## Considerations

## for the Precise Measurement of Amplifier Noise

## NATIONAL BUREAU OF STANDARDS

The National Bureau of Standards ${ }^{1}$ was established by an act of Congress March 3, 1901. The Bureau's overall goal is to strengthen and advance the Nation's science and technology and facilitate their effective application for public benefit. To this end, the Bureau conducts research and provides: (1) a basis for the Nation's physical measurement system, (2) scientific and technological services for industry and government, (3) a technical basis for equity in trade, and (4) technical services to promote public safety. The Bureau consists of the Institute for Basic Standards, the Institute for Materials Research, the Institute for Applied Technology, the Institute for Computer Sciences and Technology, and the Office for Information Programs.

THE INSTITUTE FOR BASIC STANDARDS provides the central basis within the United States of a complete and consistent system of physical measurement; coordinates that system with measurement systems of other nations; and furnishes essential services leading to accurate and uniform physical measurements throughout the Nation's scientific community, industry, and commerce. The Institute consists of a Center for Radiation Research, an Office of Measurement Services and the following divisions:

Applied Mathematics - Electricity - Mechanics - Heat - Optical Physics - Nuclear Sciences ${ }^{2}$ - Applied Radiation ${ }^{2}$ - Quantum Electronics ${ }^{3}$ - Electromagnetics ${ }^{3}$ - Time and Frequency ${ }^{3}$ - Laboratory Astrophysics ${ }^{3}$ - Cryogenics ${ }^{3}$.

THE INSTITUTE FOR MATERIALS RESEARCH conducts materials research leading to improved methods of measurement, standards, and data on the properties of well-characterized materials needed by industry, commerce, educational institutions, and Government; provides advisory and research services to other Government agencies; and develops, produces, and distributes standard reference materials. The Institute consists of the Office of Standard Reference Materials and the following divisions:

Analytical Chemistry - Polymers - Metallurgy - Inorganic Materials - Reactor Radiation - Physical Chemistry.

THE INSTITUTE FOR APPLIED TECHNOLOGY provides technical services to promote the use of available technology and to facilitate technological innovation in industry and Government; cooperates with public and private organizations leading to the development of technological standards (including mandatory safety standards), codes and methods of test; and provides technical advice and services to Government agencies upon request. The Institute consists of a Center for Building Technology and the following divisions and offices:

Engineering and Product Standards - Weights and Measures - Invention and Innovation - Product Evaluation Technology - Electronic Technology - Technical Analysis - Measurement Engineering - Structures, Materials, and Life Safety* - Building Environment 4 - Technical Evaluation and Application ${ }^{4}$ - Fire Technology.

THE INSTITUTE FOR COMPUTER SCIENCES AND TECHNOLOGY conducts research and provides technical services designed to aid Government agencies in improving cost effectiveness in the conduct of their programs through the selection, acquisition, and effective utilization of automatic data processing equipment; and serves as the principal focus within the executive branch for the development of Federal standards for automatic data processing equipment, techniques, and computer languages. The Center consists of the following offices and divisions:

Information Processing Standards - Computer Information - Computer Services Systems Development - Information Processing Technology.

THE OFFICE FOR INFORMATION PROGRAMS promotes optimum dissemination and accessibility of scientific information generated within NBS and other agencies of the Federal Government; promotes the development of the National Standard Reference Data System and a system of information analysis centers dealing with the broader aspects of the National Measurement System; provides appropriate services to ensure that the NBS staff has optimum accessibility to the scientific information of the world. The Office consists of the following organizational units:

Office of Standard Reference Data - Office of Technical Information and Publications Library - Office of International Relations.

For the best accuracy in measuring noise figure, attention needs to be given to the choice of the hot and cold noise standards and to mismatch problems. Tables and graphs are presented to aid in choosing the proper measurement conditions, and an example is given to demonstrate their use. This paper essentially supplements a previous paper (included in an appendix), treating in more detail topics that become important when state-of-the-art measurements are required.

Key words: Amplifier noise; effective input noise temperature; mismatch error; mismatch uncertainty; noise figure.

## 1. Introduction

The problem of measuring amplifier noise is extensively documented in the literature [1,2]. For the reader's convenience, a general overview of this problem is reprinted in Appendix $E$ (along with other related papers). This technical note provides additional detailed information concerning the accuracy of measuring amplifier noise with the various noise standards presently available. This additional information should be helpful in evaluating or designing measurements of amplifier noise as accurate as $\pm 0.3 \mathrm{~dB}$ in noise figure or $\pm 7 \%$ in effective input noise temperature.

With the present state-of-the-art, the least inaccuracy to which amplifier noise figures can be measured is approximately 0.1 dB in noise figure or $2 \%$ in effective input noise temperature. This paper is especially addressed to those who intend to make such a state-of-the-art noise measurements.

### 1.1 The Basic Measurement

The most accurate measurements of amplifier noise use some version of the so-called Y-factor method. In this method, two noise standards with noise temperatures of $T_{\text {hot }}$ and $T_{\text {cold }}$ are sequentially connected to the input of the unknown amplifier*, and the ratio of the noise powers, Y, out of the unknown amplifier is measured. This parameter $Y$ may be written in terms of the Effective Input Noise Temperature** of the unknown amplifier, $\mathrm{T}_{\mathrm{e}}$, as follows:

$$
\begin{equation*}
Y=\left(T_{\text {hot }}+T_{e}\right) /\left(T_{\text {cold }}+T_{e}\right) \tag{1}
\end{equation*}
$$

Because $T_{\text {hot }}$ and $T_{\text {cold }}$ are known, and $Y$ is measured, then $T_{e}$ is known:

$$
\begin{equation*}
T_{e}=\left(T_{\text {hot }}-Y T_{\text {cold }}\right) /(Y-1) \tag{2}
\end{equation*}
$$

Also in common use as a measure of amplifier noise is noise figure, $F_{d B}$. To avoid the ambiguities and difficulties of the IEEE definition of $\mathrm{F}_{\mathrm{dB}}$ discussed in [1], the definition of $\mathrm{F}_{\mathrm{dB}}$ used in [1] is used here, namely

$$
\begin{equation*}
\mathrm{F}_{\mathrm{dB}} \equiv 10 \log \left[1+\mathrm{T}_{\mathrm{e}} / 290\right] \tag{3}
\end{equation*}
$$

*In this paper, the term "unknown amplifier" is used to refer to the amplifier whose Effective Input Noise Temperature, or Noise Figure we want to know.
**The definition of $\mathrm{T}_{\mathrm{e}}$ and $\mathrm{F}_{\mathrm{dB}}$ are discussed in [1] which is reprinted in Appendix E.

### 1.2 Accuracy Considerations

In crude terms, measurements of $\mathrm{T}_{\mathrm{e}}$ within $2 \%$ or $\mathrm{F} \mathrm{aB}_{\mathrm{B}}$ within 0.1 dB require $\mathrm{T}_{\text {hot }} \gg \mathrm{T}_{\mathrm{e}} \gg \mathrm{T}_{\text {cold }}$, and require that the $\mathrm{re}-$ flection coefficients of the noise standards closely match the reflection coefficient of the "antenna"* in both magnitude and phase angle.

There are at least seven important sources of error in a typical measurement of $\mathrm{T}_{\mathrm{e}}$ : (1) uncertainty in the value of $T_{\text {hot }}$, (2) uncertainty in the value of $T_{\text {cold, (3) }}$ uncertainty in the measurement of $Y$, (4) amplifier-gain instability during the time required to measure the ratio $Y$, (5) inequality of the reflection coefficients of the "antenna" and the two standard noise sources, (6) uncertainties in input connector losses with the "antenna" and each of the two standard noise sources connected to the unknown amplifier, and (7) errors in correcting for the noise originating in the measuring system (cascade error). As we shall see, the magnitude of these various errors depend on the choice of $T_{\text {hot }}$ and $T_{\text {cold }}$.

To minimize the measurement error requires two steps. First the hot and cold standards are selected, then the other measurement conditions are investigated. Some major factors that influence measurement accuracy are discussed first, then the state-of-the-art is discussed, and last a measurement example is given to clarify the use of this technical note.
*The term "antenna" in this paper refers to all of the components that will be attached to the input of the unknown amplifier when it is being used in its intended application. (If the end use is not known, then it is usual to assume that the "antenna" is reflectionless. However, the concept of an unknown "antenna" is not in the spirit of a precision amplifier noise measurement.)
lo avoid breaking up the text, the long series of tables or graphs are collected in the appendices.

## 2. Hot and Cold Standards

Some of the choices for the hot and cold standard noise temperatures that are available are shown in Table 1.

Table 1. Thermal Noise Sources
Typical Effective Temperature

11. Commercial LHe standard $4 \pm 0.5$ (12.5\%)
12. WR90--NBS LHe standard
$4 \pm 0.1$
(2.50\%)

Four of the error contributions to $\mathrm{T}_{\mathrm{e}}$ or $\mathrm{F}_{\mathrm{dB}}$, namely the uncertainty in the values of $T_{\text {hot }}, T_{\text {cold }}, Y$, and gain instability, depend on the choice of $\mathrm{T}_{\text {hot }}$ and $\mathrm{T}_{\text {cold }}$. Appendix A

[^1]contains tables that list these dependent measurement error contributions for various values of $\mathrm{T}_{\mathrm{e}}$ or $\mathrm{F}_{\mathrm{dB}}$ for combinations of $T_{\text {hot }}$ and $T_{\text {cold }}$ selected from Table 1 . Table 2 summarizes some of the results given in Appendix $A$. The error listed under $F_{d B}$ in Table 2 is the magnitude of the uncertainty of $F_{d B}$. Thus by $F_{d B}=8 \pm 0.1 \mathrm{~dB}$, we mean the true value of $F_{d B}$ is between 7.9 and 8.1 dB. The uncertainty in $Y$, and variations in amplifier gain used in Table 2 and Appendix A approximate the present state-of-the-art. For different uncertainties in the parameters used, one needs to refer back to Appendix $A$ and make the modifications explained there.

## 3. Mismatch Ambiguity

Mismatch ambiguity (or uncertainty as it is called in [1]) is the ambiguity in effective input noise temperature because of an ambiguity in specifying the reflection coefficient of the "antenna," $\Gamma_{\text {ant. }}$ It is best to measure the mismatch ambiguity (see [1] in Appendix E), but to give an idea of the magnitude of the mismatch ambiguity, it is examined below.

The simplest assumption for amplifier noise is that the amplifier is linear (that is, its output voltage y is related to its input voltage $x$ in the form $y=a x+b$, where $a$ and $b$ are constants). If in addition to being linear, we assume isolation such that an impedance change at the amplifier's
The resultant error in $T_{e}$ and $F_{d b}$ listed is caused by the uncertainties（as indicated）

output termination does not alter $T_{e}$, then the most general dependence of $T_{e}$ with input reflection coefficient is [3]

$$
\begin{equation*}
T_{e}(\text { ant })=\frac{T_{a}\left(1+b\left|\Gamma_{a n t}^{\prime}-\beta\right|^{2}\right)}{1-\left|\Gamma_{a n t}^{\prime}\right|^{2}} \tag{4}
\end{equation*}
$$

where the parameters $T_{a}, b,\left|\Gamma_{\text {ant }}^{\prime}-\beta\right|$ and $\left|\Gamma_{\text {ant }}^{\prime}\right|$ are chosen to be terminal invariant (i.e., their value does not depend on the location of the input or output terminals provided the choice is limited to lossless regions). The parameter $\mathrm{T}_{\mathrm{a}}$ is the amplifier's characteristic noise temperature, $b T_{a}$ is the magnitude of reverse radiation (i.e., the noise temperature of the radiation from the amplifier as seen by the "antenna"), $\beta$ can be thought of as a measure of the correlation of the reverse radiation with the internal noise or alternately it may be thought of as a measure of the difference in conditions for maximum power transfer and minimum noise figure, and

$$
\begin{equation*}
\Gamma_{\text {ant }}^{\prime} \equiv \frac{\Gamma_{\text {ant }}-\Gamma_{a m p}^{*}}{I-\Gamma_{a n t}^{\Gamma_{a m p}}} \tag{5}
\end{equation*}
$$

where the asterisk implies the complex conjugate of the "amplifier's" reflection coefficient. Note that $\Gamma_{\text {ant }}^{\prime}=0$ for maximum power transfer, and has magnitude unity when $\left|\Gamma_{\text {ant }}\right|=1$. For the case that $\Gamma_{\text {ant }}$ and $\Gamma_{\text {amp }}$ are small, then it is convenient to use the approximate form of equation (5),

$$
\begin{equation*}
\Gamma_{\text {ant }}^{\prime} \simeq \Gamma_{\text {ant }}-\Gamma_{\text {amp }}^{*} \tag{6}
\end{equation*}
$$

In Appendix $B$ are graphs which can be used to estimate mismatch ambiguity.

Frankly, it is a bit of a problem to decide what value of $b$, and $\beta$ to use for any given amplifier because so little is known about what are typical values of $b$ and $\beta$. Engen [3] has measured $|\beta|=0.13, b=0.65, \mathrm{~T}_{\mathrm{a}}=496 \mathrm{~K}$ for an X -band crystal mixer amplifier. For an X-band tunnel-diode amplifier $|\beta|=0.03, \mathrm{~b}=0.35, \mathrm{~T}_{\mathrm{a}}=825 \mathrm{~K}$ was measured. For a 30 MHz vacuum tube amplifier, $|\beta|=0.22, \mathrm{~b}=0.59, \mathrm{~T}_{\mathrm{a}}=161 \mathrm{~K}$ was measured.

For any case, and a typical value of $\left|\Gamma_{\text {ant }}-\Gamma_{\text {amp }}^{*}\right| \simeq 0.1$, the mismatch ambiguity is less than about $2 \%$ of $T_{e}(0.1 \mathrm{~dB}$ of $F_{d B}$ ) if the magnitude of the uncertainty of $\Gamma_{\text {ant }}$ is less than 0.02. This means that precise measurements of amplifier noise require fairly accurate knowledge of $\Gamma_{\text {ant }}$.

## 4. Mismatch Error

Mismatch error is the error resulting when the "antenna," the hot standard, and the cold standard do not have identical reflection coefficients. The maximum mismatch error is listed in tables B-III to B-XXII for ideal linear amplifiers.

As pointed out in [1] (see Appendix E), estimates of mismatch errors using the tables in Appendix $B$ are hazardous. When it is practical, the measurements suggested in [1] are preferable.

