommended loads were chosen based on the data collected in the surveys of the facilities and in consideration of the fact that the data does not reflect the loads at Christmas time. Due to the manner in which the loads for categories 1 and 2, above, relate to processing operation controls and to the structure itself
their upper limit boundaries are assumed with a high degree of confidence. This is not the case for category 3 , live floor loads; and substantial comment is presented in support of the choice of a load value and options for design.

> For bulk mail load on storage conveyors, it is recommended that 30 psf be used for design. This is the value that is currently being used.

For suspended mechanization loads, it is recommended that 100 psf be used without any load reduction.

In choosing a live floor load to be used for the design of a building, many questions must receive attention and be satisfied before the choice can be considered a reasonable one. The important questions all bear on safety and economy. But in the final analysis, the questions all tend toward a consideration of the "consequence of failure." For slab-on-ground construction, loading to failure would mean, at most, a costly repair. However, the complete failure of an upper level floor section in a multi-story building could cause serious injury or death to people involved.

For single story facilities with slab-on-ground construction, it is recommended that a design load of 60 psf be used. This is suggested for use with the load factors involved in the design methods presently used.

Since a facility should be designed to safely and economically support the maximum loading that it can be expected to experience over its lifetime, recurring Christmas loads should be recorded and analyzed to determine their effect on the presently available frequency distributions. To select a design value for live floor loads without inclusion of such data necessitates a more conservative choice in order to avoid excessive risk of overloading. Therefore, for multi-story facilities, it is recommended that the live floor load design values in current use continue to be used.