## 5. The Bandwidth Problem

One problem that complicates the measurement of amplifier noise figure is caused by the dependence of the amplifier's noise on the variations in the "antenna" reflection coefficient versus frequency. For example, if local oscillator power in the superheterodyne amplifier leaks out the signa1 input port, then the mixer diode bias depends in part on the amplitude and phase of the reflection coefficient of the "antenna." This causes the noise figure and other amplifier parameters to vary depending on the phase of the "antenna" reflection coefficient at the local oscillator frequency. In addition, the noise figure depends on the phase of the "antenna" reflection coefficient at the signal frequency. The resulting combination effect modulates the amplifier noise figure and other parameters with a period characteristic of the IF amplifier frequency. In addition, the noise figure in theory can depend on the reflection coefficients of any pair of frequencies within the passband of the amplifier so that to check out reflection coefficient dependent effects, one needs to consider an unwieldly range of possible frequency dependences. These difficulties can be e1iminated or reduced if the reflection coefficient of the standard noise sources can be adjusted to equal that of the "antenna" at all frequencies. There is evidence in the literature that significant measurement errors can occur by not using the correct frequency dependent reflection coefficient [9].

## 6. The State-of-the-Art

Several factors which affect the accuracy of measuring amplifier noise have been mentioned, and details of their effects examined in the appendicies. In figures 1-4, the resulting error caused by the uncertainties of $T_{\text {hot }}, T_{\text {cold }}$, Y, gain, connector loss, and mismatch are shown for four combinations of hot and cold noise standards. For these figures it is assumed that $Y$ is measured within 0.01 dB , gain is stable within $0.1 \%$ over the measurement time, and the worst case uncertainty in loss in the connectors joining the hot or cold standards to the amplifier during the measurement is 0.01 dB (see Appendix $C$ for the effect of connector loss on measurement accuracy). The mismatch error selected corresponds to $\left|\Gamma_{\text {ant }}-\Gamma_{\text {std }}\right|<0.01$ and $\left|\Gamma_{\text {ant }}^{\prime}\right|<0.05$. For the amplifier properties, $b=\beta=0$, were selected not because these are typical, but because the error of this assumption is within a factor of 2 of the probable situation for the various amplifiers represented in the range of amplifier noise indicated. In figures 1-2, the measurement error is expressed in decibels. As for Table 2, a 0.1 dB error say at 8 dB means the amplifier noise is between 7.9 and 8.1 dB . For values of $\mathrm{F}_{\mathrm{dB}}$ where the error is a sizable fraction of $\mathrm{F}_{\mathrm{dB}}$, the figures no longer have a simple interpretation other than "this is no way to be measuring amplifiers with such small noise figures."

Figure 1. The state-of-the-art errors in measuring noise figure, $F_{d B}$, using an argon gas discharge noise source (about $10,000 \mathrm{~K}$ ) as the hot standard, $\mathrm{T}_{\text {hot }}$, and a room temperature resistive termination (about 300 K ) for the cold standard, Tcold. The uncertainty assumed for $Y$-factor, gain, connector loss, and mismatch are $\pm 0.01 \mathrm{~dB}, \pm 0.1 \%, 0.01 \mathrm{~dB}$, and (for mismatch) $\left|\Gamma_{\text {ant }}{ }^{-\Gamma_{\text {std }}}\right|<0.1$ and $\left|\Gamma_{\text {ant }}^{\prime}\right|<0.05$ as discussed in the text.

Figure 2. The state-of-the-art errors in measuring noise figure using the National Bureau of Standards' WR15, WR62 or WR90 "b1ack-body" standard as the hot standard, and a room temperature resistive termination as the cold standard. Other parameters as noted in figure 1.

Figure 3. The state-of-the-art errors in measuring the effective input noise temperature, $\mathrm{T}_{\mathrm{e}}$, using a commercial hot standard near boiling water temperature and a cold standard near liquid nitrogen boiling temperature. Other parameters as noted in figure 1.

Figure 4. The state-of-the-art errors in measuring $\mathrm{T}_{\mathrm{e}}$ using a room temperature resistive termination as the hot standard, and a liquid helium cooled resistive termination as the cold standard. The other parameters as noted in figure 1 .

The inaccuracy of hot and cold standards used is indicated in each figure. In general, the measurement situation depicted is typical of the best measurement conditions, and at some frequencies (e.g., where no calibration service for noise sources exists) somewhat better than the best conditions.

The four combinations of hot and cold noise standards selected are $10,000 \mathrm{~K}$ and $300 \mathrm{~K}, 1270 \mathrm{~K}$ and $300 \mathrm{~K}, 373 \mathrm{~K}$ and 80 K , and 300 K and 4 K . The combination 1270 K and 300 K differs from the others in that it assumes the use of the NBS primary standards, or if you will -- the best NBS can measure noise figure. The results from these figures can be converted to either noise figure or effective input noise temperature using table 3. In figures $1-4$, the dashed line is the quadrature sum (root mean square addition) of the errors. As we see, the quadrature sum is typically half of the linear addition of errors. The quadrature sum is the appropriate sum if the errors meet three criteria: (1) the error sources are independent, (2) the errors are equally likely to be positive or negative, and (3) the errors are more likely to be small rather than large. In other words, quadrature addition is appropriate if the error distributions are something like a gaussian distribution about the value used in the measurement calculation.

Unfortunately, three corrections, namely clipping, connector loss, and mismatch correction, seldom satisfy the

Table 3. Translation between effective input noise temperature, $T_{e}(K)$, and noise figure, $F_{d B}$. The asymmetry in the error statements, because of the logarithmic nonlinearity of $\mathrm{F}_{\mathrm{dB}}$, is avoided by using the slope of $\mathrm{F}_{\mathrm{dB}}$ at tine corresponding $\mathrm{T}_{\mathrm{e}}$.

| 23 | $\pm$ | .1 dB | = | 57572 | $\pm$ | $2.31 \%$ |
| 24 | $\pm$ | .1 dB | $=$ | 72554 | $\pm$ | $2.31 \%$ |

quadrature conditions. In principle this can be arranged but it is more practical to keep the level of these errors low, and then add their contributions linearly to the quadratic sum of the remaining errors.

Frequently the errors due to the uncertainty in the hot noise standard, the cold noise standard, the measurement of Y, and the amplifier gain instability add in quadrature. In this case, the contributions from these four sources will be about half of their linear accumulation of error.

## 7. An Example

To illustrate a measurement problem we begin with the following measurement specification provided by a "buyer". WR15 mixer-preamplifier specifications:

| Local Oscillator: | 60 GHz |
| :--- | :--- |
| I.F. Bandpass: | $10-110 \mathrm{MHz}$ |
| Maximum Noise Figure: | $<8 \mathrm{~dB}(1500 \mathrm{~K})$ for |
| Input $\|\Gamma\|:$ | $<.1$ |
| Output $\|\Gamma\|:$ | $<.1$ |
| Gain: | $>10 \mathrm{~dB}$ |
| Gain Instability: | $<0.005 \mathrm{~dB} / \mathrm{min}$ |
| Measurement Accuracy Goal: | 0.1 dB |

First a comment on the specified accuracy goal. From reference [1] (see Appendix E) we note that a calibration from

NBS exists so figures $1-4$ can reasonably represent the state-of-the-art. Using figure 1 , we see that 0.1 dB error is near the state-of-the-art using an argon gas discharge noise standard and a room temperature standard providing some of the error contributions can be placed in quadrature. Further, from figure 2 , it appears NBS should be able to provide a measurement verification if needed. However, it is clear that the specified accuracy goal is going to be difficult to obtain.

To compare the specified accuracy goal with the estimated mismatch ambiguity, I would use figure B4 (it is my guess that $\mathrm{bT}_{\mathrm{a}} \simeq 300 \mathrm{~K}$ so that $\mathrm{b}=0.2$, and $\beta=0.2$ to be consistent with Engen's measurement [1]) with $\left|\Gamma_{\text {ant }}-\Gamma_{\text {amp }}^{*}\right| \simeq 0.2$, and $\left|\Gamma_{\text {std }}-\Gamma_{\text {ant }}\right| \simeq 0.1$. The mismatch ambiguity indicated is about $7.7 \%$. This is several times the accuracy goal specified. At this point one should stop and reevaluate whether it is economically more effective to lower the amplifier noise figure to allow for the mismatch ambiguity, or to specify the antenna impedance more precisely. If the specified accuracy goal is maintained, a difficult measurement is being undertaken with a real risk that the "buyer" cannot make use of it. In a situation like this there must be a very clear mutual understanding with the "manufacturer" of the conditions under which the amplifier will be utilized. Otherwise the measurement can unintentionally become invalid.

As a final consideration of the accuracy goal, we note from [l0] or from table 2 in [1] (see Appendix E) that connector losses as low as 0.01 dB have been measured in WR15. But from experience at NBS, a 0.1 dB loss can occur if connectors from different manufacturers are mated without careful inspection to see that the flanges close properly. Thus, flanges must be examined and handled with "laboratory" care, right through the time the amplifier is finally installed.

The gain of the WRI5 mixer-preamplifier in this example is not great enough so that the cascade noise contribution due to a post amplifier can be ignored. This contribution is approximately equal to $\mathrm{T}_{\mathrm{e}}($ post) divided by the power gain of the WR15 mixer-preamplifier. For a $\mathrm{F}_{\mathrm{dB}}$ (post) of $5 \mathrm{~dB}(627 \mathrm{~K})$, the post amplifier contribution of 63 K represents a 0.1 dB increase of $\mathrm{F}_{\mathrm{dB}}\left(\mathrm{spec}+\right.$ post) over $\mathrm{F}_{\mathrm{dB}}(\mathrm{spec})$. We need to know $T_{c}$ (post) and the gain of the specificd amplifier within about $10 \%$.

At this point, we can list a set of conditions which will make it probable that a measurement of $F_{d B}$ is within . 1 dB . 1. A quadrature crror situation using an argon-gas discharge noise standard and room temperature standard. For example
a. An argon-standard adequately calibrated by a standards Iaboratory.
b. $\quad$ Y-factor measurement system accurate to within 0.01 dB (including resolution limitations).
c. A thermometer accurate to. within about 0.1 K to measure the room temperature standard.
2. Mismatch ambiguity measured for $\left|\Gamma_{\text {std }}\right|=0.1$ (with the most unfavorable phase) preferably to better than $1 \%$. (Note: to meet the specification, the measured $F_{d B}$ must be lower than that specified by this mismatch ambiguity.)
3. Connector losses should be less than about 0.02 dB . 4. Cascade correction
a. 60 GHz amplifier gain measured within $10 \%$.
b. Post amplifier noise temperature measured within $10 \%$.
7.1 Measurement of the Post Amplifier Noise

The example of measuring the WR15 mixer-preamplifier is completed. But the problem of measuring the post amplifier noise temperature within $10 \%( \pm 0.3 \mathrm{~dB}$ at 5 dB noise figure) is a sufficiently different problem that it merits further discussion. To be specific, assume the manufacturers specifications of the amplifier chosen for this task are:

Bandpass $10-110 \mathrm{MHz}$
Noise Figure < 5 dB (627 K)
Input $|\Gamma|<0.05$
Output $|\Gamma|<.1$
Gain > 70 dB
Gain instability $<0.005 \mathrm{~dB} / \mathrm{min}$
1 dB gain compression at 100 mw or greater.

The gain selected permits one to operate a bolometer power bridge with 0.1 milliwatt output when a room temperature noise source is connected to the WR15 mixer-preamplifier. The gain compression level selected is such that less than $0.1 \%$ of the noise power will be clipped when the hot noise source is connected to the WR15 mixer-preamplifier.*

To estimate the mismatch uncertainty for the post amplifier (due to the low frequency noise standard's reflection coefficient being different than the output reflection coefficient of the mixer-preamplifier), I would use figure B7 (no hard information for this choice) with
$\left|\Gamma_{\text {ant }}-\Gamma_{\text {amp }}^{*}\right| \simeq\left|\Gamma_{\text {ant }}-\Gamma_{\text {std }}\right| \simeq 0.1$. The result is off the graph but extrapolates to be near $13 \%$ (or .4 dB via table 3 ). A $10 \%$ overall accuracy is our goal so we would like to tune the standards (which decreases their accuracy) to equal the output impedance of the mixer-preamplifier. But to match the output impedance from $10-110 \mathrm{MHz}$ is probably impractical so like it or not, we may have to accept the $13 \%$.

For the post amplifier noise measurement, a solid-state noise source with $\mathrm{T}_{\text {hot }}$ near $10,000 \mathrm{~K}$, and a room temperature cold standard are reasonable choices. Scaling the errors from

[^2]tab1e A-IV for $T_{e}=700 \mathrm{~K}, \mathrm{~T}_{\text {hot }} \pm 3 \%$ contributes $4.40 \%$, $T_{\text {cold }} \pm 10 \mathrm{~K}$ contributes $1.6 \%, \mathrm{Y} \pm 0.1 \mathrm{~dB}$ contributes $3.6 \%$, and gain stability of $1 \%$ over the measurement time contributes $1.6 \%$, connector loss of 0.05 dB contributes .05 dB to $\mathrm{F}_{\mathrm{dB}}$ (see appendix C) or $1.69 \%$ via table 3. If the noise standards both have $\left|\Gamma_{\text {std }}\right|<0.02$, then from table $B-I X, \beta=.3$, $\mathrm{bT}_{\mathrm{a}} / \mathrm{T}_{\mathrm{e}}=1$ (this is just a guess but in line with the measurements in [1]) and using $F(d B)=6$ (because 5 not listed), for $\left|\Gamma_{\text {ant }}^{\prime}\right|>.1$ a mismatch error of 0.068 dB ( $2.1 \%$ using table 3) needs to be added to the $13 \%$ mismatch uncertainty for a total mismatch error of about $15 \%$. The grand total measurement error expected is $27.9 \%$. If the errors due to the hot source ( $4.42 \%$ ), the cold source ( $1.6 \%$ ), the Y -factor ( $3.6 \%$ ) and the gain instability ( $1.6 \%$ ) are in quadrature, then the grand total error reduces to $22.8 \%$, or still uncomfortably large compared with the $10 \%$ goal.

## 8. Conclusions

Under favorable measuring situations, noise figure measurements within 0.1 dB or effective input noise temperature within $2.5 \%$ is about the best that can be done. One of the greatest problems to accurate measurements is mismatch error. This problem is compounded by the general ignorance of the magnitude and variation of the pertinent amplifier parameters.

The accuracy achieved in a particular measurement of amplifier noise depends not only on whether a commercial automatic noise figure meter is being used, or whether a refined Y-factor measurement scheme is utilized, but also on whether a national reference noise source exists at the frequency of interest. It also depends on the stability of the amplifier properties during the measurement. But in addition, the accuracy depends on the experience and skill of the metrologist. This experience and skill needs to be learned, preserved, and shared if accurate amplifier noise measurements are to become a reality. This paper provides information on the accuracy of the noise figure measurement in terms of the uncertainties of various measurement parameters without stating how to estimate the uncertainties of these measurement parameters. For these important estimates we anticipate that the average metrologist will utilize the information provided by the manufacturers of the test equipment he chooses to use. If the metrologist hopes to have individual error contributions combined in quadrature, then an even greater skill and understanding is required. We hope that for some of the amplifiers whose noise figure he has measured, he will have the National Bureau of Standards verify the measurement. This provides an opportunity to assure the metrologist that his methods and his equipment are adequate, and to give him the confidence to share his ability with others.

Appendix A. Measurement Errors that Depend on $T_{\text {hot }}$ and $T_{\text {cold }}$ The tables in this appendix are summarized in part in Table 2 on page 6. These tables are computer print outs using the program noted in Appendix D. The symbols have the following meanings (see equations (1), (2), and (3) in text):

Symbol
TH
TC
$D Y=.01 d B$
DG $=.10 \%$
TE (K)
F(DB)
Y (DB)
ETH
ETC
EY
EG
$\mathrm{T}_{\text {hot }}$
T cold
Y-factor measurement inaccuracy of
$\pm 0.01 \mathrm{~dB}$
Amplifier gain instability of $0.1 \%$
$\mathrm{T}_{\mathrm{e}}$ expressed in degrees Kelvin
$F_{d B}$
Y expressed in decibels, i.e. $\mathrm{Y}_{\mathrm{dB}}=10 \log \mathrm{Y}$
Error to $\mathrm{T}_{\mathrm{e}}$ due to uncertainty in $\mathrm{T}_{\text {hot }}$
Error to $T_{e}$ due to uncertainty in $T_{c o l d}(A-9)$
Error to $T_{e}$ due to uncertainty in $Y$ ( $\mathrm{A}-10$ )
Error to $T_{e}$ due to uncertainty in amplifier gain
$\pm$

The error listed next to value of $T_{e}$ under $T E(K)$ is the sum of the errors listed under ETH, ETC, EY and EG. Then this error is converted into the corresponding error in $F_{d B}$ and listed next to the value of the corresponding $\mathrm{F}_{\mathrm{dB}}$.

As an example of using Table A-1, note that an amplifier with an effective input noise temperature near 7000 K (noise figure of 14.0 dB ) can be measured to an inaccuracy of
$\pm 2.1 \%( \pm 0.087 \mathrm{~dB}$ in noise figure) if the hot standard is $18000 \pm 270 \mathrm{~K}$, the cold standard is $300 \pm 1 \mathrm{~K}$, the Y -factor (near 5.35 dB ) is measured with an inaccuracy of 0.01 dB , and the gain is unstable within $\pm 0.1 \%$. Of the $2.1 \%$ inaccuracy, $1.59 \%$ is caused by the $\pm 270 \mathrm{~K}$ uncertainty in the hot noise standard, $0.02 \%$ is caused by the $\pm 1 \mathrm{~K}$ uncertainty in the cold noise standard, $0.34 \%$ is caused by the 0.01 dB in measuring the $Y$-factor, and the remaining $0.15 \%$ is caused by the gain instability of $0.1 \%$ Mismatch error, connector loss error, and cascade error are neglected in these tables. If instead of the $\pm 270 \mathrm{~K}, \pm 1 \mathrm{~K}, \pm 0.01 \mathrm{~dB}$, and $\pm 0.1 \%$ inaccuracies assumed in Table $A-1$ for $T_{\text {hot }}, T_{\text {cold }}, Y(d B)$, and gain respectively we had $\pm 270 \mathrm{~K}, \pm 2 \mathrm{~K}, \pm 0.005 \mathrm{~dB}$, and $\pm 0.5 \%$, then the corresponding error contributions to $T_{c}$ in our example would expand or contract in proportion to $1.59 \%$, $0.04 \%, 0.17 \%$, and $0.75 \%$ for a total error of $\pm 2.55 \%$. Similarly for any other measurement uncertainty situation the tables can be modified to obtain the appropriate error contributions to $\mathrm{T}_{\mathrm{e}}$.

Appendix B. Mismatch
In this appendix, different mismatch errors are expressed in a set of figures and tables. The derivations of the equations used in the computer program are presented last. The computer program actually used is contained in Appendix D.

## B. 1 Mismatch Uncertainty

The following figures, referred to as the "Mismatch Uncertainty" figures, are based on Eq. (4) in the text. This set can be used to estimate the mismatch ambiguity discussed in Section 3 or they can be used to estimate the error caused by using noise standards that have a different reflection coefficient than the "antenna". The maximum uncertainty in $T_{e}$ versus $\left|\Gamma_{\text {ant }}-\Gamma_{\text {amp }}^{*}\right|$ is graphed for various values of $\beta$, $b$, and $\left|\Gamma_{\text {std }}-\Gamma_{\text {ant }}\right|$. For estimating mismatch ambiguity $\left|\Gamma_{\text {std }}-\Gamma_{\text {ant }}\right|$ is the magnitude of the uncertainty of $\Gamma_{\text {ant }}$. An upper bound for the mismatch ambiguity is obtained using the maximum value for $\left|\Gamma_{\text {ant }}-\Gamma_{\text {amp }}^{*}\right|$ consistent with uncertainty of $\Gamma_{\text {ant }}$.

The values of $\beta$ and $b$ for the various mismatch uncertainty figures is listed in Table BI.

Table B-I. Key to mismatch uncertainty figures

| Figure | $\beta$ | b |
| :---: | :---: | :---: |
| BI | 0 | 0 |
| B2 | . 1 | . 2 |
| B3 | . 1 | 1 |
| B4 | . 2 | . 2 |
| B 5 | . 2 | 1 |
| B6 | . 3 | . 2 |
| B7 | . 3 | 1 |

As an example of how to use these figures, consider an amplifier where $B=0.2$ and $b=0.2$. From Table $B-I$ we see that figure $B 4$ is appropriate. For this amplifier if $\left|\Gamma_{\text {std }}\right| \leq 0.01,\left|\Gamma_{\text {amp }}\right| \leq 0.05$, and $\left|\Gamma_{\text {ant }}\right| \leq 0.1$, then $\left|\Gamma_{\text {ant }}-\Gamma_{\text {amp }}^{*}\right| \leq 0.15$ and $\left|\Gamma_{\text {std }}-\Gamma_{\text {ant }}\right| \leq 0.11$. Thus using figure $B 4$ the maximum mismatch error caused by using a standard with a reflection coefficient different from the "antenna" is about $\pm 7 \%$. For this same example, to estimate the mismatch ambiguity (because $\Gamma$ amp can have any amplitude a phase restricted only by $\left|\Gamma_{\text {ant }}\right| \leq 0.1$ ) we use $\left|\Gamma_{\text {ant }}-\Gamma_{a m p}^{*}\right| \leq 0.15$ and $\left|\Gamma_{\text {std }}-\Gamma_{\text {ant }}\right| \leq 0.1$. The mismatch ambiguity is about $\pm 6 \%$ 。

## B.2. Mismatch Error

Mismatch error is the error in measuring either $\mathrm{T}_{\mathrm{e}}$ or Fab caused when the reflection coefficients of the "antenna", the hot standard, and the cold standard differ from each other. Part of the mismatch error, namely the error caused because the "antenna" reflection coefficient differs from
the reflection coefficient of the two standards, is already given in the mismatch uncertainty figures, and this contribution is NOT included in the mismatch error tables. In other words, the tables only include the error because the impedance of the hot and cold standards differ from each other. The magnitude of the error depends on the magnitudes of $T_{h o t, ~}^{\text {, }}$ $\mathrm{T}_{\text {cold }}, \beta$, and $\mathrm{bT}_{\mathrm{a}} / \mathrm{T}_{\mathrm{e}}$. A key to the 19 mismatch error tables is provided in Table B-II. The errors listed in the tables are decibel errors to $\mathrm{F}_{\mathrm{dB}}$. The meaning of the symbols used in the mismatch error tables compared with the symbols used in Eqs. (1), (3), and (4) are as follows:

Symbols Meaning

| $\mathrm{T}($ HOT $)$ | $\mathrm{T}_{\text {hot }}$ |
| :--- | :--- |
| $\mathrm{T}($ COLD $)$ | $\mathrm{T}_{\text {cold }}$ |
| BETA | $\beta$ |
| BTA/TE | $\mathrm{bT}_{\mathrm{a}} / \mathrm{T}_{\mathrm{e}} \simeq \mathrm{b}$ |
| ERR | $\left\|\Gamma_{\text {hot }}-\Gamma_{\text {cold }}\right\|$ |
| ANT | $\left\|\Gamma_{a n t}^{\prime}\right\| \simeq\left\|\Gamma_{a n t}-\Gamma_{a m p}^{*}\right\|$ |
| F(DB) | $\mathrm{F}_{\mathrm{ab}}$ |

As an example of how to use these tables, consider an amplifier where $\beta=0.2$ and $b=0.2$, and where $a$ hot standard of $10,000 \mathrm{~K}$ and a cold standard of 300 K will be used for the measurement of noise figure. Then from Table B-II (page 62) we note that Table B-VI is appropriate for use with these given conditions. If the amplifier has a noise figure near 6 dB , and $\Gamma_{\text {hot }} \Gamma_{\text {cold }}$
and $\Gamma_{\text {amp }} \leq 0.05$ and $\Gamma_{\text {ant }} \leq 0.15$ so that $" E R R " \leq\left|\Gamma_{\text {hot }}-\Gamma_{\text {cold }}\right|=$ 0.1 , "ANT" $=\left|\Gamma_{\text {ant }}-\Gamma_{\text {amp }}^{*}\right|=0.2$, the maximum mismatch error is $\pm 0.281 \mathrm{~dB}$.

## B.3. Derivations

The output power, $P_{\text {out }}$, out of a linear amplifier when a standard with temperature $\mathrm{T}_{\text {std }}$ and reflection coefficient $\mathrm{F}_{\text {std }}$ is attached to it is [3]

$$
\begin{equation*}
P_{\text {out }}=k G B M_{\text {std }}\left(T_{\text {std }}+T_{e}\right) \tag{B.1}
\end{equation*}
$$

where $k$ is Boltzmann's constant, $B$ is the appropriate bandwidth, $G$ is the appropriate gain, and $M_{\text {std }}$ is the mismatch factor $\left(M_{s t d}=1-\left|\Gamma_{s t d}^{\prime}\right|^{2}\right)$, where $\Gamma_{s t d}^{\prime}$ defined in eq. (5) except with the subscript "ant" replaced by "std"). Using eq. except with the subscript "ant" replaced by "std":

$$
\begin{equation*}
T_{e}(s t d)=\frac{T_{a}\left(1+b\left|\Gamma_{S t d}^{\prime}-\beta\right|^{2}\right)}{1-\left|\Gamma_{S t d}^{\prime}\right|^{2}} \tag{B.2}
\end{equation*}
$$

then

$$
\begin{align*}
\mathrm{P}_{\text {out }} /(\mathrm{GBk})= & \mathrm{T}_{\text {std }}+\mathrm{T}_{\mathrm{a}}-\left|\Gamma_{\text {std }}^{\prime}\right|^{2}\left(\mathrm{~T}_{\text {std }}-b T_{a}\right)  \tag{Br}\\
& +b T_{a}\left[|\beta|^{2}-2 \operatorname{Re}\left(\beta^{*} \Gamma_{\text {std }}^{\prime}\right)\right]
\end{align*}
$$

where Re( ) implies the real part of the vector in parenthesis, and the asterisk indicates the complex conjugate. If we let

$$
\begin{equation*}
\Gamma_{\text {std }}^{\prime}=\Gamma_{\text {ant }}^{\prime}+\varepsilon_{s t d}^{\prime} \tag{Br}
\end{equation*}
$$

then using eq. (B.3) and eq. (B.4)

$$
\begin{equation*}
P_{\text {out }} /(G B k)=M_{\text {ant }}\left(T_{s t d}+T_{e}-\Delta T_{s t d}\right) \tag{B.5}
\end{equation*}
$$

where $M_{a n t}$ and $T_{e}(a n t)$ are the mismatch factor and effective input noise temperature when the "antenna" is connected to the amplifier,

$$
\begin{align*}
M_{\text {ant }} \Delta T_{s t d} & \equiv T_{s t d}\left(1-b T_{a} / T_{s t d}\right)\left[\left|\varepsilon_{\text {std }}^{\prime}\right|^{2}+2 \operatorname{Re}\left(\Gamma_{a n t}^{\prime} \varepsilon_{s t d}^{\prime *}\right)\right] \\
& +2 b T_{a}\left[\operatorname{Re}\left(\beta^{*} \varepsilon_{\text {std }}^{\prime}\right)\right] . \tag{B.6}
\end{align*}
$$

If $G$ and $B$ do not change as $\Gamma_{\text {ant }}$ changes, then

$$
\begin{equation*}
Y=\frac{T_{\text {hot }}+T_{e}-\Delta T_{\text {hot }}}{T_{\text {cold }}+T_{e}-\Delta T_{\text {cold }}}, \tag{B.7}
\end{equation*}
$$

where the subscript "std" is changed to "hot" or "cold" as appropriate. Solving for $T_{e}$,

$$
\begin{equation*}
T_{e}=\frac{\left(T_{\text {hot }}-\Delta T_{\text {hot }}\right)-Y\left(T_{\text {cold }}-\Delta T_{\text {cold }}\right)}{Y-1} . \tag{B.8}
\end{equation*}
$$

For the computer calculations, eq. (B.6) is modified so that

$$
\operatorname{Re}\left(\Gamma_{\text {ant }}^{\prime} \varepsilon_{\text {std }}^{\prime *}\right) \rightarrow \pm \Gamma_{\text {ant }}^{\prime} \varepsilon_{\text {std }},
$$

and

$$
\operatorname{Re}\left(\beta^{*} \varepsilon_{S t d}^{\prime}\right) \rightarrow \pm \beta \varepsilon_{S t d}^{\prime} .
$$

For mismatch error we assume $\left|\varepsilon_{\text {hot }}^{\prime}\right|=\left|\varepsilon_{\text {cold }}^{\prime}\right|$, and $T_{e}$ in Eq. (B.8) is computed for the eight sign combinations of the parameters $\Gamma^{\prime}$ ant, $\pm \varepsilon_{\text {hot }}^{\prime}, \pm \varepsilon_{c o l d}^{\prime}$, and $\beta$, and the greatest difference from the value of $\mathrm{T}_{\mathrm{e}}$ with $\varepsilon_{\text {hot }}=\varepsilon_{\text {cold }}=0$ is used as the misematch error.

For mismatch uncertainty $\varepsilon_{\text {hot }}^{\prime} \equiv \varepsilon_{\text {cold }}^{\prime}=\varepsilon^{\prime}$ so that using cis. (3.2) and (B.4)

$$
\begin{equation*}
\mathrm{T}_{\mathrm{e}}(\operatorname{std})=\frac{\mathrm{T}_{\mathrm{a}}\left[1+\mathrm{b}\left|\Gamma_{a n t}^{\prime}-\beta\right|^{2}+\mathrm{b}\left|\varepsilon^{\prime}\right|^{2}+2 b \operatorname{Re}\left(\varepsilon^{\prime} *\left(\Gamma_{a n t}^{\prime}-\beta\right)\right)\right]}{1-\left|\Gamma_{a n t}^{\prime}\right|^{2}-\left|\varepsilon^{\prime}\right|^{2}-2 \operatorname{Re}\left(\Gamma_{a n t}^{\prime *} \varepsilon^{\prime}\right)} \tag{B.9}
\end{equation*}
$$

Using eq. (B.2) and eq. (B.9),

$$
\begin{equation*}
\frac{T_{e}(a n t)-T_{e}(s t d)}{T_{a}}=-\frac{L+L b\left|\Gamma_{a n t}^{\prime}-\beta\right|^{2}+b\left|\varepsilon^{\prime}\right|^{2}+2 b \operatorname{Re}\left[\varepsilon^{\prime *}\left(\Gamma^{\prime} a n t-\beta\right)\right]}{\left(1-\left|\Gamma_{a n t}^{\prime}\right|^{2}\right)(1-L)} \tag{B.10}
\end{equation*}
$$

where

$$
L=\frac{\left|\varepsilon^{\prime}\right|^{2}+2 \operatorname{Re}\left(\Gamma_{a n t}^{\prime *} \varepsilon^{\prime}\right)}{1-\left|\Gamma_{\mathrm{ant}}^{\prime}\right|^{2}}
$$

Equation (B.10) is the mismatch uncertainty and un1ike the mismatch error calculated from eq. (B. 8), the mismatch uncertainty is independent of the values for $T_{\text {hot }}$ and $T_{c o l d}$. For the computer calculation, eq. (B.10) is modified so that

$$
\operatorname{Re}\left(\Gamma_{\text {ant }}^{\prime *} \varepsilon^{\prime}\right) \rightarrow \Gamma^{\prime} \text { ant }^{\varepsilon^{\prime}}
$$

and

$$
\operatorname{Re}\left[\varepsilon^{\prime *}\left(\Gamma_{\text {ant }}^{\prime}-\beta\right)\right] \rightarrow \varepsilon^{\prime}\left(\Gamma_{\text {ant }}^{\prime}-\beta\right)
$$

Then eq. (B.10) is computed for the four different sign combinations of the parameters $\Gamma_{\text {ant }}^{\prime}, \pm \varepsilon^{\prime}$, and $\pm \beta^{\prime}$, and the greatest value is used as the mismatch uncertainty.

$$
\begin{aligned}
& \beta=0 \\
& b=0
\end{aligned}

Appendix C. Effect of Front End Loss on Noise Figure and Effective Input Noise Temperature

If the reference plane used to define the input of the amplifier is changed, then the noise figure, $F_{d B}$, and the effective input noise temperature, $T_{e}$ changes if there is any loss between these reference planes. These changes in amplifier noise are calculated in this appendix. One application of the results of this appendix is to estimate the uncertainty in amplifier noise because of the uncertainties in the connector loss.

Using figure $C-1$, the effective input noise temperature at reference plane 1 is $T_{e}$, and at reference plane 2 is $T_{e}$. The two-port between 1 and 2 has the physical temperature $T_{\text {conn }}$ and an absorption loss of $A$ so that the thermal radiation from the two-port expressed relative to port 1 is $A T_{\text {conn }}$ [8]. The effective input noise temperature at reference plane $2, T_{e}^{\prime}$, is the amplifier noise and the two-port noise expressed relative to port 2, namely

$$
\begin{equation*}
T_{e}^{\prime}=\left(A T_{c o n n}+T_{e}\right) /(1-A) \tag{C.1}
\end{equation*}
$$

or

$$
\begin{equation*}
T_{e}^{\prime}-T_{e}=\frac{A}{1-A}\left(T_{c o n n}+T_{e}\right) \tag{C.2}
\end{equation*}
$$

Expressing the absorption loss in decibels,

$$
\begin{equation*}
A_{d B}=-10 \log _{10}(1-A), \tag{C.3}
\end{equation*}
$$

then

$$
\begin{equation*}
T_{e}^{\prime}-T_{e}=\left(10^{A_{d B} / 10}-1\right)\left(T_{c o n n}+T_{e}\right) \tag{C.4}
\end{equation*}
$$

For small losses (i.e., $A_{d B} \ll 10$ )

$$
\begin{equation*}
T_{e}^{\prime}-T_{e} \simeq 0.2303\left(T_{\mathrm{conn}}+T_{e}\right) A_{d B} . \tag{C.5}
\end{equation*}
$$

To express the difference in noise figure at reference plane 2 from plane 1 , recall that $F_{d B}=10 \log _{10} F$, where $F=1+\left(T_{e} / T_{o}\right)$, and where $T_{o}=290 \mathrm{~K}$. Because $\mathrm{dF}_{\mathrm{dB}}=\left(10 \log _{10}\right.$ e) $\mathrm{dF} / \mathrm{F}$, then for small losses

$$
\begin{equation*}
F_{d B}^{\prime}-F_{d B} \simeq 4.343\left(T_{e}^{\prime}-T_{e}\right) /\left(T_{o}+T_{e}\right) \tag{C.6}
\end{equation*}
$$

or using eq. (C.5)

$$
\begin{equation*}
F_{d B}^{\prime}-F_{d B} \simeq\left(\frac{T_{c o n n}+T_{e}}{T_{o}+T_{e}}\right) A_{d B} \tag{C.7}
\end{equation*}
$$

If the two-port's physical temperature, $T_{\text {conn }}$, is nearly equal $\mathrm{T}_{\mathrm{o}}=290 \mathrm{~K}$, then

$$
\begin{equation*}
\mathrm{F}_{\mathrm{dB}}^{\prime}-\mathrm{F}_{\mathrm{dB}} \simeq \mathrm{~A}_{\mathrm{dB}} . \tag{C.8}
\end{equation*}
$$

Thus an amplifier which includes a two-port with 0.1 dB absorption loss at $290 \mathrm{~K}(16.8 \mathrm{C}$ or 62.3 F ) has a noise figure 0.1 dB greater than the same amplitude excluding this two-port.

This appendix contains the computer programs used for the figures and tables in this paper. The programs are in BASIC 1 anguage.

## D.1. Figures 1 Through 4

For figures $1-4$, the program DWll in table $D-I$ was used. A typical output of this program is shown in table D-II.

The basic relationships used for this table are as follows: using eq. (1) of reference 1 and changing the notation to correspond with the remark statements in Table $D-I$, and adding the gain function $G$ [cf step 4400 in Table D-I]

$$
\begin{equation*}
Y=G_{*}(T H+T E) /(T C+T E) \tag{D.1}
\end{equation*}
$$

or rearranging [cf steps $4300,4440,4450,4480,4490,4520$, $4530,4560,4570$ ]

$$
\begin{equation*}
\mathrm{TE}=(\mathrm{G} * \mathrm{TH}-\mathrm{Y} * \mathrm{TC}) /(\mathrm{Y}-\mathrm{G}) \tag{D.2}
\end{equation*}
$$

This eq. (D.2) is used to calculate the error contributions from TH, TC, Y and G. Equation (2) of reference 1 (cf steps 4340 and 4330 ) is used to convert from $F(D B)$ to TE,

$$
\begin{equation*}
\mathrm{F}(\mathrm{DB})=10 * \mathrm{CLG}(1+\mathrm{TE} / 290) \tag{D.3}
\end{equation*}
$$

and the derivative of eq. (D.3) is used to convert errors in $F(D B)$ to errors in $T E$ (cf step 4427 which is also divided by 100 to convert to percent)

$$
\begin{equation*}
\mathrm{DF}(\mathrm{DB})=10[(\mathrm{~F}-1) /(\mathrm{F} * \log (10))] \quad \mathrm{DTE} / \mathrm{TE} \tag{D.4}
\end{equation*}
$$

where the symbol $D$ denotes the derivative, and $F$ is defined via (cf step 4425)

$$
\begin{equation*}
F(D B)=10 \operatorname{CLG}(F) \tag{D.5}
\end{equation*}
$$

The error caused by loss in the connector uses the following relationships. First converting loss in decibels to a ratio (step 4435) uses

$$
\begin{equation*}
\text { CONNECTOR LOSS }(D B)=-10 \operatorname{CLG}(A) . \tag{D.6}
\end{equation*}
$$

The changed noise temperature $T H$ (or similar for $T C$ ) caused by a loss at 300 K is given by [8] (cf step 4640)

$$
\begin{equation*}
\mathrm{TH}+\mathrm{DTH}=\mathrm{A} * \mathrm{TH}+(1-\mathrm{A}) * 300 . \tag{D.7}
\end{equation*}
$$

For mismatch error, eq. (A.6) is used as explained in appendix A (of steps 1000 through 1150).

> D.2. Figures B1 through B7

For figures B1 through B7, the program DW21.3 listed in table D-III was used. A minicomputer was used for this calculation and call 11 in step 1052 reads a switch position on the front panel for a diagnostic routine. A typical output from this program is listed in table D-IV. For the calculation, eq. (B.9) is used as explained in appendix B.

Table D-III. Computer program for figures Bl-B7.

# Measurement of Amplifier Noise 

mismatch errors and amplifier noise measurements are interrelated -other errors are exposed

D. F.WA!T National Bureau of Standards, Boulder, CO

#### Abstract

Measurement of amplifier noise, in particular a state-of-the-art measurement using hot-cold noise standards of $10,000 \mathrm{~K} \cdot 300 \mathrm{~K}$ or $373 \mathrm{~K}-80 \mathrm{~K}$, is discussed. An error that is especially difficult to estimate is the mismatch error. Measurements are suggested to help with this problem. Also, the traditional NBS thermal noise services are briefly sketched.

In its RF and microwave thermal-noise services, the National Bureau of Standards has in the past concentrated on developing means for transferring the fundamental standards of noise power to the scientific and engineering community of the Nation. With substantial capability for doing this now on hand, NBS has turned its attention to the application of these standards, and of re! ated techniques, to measurements of more direct concern to the "ultimate user." One of the key objectives of these more recent efforts is to transfer to the user the ability to make his own measurements and/or to verify that these are in. deed valid. In special instances NBS may simply make measurements for the user; in others it may repeat the customer's measurement, if necessary at the customer's own laboratory, to validate his technique and results.

This paper outlines and discusses the amplifier noise figure that has been used by NBS in the validation process and that, most important, can be used by others. It is typical of the new directions in NBS noise services.

The emphasis in this paper is on how to make amplifier noise measurements and on sources of measurement error and uncertainty. But because these and so many other similar measurements critically depend on the availability of noise standards, the standards that can be made avail. able through the more traditional NBS calibration services are first briefly sketched.

## TRADITIONAL CAPABILITIES IN NOISE

The National Bureau of Standaro's maintains reference noise standards and calibration radiometers, and has been active in developing the theory to support these areas. The most utilized noise service is that of noise-source calibration, although more and more frequently NBS is asked to analyze a radiometer rather than to calibrate a noise source.

[^4]
## Reference Standards

All NBS noise standards are resistive elements maintained at a uniform and known temperature $T^{1-5}$. The theoretical power $P_{a}$ available from these blackbody radiators is $P_{a}=k$ TB where $k$ is Boltzmann's constant, and $B$ is the bandwidth being viewed. The cold standards maintained by NBS are liquid-nitrogen cooled and have norse temperature near 80 K . The temperatures of the hot standards vary: the NBS 14 mm coaxial hot standard operates at 373 K ; the WR284 standard ( $2.60 \cdot 3.95 \mathrm{GHz}$ ) at 692 K ; and the WR90 (8.2 12.5 GHz$)$, WR62 111.9 18.0 GHz ) , and WR $15(50.75 \mathrm{GHz})$ standards near 1250 K . Figure 1 indicates treouencies at which NBS maintains the hot and cold primary standards.

## Calibration Services

The comparison radiometer, used to calibrate an un known noise source relative to the primary standard, is

Fig. 1 NBS calıbration services and standards.
the most elaborate part of any calibration service, and the need to understand its operation spawns most of the NBS experimental and theoretical noise studies ${ }^{4-16}$. The fre. quencies at which both reference standards and comparison radiometers exist are the frequencies of the available no ise calibration services shown in Figure 1. Typicaliy noise temperatures between 1000 to 300.000 K are calibrated to within $2 \%$ total uncertainty (excess noise ratios between 4 and 30 dB to within 0.1 dB$\}^{17}$. The calibration uncertainty is degraded somewhat if the connector of the source to be calibrated differs from that of the corresponding NBS standard. For frequencies at which cold-source calibrations are indicated in Figure 1, noise sources are typically calibrated to within $1 \%$ at temperature above 75 K.

## MEASUREMENT OF AMPLIFIER NOISE

At present, the National Bureau of Standards can measure effective input noise temperature only in WR 15 waveguide but, in principle, the noise figure service can be readily implemented at any frequency where an NBS primary noise source exists (see Figure 1). Thus, the potential frequency coverage of NBS noise-figure-measurement capability is greater than the coverage of the noise-source calibration services, which are limited by the frequency ranges of the comparison radiometers.

## An Overview

The most crisply defined measure or amplifier noise is $T_{e}$, the effective input noise temperature. "If two nose standards with corresponding noise temperatures $T_{\text {hot }}$ and $T_{\text {cold }}$ are sequentially connected to the input of an amplifier, then the change in output power of the amplifier. measured as a ratio $Y$, is

$$
\begin{equation*}
Y=\left(T_{\text {hot }}+T_{e}\right) /\left(T_{\text {cold }}+T_{e}\right) \tag{1}
\end{equation*}
$$

We see that $T_{e}$ is essentially a measure of the amplifier's internal noise expressed in terms of the available ** power density of a noise generator at the inpur of the amplifier.

Another popular measure of amplifier noise is noise figure ${ }^{18}$, but the ambiguities and difficulties ${ }^{19.26}$ with the IEEE definition of noise figure limits the usefulness of noise figure. The most serious ambiguity is related to superheterodyne amplifiers for which two different input channels contribute to the same output channel. The noise figure for the same amplifier differs depending on whether the user expects useful information through only

Conversion between effective input noise temperature, $T_{e}(K)$, and noise figure, $F_{d B}$. The asymmetry in the error statements resulting from the logarithmic non-linearity of $F_{C B}$ is avoided by using the slope of $F_{d B}$ at the corresponding $T_{e}{ }^{\text {. }}$
the signal channel, or through both channels. Nevertheless, noise figure is still used as a measure of amplifier noise.
To bypass the past difficulties an unorthodox definition is used here, namely

$$
\begin{equation*}
F_{d B} \equiv 10 \log \left[1+T_{e} / 290\right] \tag{2}
\end{equation*}
$$

This definition corresponds approximately to doublechannel noise figs-s as discussed by Mumford and Sheibe ${ }^{24}$, and is Equivalent to the IEEE definition of noise figure for a single-response amplifier. Defined this way, $F_{d B}$ can be siewed as a cnange in scale of $T_{e}$. The conversions between $T_{e}$ and $F_{d B}$ are given in Table 1.

## The Accuracy Gind

The most accurate and easiest measurements of $T_{e}$ are based on Equation 1. The effective input noise temperature $T_{e}$ is known irom a measurement of $Y$ because

$$
\begin{equation*}
T_{e}=\left(T_{\text {hot }}-Y T_{\text {cold }}\right) /(Y+1) \tag{3}
\end{equation*}
$$

There are seven important sources of error in a measurement of $T_{e}$ : uncertainty in the value of $T_{\text {hot }}$; uncertaint in the value of $T_{\text {exld }}$, uncertainty in the measurement of $Y$; the amplifiertan instablity during the time required to measיre the retio Y ; the inequality of the three reflec-
tion coefficients, vis., the hot and cold nose standards, and the reflection coefficient "seen" by the amplifier input port when it is in actual use (mismatch error); difference in tosses associated with the connector of the hot and cold standards and the amplifier under operating conditions are either not reproducible or are unknown; uncertainty in the noise generated in the measuring system is not accurately known (cascade error).

Fig. 2 Physical parameter contributions to noise-figure measurement limit of error.

Fig. 3 Physical parameter contributions to effective input noisetemperature measurement limit of error:

In setting an accuracy goal for the measurement of amplifier noise, it is useful to keep in mind the state of
the art, the magnitude of mismatch uncertainty that can be expected, and the quality of available connectors.

The State of the Art in establishing an accuracy goal, one of the best guides is an awareness of how closely one wishes to approach the state-of-the-art.

Figures 2 and 3 show the accumulated errors for state-of-the-art measurements of $F_{d B}$ and $T_{e}$, using two fre. quently employed hot-cold standard combinations; namely, $10,000 \mathrm{~K}$ and 300 K , or 373 K and 80 K . With one of these combinations, measurement uncertainties of about 0.1 dB in noise figure or effective temperature uncertainties of about $2.5 \%$ are state of the art.

Mismatch Uncertainty The effective noise temperature $T_{e}$ is a function of the reflection coefficient (i.e., impedance) of the "antenna" (components attached to the input of the amplifier). If the reflection coefficient of this "antenna" is not known exactly, then the $T_{e}$ that the amplifier will have when in use cannot be known exactly.

This uncertainty in effec::ve input noise temperature is referred to here as the --ismatch uncertainty. One should be hesitant to set an aczuracy goal better than this mismatch uncertainty.

In Figure 4, the max mum mismatch uncertainty is plotted for an ideal amm:-! fier as described by Engen ${ }^{23}$. It is clear from Figure 4 tr it the mismatch uncertainty becomes very important :- the magnitude of the difference between the "antenna's" and standard's reflection coeffjcient is expected to $\mathrm{di}^{2}{ }^{4} \mathrm{y}$ by more than 0.01 .

Connector Quality Tible 2 is a list of connector loss measurement results. The change in $F_{d B}$ due to the connector loss is equal to the decibel loss of the connector when it is at the temperze.re 290 K . Experience in wave. guide has shown that $\mathfrak{\varrho}$ edeal of care is required to duplicate these values. A. carelessly marred flange, or a
poorly mating pair can easily be worse by a factor of ten. It is good practice to remeasure the noise figure after a break and a remake of some of the connectors. Bad connectors can sometimes be spotted in this way.

## Measurement Technique

in principle the measurement of $T_{e}$ is simple. The hot standard is connected, then the cold standard is connected and $Y$, the ratio of output powers, is measured. The details of changing from hot to cold le.g., by changing current through a solid-state noise source), of measuring $Y$, and displaying the results depend on the equipment used. The manufacturer's literature and the prior literature ${ }^{23-33}$ are very helpful but often the information needed to establish error limits is difficult to obtain, especially for the automatic noise-figure meters. Often the straightforward (connect a hot standard and measure the output power, then connect a cold standard and measure the output power) technique is best. One precaution however: it has been found ${ }^{34}$ at NBS that, for $1-d 8$ gain compression in the power measuring system, the power level needs to be about a factor of 10 greater than the mean noise power if the error from clipping the noise is to be less than $0.1 \%$. This is also true for the commercial noise-figure measuring systems. Systems operating with too much gain can produce serious errors ${ }^{35-37}$

The most insidious measurement hazard is "mismatch" error, ${ }^{23,38.40}$. The problem of using standards having a different reflection coefficient from the "antenna" has already been discussed as mismatch uncertainty. The additional problem of the hot-standards and the cold standards having different reflection coefficients from each other is the mismatch error displayed in Figure 2 and 3. Here the two standards reflection coefficients have arbitrary amplitude and phase within the limits indicated. When the reflection coefficients are different many ugly things can

Fig. 4 Maximum mismatch uncertanty - "antenia" reflection coefficients vs amplifier input reflection complex conjugate.
happen as these standards are exchanged for each other: changes in gain, in gain stability, in bandwidth, and in linearity. In Figure 2 and 3 these ugly possibilities were ignored, and only the changes for the best possible ideal amplifier described by Engen ${ }^{2.3}$ were considered. It is safer to estimate mismatch error from the measurements suggested below.

The change of $T_{e}$ with a change of reflection coefficient can be measured by inserting an isolator and a slidescrew tuner (or the appropriate equivalent) between the

Fig. 5 Block diagram for measure ment of mismatch uncertainty as related to reflection ccefficient.
noise standards and the amplifier as shown in Figure 5. From this variation of $T_{e}$ the mismatch uncertainty can be estimated. This measurement is not exact because the losses change in the tuner-isolator combination as the reflection coefficient changes, but this loss change is usually small. For example, for commercial $X$-band slide-screw tuners, measured changes in absorption loss are less than 0.015 dB as reflection coefficient is changed from zero to 0.5 (any phase). Because of the definition of the noise figure (Equation 2), a $0.015-\mathrm{dB}$ increase in absorption loss (at 290 K ) increases the noise figure by 0.015 dB .

One estimate of mismatch error is obtained oy measuring $T_{e}$ with and without the isolator-tuner shown in Figure 5. If the isolator-tuner is adjusted to the "antenna" impedance, then the change in noise figure should be equal to the absorption loss of the isolator tuner. If this absorption loss can be estimated (insertion loss for lowreflection elements is nearly equal to the absorption loss). then any serious mismatch errors will be spotted. A better method, if it can be implemented, is to attach a slide-screw tuner to the hot standard only, and to observe the change in $T_{e}$ with the change of reflection coefficient. This procedure is then repeated with the slide-screw tuner attached to the cold standard only.

## Estimating Measurement Error

Figures 2 and 3 are useful for estimating measurement errors because the error contributions to $F_{d 8}$ or $T_{e}$ are essentially in direct proportion to the magnitudes of the respective error source parameters. Therefore, if $Y$ is measured to within $\pm 0.02 \mathrm{~dB}$, the $Y$-factor contribution error bands in Figures 2 and 3 double. However, this proportionality is not a good approximation of the mismatcherror estimate, but direct measur ement of $T_{e}$ versus $\Gamma_{\text {std }}$ should be used for estımates of the mismatch errors. Thus, Figures 2 and 3 can be used to translate from uncertainties in the various measurement parameters into the error induced in $T_{e}$

The cascade error is not shown in Figures 2 or 3. The desired $T_{e}$ can be deduced ${ }^{25,41}$ from the measured $T_{\text {total }}$ when the effective in put nose temperature of the measuring system is $T_{e 2}$ from

$$
T_{e}=T_{\text {total }}-T_{e 2} / G_{1}
$$

where $G_{1}$ is the available power gain of the amplifier being measured. The cascade error depends on how accurately $T_{e 2}$ and $G_{1}$ are known.

## CONCLUSIONS

An accurate measurement of amplifier noise requires that particular attention be paid to the mismatch error. This error depends on several amplifier characteristics and their changes with the different terminations on the amplifier. It is therefore important to make measurements of the the change in amplifier noise with a change in terminating reflection coefficient, in order to estımate this mismatch error.

From a discussion of the state-of-the-art measurements for hot cold standards of $10,000 \mathrm{~K} \cdot 300 \mathrm{~K}$ or 373 K 80 K , it is seen that measurements of noise figure to with. in about 0.1 dB , or effective input noise temperature to within about $2.5 \%$, is the best that can be done. Such small uncertainties are possible only at those frequencies at which NBS calibration of noise sources exist.

# A New Method of Characterizing Amplifier Noise Performance 

GLENN F. ENGEN

#### Abstract

Although the use of noise figure or noise temperature to characterize amplifier performance is a well-estahlished practice, It is also recognized that this parameter provides only a partial description of the amplifier noise properties. In general, the noise figure (or temperature) depends upon the generator impedance and is thus a function of the signal-source and amplifer comhination.

Typically, the noise figure is messured by the Y-factor method using hot and cold noise sources that are nominally matched (reflectionless). The result of this measurement is of value as a figure of merit; however, if optimum performance is to be realized, the applications engineer must know whether to adjust the signal source impedance for maximum power transfer, minimum noise figure, or some other criterion, and he must know the deterioration in performance that results if this is not done. It is the purpose of this paper to present an alternative method of characterizing smplifier noise performance in terms of parameters that provide ready answers to these questions. In addition, the measurement of these parameters via a simple extension of the $Y$-factor method will he described.

## I. Introduction

ALTHOUGH the use of noise figure or noise temperature to describe amplifier performance is a well-established practice, it is also recognized that this parameter provides only a partial description of the amplifier noise properties. More recently, the use of noise measure [1] has been proposed, but again, this provides only a partial description. As usually defined [2], the noise figure dcpends upon the generator impedance and thus is a function of the signal-source and amplifier combination.

If optimum use is to be made of a given amplifier, its performance characteristics must be known in sufficient detail. to predict its operation in arbitrary systems, and the options available in attempting to optimize the overall system performance. It is quite possible, for example, for two amplifiers to have the same noise figures and yet have markedly different sensitivities to changes in source impedance. In order to account for this and other phenomena, it is necessary to begin with a "complete" description. The remaining problem is one of putting this description in the most convenient form.

This is certainly not to suggest that this point of view is new, and indeed a number of useful descriptions have been given (for example [3], [4]). It is the purpose of

[^6]this paper to put this description in an alternative form that provides additional insights for certain problem areas.

## II. General Theory

Undoubtedly it would be possible to obtain the material that follows as an extension or reinterpretation of a number of earlier results. It will prove more instructive, however, to give its derivation from an elementary model; this provides the additional benefit that the presentation is "self-contained."

The model chosen for the amplifier is a two-port that is linear and active (both in that it provides gain and includes noise sources). This device, shown in Fig. 1, is conveniently described by the equations

$$
\begin{align*}
& b_{1}=S_{11} a_{1}+S_{12} a_{2}+b_{1 \star}  \tag{1}\\
& b_{2}=S_{21} a_{1}+S_{22} a_{2}+b_{2 \mathrm{n}} \tag{2}
\end{align*}
$$

where $b_{1}, b_{2}$ are the emergent wave amplitudes at ports 1 and 2 , respectively, and $a_{1}, a_{2}$ are the corresponding incident waves. The $S_{m n}$ are the scattcrin, pacfficients of the two-port. Finally, the internal noise suurces are represented by the terms $b_{1 n}, b_{2 n}$, such that the power spectral density (per cycle of bandwidth) delivered to passive and matched (reflctionless) terminations on ports 1 and 2 is given by $\left|b_{\text {in }}\right|^{2}$ and $\left|b_{2 n}\right|^{7}$, respectively.

It will prove convenient to express $b_{2 n}$ as the sum of two components: the first $\alpha b_{1 n}$ is complctely correlated with $b_{1 n}$, the second $b_{20}$ is uncorrelated. Thus,

$$
\begin{equation*}
b_{2, n}=\alpha b_{1,}+b_{20 .} \tag{3}
\end{equation*}
$$

In keeping with the usual design objectives, it will be assumed that $\left|S_{12}\right|$ is negligibly small. In addition, it is also convenient ${ }^{1}$ for the present discussion to assume $S_{29}=0$.

The boundary condition imposed on $b_{1}$ and $a_{1}$ by the generator is conveniently expressed in the form:

$$
\begin{equation*}
a_{1}=b_{0}+b_{1} \Gamma_{0} \tag{4}
\end{equation*}
$$

[^7]

Fig. 1. Basic circuit for discussion of amplifier noise.
Here, $b_{a}$ is the source term and $\Gamma$, is the generator reflection coefficient. In order to examine the dependence of the amplifier noise upon the sourcc impedance, it is convenient initially to assume that $b_{0}=0$.
These equations and assumed conditions may now be combined to yicld the following expression for the noise power delivered to a (matched) load at the amplifier output terminals:

$$
\begin{equation*}
\left|b_{2}\right|^{2}=\left|\alpha+\frac{S_{21} \Gamma_{0}}{1-S_{11} \Gamma_{0}}\right|^{2}\left|b_{18}\right|^{2}+\left|b_{20}\right|^{2} . \tag{5}
\end{equation*}
$$

This result explicitly displays the dependence upon source impedance $\Gamma_{0}$ and this dcpendence is a rather complicated one.
A substantial simplification in this expression may be effected by introducing "terminal invariant" parametcrs. (For an earlier discussion see [j]].) The desired transformation begins with the substitution::

$$
\begin{equation*}
\Gamma_{\dot{\theta}}^{\prime}=\left(\Gamma_{\bullet}-S_{11}^{*}\right) /\left(1-S_{11} \Gamma_{\theta}\right) \tag{6}
\end{equation*}
$$

so that (5) can be written ${ }^{3}$

$$
\begin{equation*}
T_{0}=\left|b_{2}\right|^{2}=T_{a} G\left(1+b\left|\Gamma_{a}^{\prime}-\beta\right|^{2}\right) \tag{7}
\end{equation*}
$$

where $T_{0}$ is the noisc power output (to the matched load),

$$
G=\frac{\left|S_{22}\right|^{2}}{1-\left|S_{11}\right|^{2}}=\text { amplifier power gain, }
$$

$T_{a}=\frac{\left|b_{20}\right|^{2}}{G}=\begin{aligned} & \text { minimum amplifier noise temperature (as }\end{aligned}$ to amplifier input,
$b=\frac{1}{T_{a}}\left(\frac{\left|b_{12}\right|^{2}}{1-\left|S_{11}\right|^{2}}\right)=\begin{aligned} & \text { ratio of the noise temperature of } \\ & \text { the input port }\end{aligned}$ $\beta=-S_{11}^{*}-\frac{\alpha\left(1-\left|S_{11}\right|\right)}{S_{21}}$.
The physical significance of $\beta$ may be interpreted as expressing to what extent the conditions for maximum power transfer and minimum amplifier noise differ.
In (7), the parameters $T_{a}, G, b$, and $|\beta|$ are dependent on the amplifier properties only, and moreover their values are "terminal invariant" (i.e., their values do not change if a "lossless" tuner is added to the amplifier input). The entire dependence upon the generator impedance is found in the term $\Gamma_{g}^{\prime}$.

## III. Evaluation of Parameters

The terms $T_{a}, b$, and $|\beta|$ may be evaluated by an extension of the $Y$-factor method.

Let a tempcrature $T_{0}$ be assigned to the generator of Fig. 1. Then (7) becomes ${ }^{5}$

$$
\begin{equation*}
T_{0}=T_{a} G\left(1-\left|\Gamma_{0}^{\prime}\right|^{2}\right)+T_{a} G\left(1+b\left|\Gamma_{a}^{\prime}-\beta\right|^{2}\right) . \tag{8}
\end{equation*}
$$

As in the $Y$-factor method, the measurement procedure calls for the use of "hot" and "cold" loads (noise sources). These will be designated $T_{\sigma k}, T_{\sigma \theta}$, respectively, and $T_{\text {of }}, T_{\text {oc }}$ the corresponding outputs when the noise sources are connected to the amplifier input. As a further condition it is assumed that the impedances of these loads is such that $\Gamma_{\rho}^{\prime}=0$ (see the Appendix). After the obgervation of $T_{o \lambda}$ and $T_{o c}$, a sliding short is connected to the amplifer input and the maximum and minimum values of $T_{0}$ observed in response to motion of the short. These will de designated $T_{o s}$ and $T_{o m}$, respectively.

These four observations provide a set of simultaneous equations, which can be solved to yield

$$
\begin{equation*}
|\beta|=\frac{\left(T_{o \mu}-T_{o m}\right)\left(T_{o \lambda}-T_{o c}\right)}{2\left\{\left(T_{o \Delta t}+T_{o m}-2 T_{o c}\right)\left(T_{o h}-T_{o c}\right)+2 T_{o c}\left(T_{o A}-T_{o c}\right)\right\}} \tag{9}
\end{equation*}
$$

[^8]\[

$$
\begin{align*}
T_{a} b & =\frac{\left(T_{o \mu}-T_{o o n}\right)\left(T_{o \lambda}-T_{o c}\right)}{4|\beta|\left(T_{o \lambda}-T_{o c}\right)}  \tag{10}\\
T_{a} & =\frac{T_{o n}-\left(T_{o h} / T_{o c}\right) T_{o c}}{\left(T_{o n} / T_{o c}\right)-1}-|\beta|^{2} \overline{T_{o} b .} \tag{11}
\end{align*}
$$
\]

[^9]The last two equations can also be solved explicitly for ' 1 's and $b: \ln$ terins of she cbserved guantities; howevcr; the suggested coriputation follows the indicated steps. [Note that (10) requires the value of $|\beta|$, and (11) the value of both $|\beta|$ and $2^{\prime}{ }^{\prime}$ b.] Finally, $b$ is determined by taking the ratio of (10) and (11).

It is of interest to note that the first term on the right in (11) is just the usual one for detcrmining amplifier noise temperature via the $Y$-factor method. In addition it may be recognized that these equations call (implicitly) only for ratios between the different output temperatures (e.g., $T_{a \mathrm{a}} / T_{o c}$, etc.). If the absolute value of these terms is measured, it is also possible to obtain the amplifier gain.

The only remaining quantity to complete the description is the argument of $\beta$. This may be obtained by computing the argument of $\Gamma_{o}^{\prime}$ that provides $T_{\mathrm{om}}$. This argument may, in turn, be obtained from (6) provided that $S_{11}$ and the corresponding argument of $\Gamma_{0}$ are known.

## IV. Power Matching Versus Noise Matching

Assuming that the applications engineer wishes to obtain the best overall performance, (i.e., the maximum signal-to-noise ratio at the amplificr output) it is necessary to know whether to adjust the gencrator impedance for maximum power transfer, minimum amplifier noisc, or according to some other critcrion, and the penalty that results if this is not done. These topics will now be investigated.

Returning to Fig. 1, it will be assumed that the signal source is of variable impedance and that its available power includes a signal component $S_{0}$ and a noise component $k T_{0} B$. The signal power $S_{0}$ at the amplifier output is given by

$$
\begin{equation*}
S_{0}=S_{0} G\left(1-\left|\Gamma_{0}^{\prime}\right|^{2}\right) \tag{12}
\end{equation*}
$$

while the noise power output $N_{0}$ is given by
$N_{\circ}=k T_{0} B G\left(1-\left|\Gamma_{\bullet}^{\prime}\right|^{2}\right)+k T_{a} B G\left(1+b\left|\Gamma_{\theta}^{\prime}-\beta\right|^{2}\right)$.
The signal-to-noise ratio at the amplifier output is
$\frac{S_{0}}{N_{0}}=\frac{S_{0}\left(1-\left|\Gamma_{0}^{\prime}\right|^{2}\right)}{k T_{0} B\left(1-\left|\Gamma_{0}^{\prime}\right|^{2}\right)+k T_{0} B\left(1+b\left|\Gamma_{0}^{\prime}-\beta\right|^{2}\right)}$.
By inspection, for maximum signal-to-noise ratio, the argument of $\Gamma_{\theta}^{\prime}$ should equal that of $\beta$. The remaining problem is that of maximizing

$$
\left(1-\left|\Gamma_{\theta}^{\prime}\right|^{2}\right) /\left[1+b\left(\left|\Gamma_{0}^{\prime}\right|-|\beta|\right)^{2}\right] .
$$

[^10]By use of the calrulus, this maximum occurs for

$$
\begin{equation*}
\left|1_{0}^{\prime \prime}\right|=(1 / D)\left[1-\sqrt{1-D^{2}}\right] \tag{15}
\end{equation*}
$$

where

$$
\begin{equation*}
D=(2 b|\beta|) /\left[1+b\left(1+|\beta|^{2}\right)\right] . \tag{16}
\end{equation*}
$$

It can be shown that $D<1$ and (15) can be expanded to yield

$$
\begin{align*}
\left|\Gamma_{\circ}^{\prime}\right|= & \frac{b|\beta|}{1+b\left(1+|\beta|^{2}\right)} \\
& \cdot\left[1+\frac{(b|\beta|)^{2}}{\left[1+b\left(1+|\beta|^{2}\right)\right]^{2}}+\cdots\right] \tag{17}
\end{align*}
$$

These results can now be substituted back into (14) to obtain an expression for the optimum signal-to-noise ratio. Because of its complexity, this result will not be given. If $|\beta|$ is small, however, the following approximation is useful:

$$
\begin{equation*}
\left.\frac{S_{0}}{N_{0}}\right|_{\text {max }} \simeq \frac{S_{0}}{k B\left[T_{0}+T_{0}\left(1+b|\beta|^{2} /(1+b)\right)\right]} \tag{18}
\end{equation*}
$$

It is of interest to evaluate the potential improvement over matching on a maximum power transfer or minimurn noise basis. The required expressions may be obtaincd, in turn, from (11) by letting $\Gamma_{g}^{\prime}=0$ and $\Gamma_{\theta}^{\prime}=\beta$. If the subscripts $p$ (for power) and $n$ (for noise) are used to identify these two cases, a little manipulation leads to the following approximate expressions:

$$
\begin{equation*}
\frac{\left.\left(S_{o} / N_{o}\right)\right|_{p}}{\left.\left(S_{\mathrm{a}} / N_{o}\right)\right|_{\max }} \simeq 1-\left(\frac{T_{\mathrm{a}}}{T_{a}+T_{\mathrm{a}}}\right)\left(\frac{b^{2}|\beta|^{2}}{1+b}\right) \tag{19}
\end{equation*}
$$

and

$$
\begin{equation*}
\frac{\left.\left(S_{o} / N_{o}\right)\right|_{n}}{\left.\left(S_{o} / N_{o}\right)\right|_{\max }} \simeq 1-\left(\frac{T_{o}}{T_{o}+T_{a}}\right)\left(\frac{|\beta|^{2}}{1+b}\right) \tag{20}
\end{equation*}
$$

It is worth noting that the potential improvement is small if $|\beta|$ is small, but increases rapidly as $|\beta|$ increases.

## V. Experimental Results

In an effort to explore the method further, the measurement procedures described in Section III were applied to a number of different amplifiers.

The first item to be evaluated was an $X$-band tunncldiode amplifier. In this case the measurement was straightforward and yielded the results: $|\beta|=0.03, b=0.35$, $T_{a}=825 \mathrm{~K}$. It should be noted that if the circulator, which is required in such devices, is "ideal," this would lead to $|\beta|=0$ and $b T_{a}=$ ambient tempcrature. The above results arece with the theoretical expectations.

The evaluation of an $X$-band crystal mixer gave $|\beta|=0.13, b=0.65, T_{a}=496 \mathrm{~K}$. Again the results appear plausible enough; it may be noted that $b T_{\circ}$ is only slightly above ambient while the value for $T_{a}$ is
half the usually quoted value since the measurement method utilized both the signal and image channels. In spite of this plausibility, however, these results are subject to some question in that a substantial shift in crystal bias was observed in response to the short motion. The source of this problem was due to a substantial coupling of local-oscillator power into the input arm, and when this was reflected back into the system, a shift in bias resulted. This, in turn, gives rise to some question as to whether or not the device was behaving in a linear manner.
An application of the method to a $30-\mathrm{MHz}$ vacuumtube amplifier gave $|\beta|=0.22, b=0.59, T_{a}=161 \mathrm{~K}$. Initially these results were believed to be in error in that this implies an input-port temperature of 94 K . Some further effort was expended in attempting to refine the impedance matching, but this proved to be a difficult broad-band problem in that the bandwidth of the de-
with "available" noise power. If the second interpretation is used, no change in (7) is required.
With regard to the $S_{12}=0$ postulate, it can be shown that the functional dependence of output power upon $\Gamma_{8}^{\prime}$ is still in the form of (7), even when $S_{13} \neq 0$. There is, however, a dependence of the different parameters (including $\Gamma_{0}^{\prime}$ ) upon $\Gamma_{t}$.
Finally, it is possible to prescribe a more general method for evaluating $T_{a}, b$, and $|\beta|$ than that outlined in Section III. Returning to Fig. 1, it is convenient to assume for the generator a noise source of temperature $T_{\text {c }}$, whose impedance can be adjusted in such a way as to vary the argument of $\Gamma_{0}^{\prime}$ while keeping its magnitude constant. Inspection of ( 8 ) shows that the first term on the right will remain constant while the second will go through maxima and minima. An observation of this response can be substituted for the sliding-short operation described in Section III. The appropriate equations are

$$
\begin{equation*}
|\beta|=\frac{\left|\Gamma_{c}^{\prime}\right|\left(T_{o M}-T_{o m}\right)\left(T_{o \wedge}-T_{o c}\right)}{2\left\{\left(T_{o M}+T_{o m}-2 T_{o c}\right)\left(T_{o h}-T_{o c}\right)+2\left[T_{o c}-T_{o,}\left(1-\left|\Gamma_{\mid}^{\prime}\right|^{2}\right)\right]\left(T_{o h}-T_{o c}\right)\right\}} \tag{22}
\end{equation*}
$$

tection system was a significant fraction of the operating frequency. An indirect confirmation of this result was finally obtained by an evaluation of the input-port temperature using a narrow-bandwidth radiometer. This gave the value 120 K , which may be regarded as a "confirmation" even if the agreement is not very good. It is unfortunate that it has not, as yet, been possible to repeat the entire evaluation with this narrow-band radiometer.
Although these results represent only a cursory evaluation of the nethod, they do call attention to certain practical problems that must be considered in its application.

## VI. Extension to More General Operating Conditions

In the preceding analysis, a number of simplifying approximations were introduced. These will now be examined in greater detail.
The theory can be easily generalized to account for arbitrary impedance conditions ( $S_{22} \neq 0$, etc.) at the output port. In order to retain the terminal-invariant character of $G$, it is redefined as the ratio of the net power delivered (to the amplifier input) to the available power at the output port. (That is, the definition that follows (7) should contain the factor ( $\left.1-\left|S_{22}\right|^{2}\right)^{-3}$ ). The right-hand side of (12) and (13) should be nultiplied by $\left(1-\left|\Gamma_{i}^{\prime}\right|^{2}\right)$ where

$$
\begin{equation*}
\left|\Gamma_{i}^{\prime}\right|=\left|\frac{\Gamma_{1}-S_{2-}^{*}}{1-S_{22} \Gamma_{l}}\right| \tag{21}
\end{equation*}
$$

and $\Gamma_{l}$ is the reflection coofficient of the terminating load. The same is true of ( $\bar{\sigma}$ ), provided that $T_{0}$ is associated with the "delivered" noise power as contristed

$$
\begin{align*}
T_{a} b & =\frac{\left(T_{o M}-T_{o m}\right)\left(T_{o h}-T_{o c}\right)}{4\left|\Gamma_{o}^{\prime}\right| \beta \mid\left(T_{o h}-T_{o c}\right)}  \tag{23}\\
T_{o} & =\frac{T_{o h}-\left(T_{o h} / T_{o c}\right) T_{o c}}{\left(T_{o s} / T_{o c}\right)-1}-|\beta|^{2} T_{a} b . \tag{24}
\end{align*}
$$

By a proper choice of $\left|\Gamma_{0}^{\prime}\right|$ it should be possible to avoid the nonlinear operating region noted earlier. On the other hand, the realization of the required noise source, for which the argument of $\Gamma_{0}^{\prime}$ is adjustable without changing its magnitude, is somewhat more of a problem. One possible solution is to add a tuning transformer to the amplifier input terminals and adjust for an impedance match. To the extent that it may be considered lossless, the presence of this transformer will not affect "the values of $T_{a}, b$, and $|\beta|$. For the tuned amplifier, $S_{11}=0$ and $\Gamma_{0}^{\prime}=\Gamma_{8}$. An adjustable generator (at ambient temperature) is now conveniently provided by a matched attenuator followed by a sliding short.
At this point it is possible to consider the tuner either as part of the amplifier or part of the adjustable noise generator. The former interpretation is convenient when the tuner losses are ncgligible since the resulting impedance requircment on the "hot" and "cold" loads (required to complete the evaluation of $T_{a}, b,|\beta|$ ) is now that these are also matched. In the projected evaluation of cryogenic systems, however, these losses may not be negligible and further study is indicated.

## VII. Summary

An alternative method of characterizing amplifier noisc has been presented, which (assuming linearity) completely accounts for variations in source impedance and in which all the parameters have a simple physical meaning. With the exception of the argument of $\beta$, these
parameters are "terminal invariant." In addition, methods for mosasuring thesc terms have been described and an analysis, leading to optimum source impedance, presented.

The preliminary experimental evaluation suggests that the methods should prove of value in system optimization, although confirmation of this awaits further work.

In particular it appears that the method may be of real valuc in the evaluation of parametric- and masertype amplifiers, since hore there is somc reason to anticipate larger values of $b$ and $|\beta|$ than those reported above. On the other hand, in the case of the parametric amplifier at least, this expectation is scriously qualified by recognition that these devices typically exhibit a substantial sensitivity to changes in source impedance, and the region of linear operation may be difficult to establish.

The possible use of a moving short alone for the evaluation of maser noise has been previously suggested. From (7) it appears that it is indeed possible thus to detcrmine an upper limit to $T_{\mathrm{a}}$, provided that $G$ is known.

At the present, the most serious limitation to this description appears to be in the assumed amplifier linearity (in respect to changes in source impedance, not output versus input). However, if this method puts this aspect in better focus, even this may prove to be a contribution.

## Appendix

The measurement procedure outlined in Section III calls for the adjustment of the hot and cold load impedances to equal the complex conjugate of the amplifier input reflection coefficient $\Gamma_{a}$. In principle, this can be effected by measuring this impedance (by use of a slotted line, for example) and then using the impedance meter to rccognize when the hot and cold load impedances are the conjugate of this value. An alternative procedure follows.

Referring to Fig. 2 it is convenicnt to assume a system comprised of a directional coupler, tuning transformers ( $T_{x}, T_{v}$ ), load isolators, generator, and detector as shown.

Scattering equations can be written for this system as follows:

$$
\begin{align*}
& b_{1}=S_{11} a_{1}+S_{12} a_{2}+S_{13} a_{3}  \tag{25}\\
& b_{2}=S_{21} a_{1}+S_{22} a_{2}+S_{23} a_{3} . \tag{26}
\end{align*}
$$

The boundary conditions imposed by the different terminations are

$$
\begin{align*}
& a_{1}=b_{1} \Gamma_{d}  \tag{27}\\
& a_{2}=b_{2} \Gamma_{t}  \tag{28}\\
& a_{3}=b_{0}+b_{3} \Gamma_{n} \tag{29}
\end{align*}
$$

In the operation to follow, therc is no occasion to change

Fig. 2. Measurement system for recognizing conjugate impedance match.
either $\Gamma_{d}$ or $\Gamma_{0}$; thus there is no loss in generality ${ }^{7}$ in assuming $\Gamma_{d}=\Gamma_{g}=0$.

Combining these results with (25) and (26) leads to

$$
\begin{equation*}
b_{1}=b_{0} \frac{\left(S_{12} S_{23}-S_{13} S_{22}\right) \Gamma_{t}+S_{13}}{1-S_{22} \Gamma_{t}} . \tag{30}
\end{equation*}
$$

Next it is assumed that $T_{z}$ has been adjusted such that $b_{1}$ vanishes when port 2 is terminated by the load of interest $\left(\Gamma_{1}=\Gamma_{a}\right)$, and $T_{y}$ has been adjusted such that $\left|b_{1}\right|$ is constant in response to a moving short at port 2. The conditions imposed on the scattering parameters by these adjustments are, respectively,

$$
\begin{equation*}
S_{13}+\left(S_{12} S_{z 3}-S_{13} S_{22}\right) \Gamma_{\mathrm{a}}=0 \tag{31}
\end{equation*}
$$

and ${ }^{8}$

$$
\begin{equation*}
S_{13}+\left(S_{12} S_{23}-S_{1 \frac{1}{3}} S_{22}\right) S_{22}^{*}=0 \tag{32}
\end{equation*}
$$

By inspection,

$$
\begin{equation*}
S_{22}=\Gamma_{0}^{*} . \tag{33}
\end{equation*}
$$

Equation (26) may now be written

$$
\begin{equation*}
b_{2}=S_{23} b_{0}+\Gamma_{0}^{*} a_{3} \tag{34}
\end{equation*}
$$

or, stated in words, the equivalent generator that obtains at port 2 has the source reflection coefficient $\Gamma_{0}^{*}$. To obtain a termination with this reflection, it is only necessary to replace the generator on arm 3 by a passive load of the same impedancc. The purpose of the isolator on arm 3 is to minimize the requirement that this impedance be the same as for the generator and to avoid possible pulling effects with the short motion. The isolator on arm 1 avoids the requirement of a constant detector impedance with changes in power level.

Finally, the adjustment. of other impedances (e.g., the hot and cold loads) to equal this value may be effected by any of the procedures for recognizing the equality of two impedances.

[^11]
## Acknowlfedgment

The author expresses his appreciation to O. L. Patty and M. G. Arthur for providing the experimental results described.

# Thermal Noise from a Passive Linear Multiport 

DAVID F. WAIT

#### Abstract

The thermal noise from passive mulliports is discussed from fundamentals so thal it can be understood, measured. or calculaled by a microwave engincer. The multiports are assumed to have a uniform temperature, but with no restrictions on reciprocity or mismatch. The noise temperature, $T_{N}$, contrihuted hy such a multiporl is $T_{v}=A T$ where $T$ is its physical temperature and $A$ is its absorption coefficient. An approximate method of measuring $A$, and a method of measuring an $A$ as small as 0.008 within 5 percent, are pointed out. Also, exact and approximale expressions for $A$ in terms of scallering matrix elements and termination reflection coefficients are derived. Finally, the crosscorrelation of the noise from different ports is briefly considered.

## I. Introduction

MORE TIIAN 40 percent of the noise in low-noise communication systems and 95 percent of the noise in low-noise radio astronomy receivers is due to "black body" radiation from passive linear clements. Likewise, this type of noise accounts for most of the noise in a Blum radiometer [1], [2] used at the National Bureau of Standards to compare cryogenic noisc sources [3].

The literature on the subject of noise is very extensive. Some of it applies to the problem of describing the noise from multiports like those used in modern low-noise communications and measuring systems [4]-[7]. But if one wants to determine how much of the noise power a threeport switchable circulator,' or a four-port hybrid tee, or other multiport element contributes to the systeni noise, the literature is sometimes inconvenient to use, especially if the elements used to terminate the multiport are mismatched. This inconvenience may be due to unfamiliar mathematical language, but more likely, it is because a conversion is required to reexpress the results in more useful terms. What is useful depends on the details of the system involved. Thus, a laboratory measurement of the scattering matrix parameters might prove helpful in estimating the noise contributed from a circulator, but relatively uscless in estimating the noise contribution from a hybrid tee.
This paper will discuss the thermal noise from passive linear multiports in various terms that might be useful to a microwave engincer. The results are derived from fundamentals to make them more understandable. An exception is the discussion of the correlation of noise from difierent ports where the results can be obtained from the literature with little difficulty. Since a tractable extension to mismeitched multiporss is not known, this is not belabored.

[^12]In Section II, junctions with uniform physical temperature are considered. For them, the noise contribution is directly proportional to their physical temperature. The constant of proportionality is referred to as the absorption coefficient which may either be measured (Section III) or calculated (Section IV). The calculated form is stated in terms of scattering matrix elements and reflection coefficients of the port terminations. In Section V, the correlation of noise from different ports is discussed. Multiports with almost reflectionless terminations are treated in Section VI. In Section VII, the absorption coefficient is related to loss concepts known for two-ports. Conclusions are given in Section VIII.

## II. The Noise Temperature of a Passive Multiport

Neglecting quantum effects, the power $P$ available in each waveguide mode from a thermal source at a uniform temperature $T$ is $P=k T B$. where $k$ is Boltzman's constant and $B$ is the bandwidth. Thus, the available power per unit bandwidth (available power spectral density) may be expressed as a temperature, and conversely, a temperature can be used to express an available power spectral density. In a somewhat similar way the available noise from a "passive" multiport is described. Specifically, if all ports of a multiport are terminated with loads at the absolute zero of temperature, while the multiport itself is at a different temperature, then the radiation emerging from any port is due only to thermal sources within the multiport. The acailable noise power spectral density ${ }^{2}$ at, say. port $i$ expressed as a temperature is known as the noise temperature of the multiport at port $i$. Thus defined, the value of the noise temperature depends on which port is being considered and also upon the retlection coefficients of the other port terminations. i.e., the reflection coefficient "looking" out of the multiport.

A multiport with independent port generators is shown in Fig. 1. Because the sources are independent (thus uncorrelated) they each make an additive contribution to the total available output of port $i$, so

$$
\begin{equation*}
T_{\text {total. } \mathrm{i}}=\sum_{j \neq i} \alpha_{1,} T_{j}+T_{N_{-1}} \tag{1}
\end{equation*}
$$

where $T_{j}$ is the available power spectral density of the $j$ th generator at its own output port and $T_{Y_{i, i}}$ is the remaining contribution due to the ihermal sources within the multiport itself. The proportionalit! fictor $\alpha_{1,}$ is the ratio of the power spectral density available out of port $i$ to the power spectral density available from the generator on port $j$ when only the

[^13]

Fig. 1. A multiport with independent thermal noise generators.
generator $j$ has nonzero amplitude. The proportionality factors $\alpha_{i j}$ depend on the reflection coefficients of the other port terminations. It should be intuitively obvious that $\alpha_{1 j}$ is also equal to the ratio of available power out of port $i$ to the available power from the generator on port $j$ when a CW source is used on port $j .{ }^{3}$ Thus $\alpha_{1 j}$ will be referred to as the available power ratio. The noise temperature of the multiport $T_{x_{, i} \text { is }}$ a characteristic of the multiport and the reflection coefficients of its terminations but independent of the amplitudes of the port generators.

To determine $T_{N . i}$, consider the multiport when it is in thermal equilibrium with all its port generators at temperature $T$. Then from the second law of thermodynamics, $T_{\text {totat,i }}$ as well as all the $T_{n}$ 's must equal $T$. Thus

$$
\begin{equation*}
T_{N, i}=A_{i} T \tag{2}
\end{equation*}
$$

where

$$
\begin{equation*}
A_{i} \equiv\left\{1-\sum_{j \neq 1} \alpha_{i j}\right\} \tag{3}
\end{equation*}
$$

The constant $A_{i}$ is here called the absorption coefficient for port $i$ of the multiport. For a two-port. (1) reduces to the form given by Daywitt [10]: $T_{\text {total }}=\alpha T_{s}+(1-\alpha) T$, where $\alpha$ is the ratio of available power at the output to the available power at the input, and $T_{s}$ is the temperature of the source.

## IIl. Measurement of the Absorption Coefficient

The losses within a junction can change the power available at the output port, and the anrount of the change can be used to determine the absorption loss. For example, if the junction is lossless and each port of the junction is terminated by a noise generator with the noise tenperature $T_{y,}$, then the output from the junction $T_{\text {tutal, }}$ would be $T_{0}$. But if the junction has a nonzero absorption coefficient $A_{i}$, then from Section 11 the difference between $T_{\text {, and }} T_{\text {total., }}$ is

$$
\begin{equation*}
T_{0}-T_{\text {total. }, ~}=A_{1}\left(T_{g}-T\right) \tag{4}
\end{equation*}
$$

[^14]where $T$ is the physical temperature of the junction. Thus to measure $A_{t}$, one needs to adjust a set of noise generators ${ }^{4}$ to have the same known noise temperature $T_{g}$, attach them to the ports of the junction to be measured, and then measure the available power spectral density [11], $T_{\text {tutal.i }}$ from the output port. Because the absorption coefficient depends upon the reflection coefficients of the port terminations, the noise generators used in the measurements must have the appropriate reflection coefficients.

If the reflection coefficients are less than one tenth, then the small difference of ( $T_{a}-T_{\text {total, } i}$ ) can be measured within $2^{\circ} \mathrm{K}$ when $T_{n}$ is $10800^{\circ} \mathrm{K}[8]$ and $\left(T_{g}-T\right)$ can be known to 2.5 percent [12]. Thus $A_{i}$ as small as 0.008 (a two-port loss of 0.03 dB ) may be measured within 5 percent.

In case only an approximate measure of absorption coefficient is needed, a simpler measurement will suffice. For example, consider the problem of determining the approximate thermal contribution of a two-port placed between an antenna and a low-noise receiver as shown in Fig. 2. The two-port might be a directional coupler terminated with a gas tube which, when fired, adds a known amount of noise to the system for calibration purposes. When the tube is off, the terminated directional coupler may be treated as a twoport at uniform temperature.

For small $A_{i}$ and $T_{0} \gg T$, (4) becomes

$$
\begin{equation*}
A_{i} \simeq 0.230 \Delta P_{\mathrm{dB}}\left(1+T / T_{g}\right) \tag{5}
\end{equation*}
$$

where $\Delta P_{\mathrm{dB}}$ is the relative change in available power expressed in decibels when the two-port is inserted into the system.

Ignoring the receiver noise, $\Delta P_{\mathrm{dB}}$ can be determined by measuring the relative change in power when a noise source feeds the receiver directly (from reference plane 1 in Fig. 2) compared with when a source with the same noise temperature feeds the receiver through the two-port (from reference plane 2). The noise sources used must have the same reflection coefficients, amplitude, and phase as the circuit they replace ${ }^{5}$ ( $\bar{\Gamma}_{1}$ and $\Gamma_{2}$, respectively) so that the same fraction of the available power is delivered to the receiver for both parts of the measurement.

The precision of measuring $\triangle P_{a B}$ depends on the precision of the readout of the receiver, on the stability and resolution of the receiver, on the noise temperature of the receiver, and on the relative accuracy of the noise sources. If a single noise source with adjustable reflection coefficient. like that shown in Fig. 3, is used for both parts of the measurement, the change in noise temperature due to the change in tuner losses is typically less than 0.15 percent at $X$-band for reflection coefficients in the range of zero to 0.3 [14]. The error due to neglecting the receiver noise is on the order of $\left(A_{1} T_{\text {rea }} T_{v}\right)$, where $T_{\text {rec }}$ is the receiver noise temperature.
"An "internal" attenuator is the usual way to modify the noise temperature of a noise source.
${ }^{3}$ A smple proedure for adjusting the reflection coefficient of one circuit to be equal in amplitude and phase to another is described by Engen [13].

Fig. 2. A receiving system with a two-port between the antenna and the low-noise receiver.

Fig. 3. An adjustable reffection coefficient noise source. If necessary, the noise temperature of the source is reduced by the level set attenuator so that the source does not saturate the receiving system.

## IV. Calcllation of the Absorption Coefficient

At times it is useful to know the relationship between the absorption coefficient and the parameters that describe the multiport and its terminations. To do this, the available power ratios $\alpha_{1 j}$ are first expressed in terms of the scattering matrix elements of the multiport and the reflection coefficients of the port terminations, and then the absorption coefficient is obtained using (3).

The available power ratio will be calculated as the ratio of the CW power available at port $i, P_{\mathrm{b}}{ }^{\text {avaii }}$, to the CW power available from the generator on port $j, P_{a j}{ }^{\text {avail }}$.

$$
\begin{equation*}
\alpha_{i j}=P_{b i^{\text {avail }} / P_{a j}{ }^{\text {ava il }} .} \tag{6}
\end{equation*}
$$

The power available from port $i$ expressed in terms of the equivalent "generator" wave ${ }^{6}$ amplitude $\hat{b}_{i}$ is [16]

$$
\begin{equation*}
P_{b_{\mathrm{a}}}^{\text {avail }}=\left|b_{i}\right|^{2} /\left(1-\left|\hat{\Gamma}_{i}\right|^{2}\right) \tag{7}
\end{equation*}
$$

whare $\Gamma_{i}$ is the reflection coefficient "looking" into port $i$. Similarly, the power available from the generator in terr" of its "generator" wave amplitude $\vec{a}_{j}$ is

$$
\begin{equation*}
P_{a}{ }^{\text {avail }}=\left|\hat{a}_{j}\right|^{2} /\left(1-\left|\Gamma_{j}\right|^{2}\right) \tag{8}
\end{equation*}
$$

where $\Gamma_{j}$ is the reflection coeffieient of the generator. The relationship between $\hat{b}_{\imath}$ and $\hat{a}_{j}$ can be established by matrix techniques (see the Appendix). A compact and convenient expression of this relationship is

$$
\begin{equation*}
b_{i}=\left\{D_{(i S j)} / D_{(i i)}\right\} \hat{a}_{j} \tag{9}
\end{equation*}
$$

where $D_{\left(i S_{j}\right)}$ is the determinant of the matrix $(1-S \Gamma)$ when its $i$ th column is replaced by the $j$ th column of scattering matrix $S, \mathbf{\Gamma}$ is the diagonal matrix with elements ( $\mathbf{\Gamma}$ ) ic equal $^{\text {equ }}$ to the reflection coefficient of the load on port $i$. and $D_{(i i)}$ is the determinant of $(1-S \Gamma)$ when its $i$ th row and column are

[^15]deleted. Thus for $i \neq j$
\[

$$
\begin{equation*}
\alpha_{i j}=\frac{\left(1-\left|\Gamma_{,}\right|^{2}\right)}{\left(1-\left|\Gamma_{\imath}\right|^{2}\right)} \frac{\mid D_{\left.(i S j)\right|^{2}}}{\left|D_{(w)}\right|^{2}} \tag{10}
\end{equation*}
$$

\]

so that

$$
\begin{equation*}
A_{i}=1-\sum_{k \neq i} \frac{\left(1-\left|\Gamma_{k}\right|^{2}\right)\left|D_{(i S k)}\right|^{2}}{\left(1-\left|\hat{\Gamma}_{i}\right|^{2}\right)\left|D_{(i i)}\right|^{2}} \tag{11}
\end{equation*}
$$

For example, for the three-port, ${ }^{7}$

$$
\begin{gather*}
D_{\left(i, S_{j}\right)}=\left|\begin{array}{cc}
S_{i j} & -S_{\imath k} \Gamma_{k} \\
S_{k j} & \left(1-S_{k k} \Gamma_{k}\right)
\end{array}\right|  \tag{12}\\
D_{(i i)}=\left|\begin{array}{cc}
\left(1-S_{j j} \Gamma_{j}\right) & -S_{j k} \Gamma_{k} \\
-S_{k j} \Gamma_{j} & \left(1-S_{k k} \Gamma_{k}\right)
\end{array}\right| \tag{13}
\end{gather*}
$$

and

$$
\hat{\Gamma}_{\imath}=\left[D_{(i i)}\right]^{-1}\left|\begin{array}{ccc}
S_{11} & -S_{i j} \Gamma_{j} & -S_{i k} \Gamma_{k}  \tag{14}\\
S_{\mu 1} & \left(1-S_{ر,} \Gamma_{j}\right) & -S_{j k} \Gamma_{k} \\
S_{k i} & -S_{k j} \Gamma_{j} & \left(1-S_{k k} \Gamma_{k}\right)
\end{array}\right|
$$

## V. Crosscorrelations for the Matched Mlltiport

In some applications it is interesting to know if the internal junction noise emitted from one port is crosscorrelated to the noise emitted at another port. A measure of crosscorrelation is the time average of the product of the time dependent voltages. However, the anaiysis of this paper is entirely in the frequency domain. In the frequency domain, the Fourier transform of the crosscorrelation is appropriate, namely, the cross-spectral density $W_{i j}$ [17].

$$
\begin{equation*}
W_{i j}=\frac{1}{2}\left\{\left\langle n_{\mathrm{v}} n_{j}{ }^{*}\right\rangle_{\mathrm{av}}+\left\langle n_{\mathrm{s}}^{*} n_{j}\right\rangle_{\mathrm{av}}\right\} \tag{15}
\end{equation*}
$$

where < $\rangle_{\text {av }}$ denotes the ensemble average and the asterisk denotes the complex conjugate. If $n_{1}$ and $n_{j}$ are the voltages from port $i$ and port $j$, respectively, of the generator waves due to the noise sources within a matched multiport, then [5]

$$
\begin{equation*}
\left\langle n_{i} n_{j}^{*}\right\rangle_{\mathrm{av}}=N_{\mathrm{i} j} T \tag{16}
\end{equation*}
$$

where $T$ is the physical temperature of the multiport and $N_{i j}$ is an element of

$$
\begin{equation*}
N \equiv 1-\mathrm{SS} \dagger \tag{17}
\end{equation*}
$$

where the dagger indicates the Hermitian conjugate (transpose. complex conjugate). Bosma [5] refers to $N$ as the noisc distribution matrix. For the matched multiport, a "generator" wave is the same as the emergent wave.

The special case of $i=j$ may also be obtained from (2) and (11) by setting all $\Gamma$ 's equal to zero, that is

$$
\begin{equation*}
\left\langle n_{1} n_{i}^{*}\right\rangle_{\mathrm{nv}}=\left(1-\left|\hat{\Gamma}_{i}\right|^{2}\right) T_{N, i}=\left\{1-\sum_{k} S_{i h} S_{\mathrm{ik}}^{*}\right\} T \tag{18}
\end{equation*}
$$

[^16]An interesting special case is the two-port

$$
\begin{equation*}
\left\langle n_{1} n_{2}^{*}\right)_{\mathrm{av}}=-\left(S_{11} S_{21}{ }^{*}+S_{12} S_{22}{ }^{*}\right) \eta^{\prime} \tag{19}
\end{equation*}
$$

Thus, if the two-port is matched to rcllectionless loads so that $S_{12}$ and $S_{22}$ are zero, then there is no correlation ${ }^{5}$ in the thermal noise emitted out the two ports.

## Vi. Multiports with Low-Reflection Port Terminations

In many situations the port terminations have small reflection coefficicnts. For this situation, the results of Section 111 simplify. In particular, neglecting the squares of the reflection coefficients [15],

$$
\begin{equation*}
D_{(i S j)} / D_{(i i)} \simeq S_{i j}+\sum_{m \neq i} S_{i m} \Gamma_{m} S_{m j} \tag{20}
\end{equation*}
$$

If in addition $\left|\hat{\Gamma}_{i}\right|^{2}$ is negligible, then the absorption coefficient simplifies to

$$
\begin{equation*}
A_{i} \simeq A_{1}{ }^{0}+\epsilon_{1} \tag{21}
\end{equation*}
$$

where $A_{i}{ }^{0}$ is the absorption coefficient of the junction when all $\Gamma$ ' $s=0$ and

$$
\begin{equation*}
\epsilon_{i}=\sum_{m \neq i}\left(S_{i m} \Gamma_{m 2} N_{m i}+S_{1 m} * \Gamma_{m}{ }^{*} N_{m 2}{ }^{*}\right) \tag{22}
\end{equation*}
$$

where $N_{m i}$ are defined in (17). If the elements $N_{m i}$ are not known, then it is of interest to detcrmine an upper limit for the magnitude of the $N_{i j}$ 's. From the definition of $N_{i j}$ in (17) it is clear that

$$
\begin{equation*}
N_{i j}=N_{j 2}{ }^{*} \tag{23}
\end{equation*}
$$

Because $N \equiv(1-S S \dagger)$ is a positive semidcfinite matrix for a passive multiport [5], [16], then [18]

$$
\begin{equation*}
\left|N_{i j}\right|^{2} \leqq N_{i i} N_{j j} . \tag{24}
\end{equation*}
$$

This in turn implies

$$
\begin{equation*}
N_{i j}+N_{j i} \leq N_{i i}+N_{j j} \tag{2.5}
\end{equation*}
$$

The diagonal elements of $N$ are directly related to the absorption coefficients of the multiport, viz.,

$$
\begin{equation*}
N_{i i}=\left(1-\left|S_{i t}\right|^{2}\right) A_{i}{ }^{0} \tag{26}
\end{equation*}
$$

where $A_{1}{ }^{0}$ is defined in (21). Thus, because $\sum_{m}\left|S_{\mathrm{im}}\right|^{2} \leq 1$ and all $\left|\Gamma_{m}\right|^{2}$ and $A_{1}{ }^{0}$ arc less than some maximums $\left|\Gamma_{\text {max }}\right|$ and $A_{\text {max }}{ }^{0}$, then

$$
\begin{equation*}
\left|\epsilon_{2}\right|<2(n-1)^{\frac{1}{2}} A_{\max }{ }^{0}\left|\Gamma_{\max }\right| \tag{27}
\end{equation*}
$$

where $n$ is the number of ports.

## Vil. The Absorpition Coffricievit as a Loss

Many types of losses have been distinguished in the literature. Among those deseribed by Beatty [19], the absorption cocflicient is related most nearly to dissipative

[^17]loss $L_{D}=-10 \log _{10} \eta$ (in decibels), where $\eta$ is the efficiency. The absorption coefficient exprcssed in decibels, i.e., absorptive loss, would be $\left(A_{j i}\right)_{\mathrm{dB}}=-10 \log _{11} \alpha_{i j}$. Efficiency is a ratio of delivered powers in the same way that $\alpha_{i j}$ is the ratio of available powers. The efficiency and the available power ratio are related in the following way.
\[

$$
\begin{equation*}
\alpha_{i j}=\left(M_{j} / M_{i}\right) \eta \tag{28}
\end{equation*}
$$

\]

where $M_{i}$ and $M_{j}$ are the mismatch factors of the $i$ th and $j$ th ports, respectively. ${ }^{9}$ Thus, if both ports are conjugate matched [16], dissipative loss and absorptive loss are indistinguishable. Otherwise, dissipative loss is a loss that depends on the output load impedance, but independent of the input generator impedance, while absorptive loss is a loss that depends on the input generator impedance, but is independent of the output load impedance.

## VIII. Conclusions

The noise from the thermal sources within a multiport element is equal to the absorption coefficient of the element, times the physical temperature of the element. The absorption coefficient may be measured or calculated. The calculated absorption coefficient is simply the sum of the available power ratios from all ports to the output port. In turn, the available power ratios are expressible in terms of scattering matrix elements and reflection coefficients. Only linearity was assumed: no restrictions on reciprocity, symmetry, loss, or condition of match are needed.
The corrclation of the junction noise emitted from different ports when the junction has reflectionless terminations depends on the appropriate matrix elements of $N \equiv 1-S S \dagger$ and the junction temperature. When all ports of the junction have nearly reflectionless terminations, the expression for the absorption coefficient greatly simplifies, and a limit of error can be established if the port reflections are merely ignored.

## Appendix <br> Equivalent Wave Generators

The mathematics and the notation in this appendix have been influenced by Nemoto. Further detals and interpietation of the concepts introduced here are discussed elsewhere [15].

A multiport is described by a scattering matrix that relates the emerging waves $b_{\text {, }}$ to the incident waves $a_{i}$.

$$
\begin{equation*}
b=S a \tag{29}
\end{equation*}
$$

The boundary conditions imposed by terminating cach port with a load or a generator is described by

$$
\begin{equation*}
a=\hat{a}+\Gamma b \tag{30}
\end{equation*}
$$

where $\hat{a}_{i}$ is a gencrator wave, that is, a wave a generator would deliver to a reflectionkess load, and $\Gamma$ is a diagonal matrix whose diagonal elements are the rellection coeflicients

[^18]looking out of the multiport. The generator wave $\hat{a}_{i}$ characterizes the gencrator on port $i$ in the sense that its amplitude depends only on the output of the generator and that it is independent of the load that terminates the generator. Eliminating a between (29) and (30),
\[

$$
\begin{equation*}
b=\text { Sá } \tag{31}
\end{equation*}
$$

\]

where

$$
\begin{equation*}
\boldsymbol{S} \equiv(1-S \Gamma)^{-1} S \tag{32}
\end{equation*}
$$

Because a matrix clement of a product $C=A^{-1} B$, where $A$ and $B$ are square and have the same dimension, is $C_{i j}=\operatorname{det} \boldsymbol{A}_{(i B j)} / \operatorname{det} \boldsymbol{A}$, where det $\boldsymbol{A}_{(1 B j)}$ is the determinant of $A$ after the $i$ th column of $A$ has been replaced by the $j$ th coiumn of $B$;

$$
\begin{equation*}
s_{i j}=D_{(i S j)} / D \tag{33}
\end{equation*}
$$

where $D$ stands for the det ( $1-S \Gamma$ ).
In the same way that the inputs $a_{i}$ were each divided into a generator wave plus a rellected wave, the outputs $b_{i}$ can be divided into an equivalent generator wave plus a rellected wave.

$$
\begin{equation*}
b=\hat{b}+\hat{\Gamma} a \tag{34}
\end{equation*}
$$

where $\hat{\boldsymbol{\Gamma}}$ is a diagonal matrix whose elements are the reflection coefficients looking into the multiport.

Eliminating $b$ from (31) using (30) and (34),

$$
\begin{equation*}
b=G \hat{a} \tag{3̄}
\end{equation*}
$$

where one form for $G$ is

$$
\begin{equation*}
G=\{(1-\Gamma \hat{\Gamma}) S-\hat{\Gamma}\} . \tag{36}
\end{equation*}
$$

From the nature of the definition of $\hat{b}$ and $\hat{a}$, the diagonal elements of $G$ must be zero. Setting the diagonal elements of (36) equal to zero and solving for $\hat{\Gamma}_{i}$ we obtain

$$
\begin{equation*}
\hat{\Gamma}_{i}=D_{\langle 1 S i)} / D_{\langle i \mathrm{i}\rangle} \tag{37}
\end{equation*}
$$

where $D_{(i i)}$ is the detcrminant of $(1-S \Gamma)$ after the $i$ th row and $i$ th column have been deleted.

Again looking at a diagonal element of (36) and solving for ( $1-\Gamma_{1} \hat{\Gamma}_{i}$ ), replacing the remaining $\hat{\Gamma}_{i}$ by (37), we obtain

$$
\begin{equation*}
D=\left(1-\Gamma_{i} \hat{\Gamma}_{i}\right) D_{(i \mathrm{i})} \tag{38}
\end{equation*}
$$

An off diagonal element of (36) is

$$
\begin{equation*}
G_{i j}=\left(1-\Gamma_{\imath} \hat{\Gamma}_{\imath}\right) D_{\left(\imath S_{j}\right)} / D . \tag{39}
\end{equation*}
$$

Using (38) we obtain

$$
\begin{equation*}
G_{1 j}=D_{(i S j)} / D_{(i i)} . \tag{40}
\end{equation*}
$$

To obtain (9), $\hat{b}_{i}$ is obtained from (40) and (35) for the calse when only the $j$ th generator, and thus only the jth gencrator wave $\hat{a}_{j}$ is nonzero.

15. SUPPLEMENTARY NOTES
16. ABSTRACT (A 200-word or less factual summary of most significant information. If document includes a significant bibliography or literature survey, mention it here.)

For the best accuracy in measuring noise figure, attention needs to be given to the choice of the hot and the cold noise standards and to mismatch problems. Tables and graphs are presented to aid in choosing the proper measurement conditions, and an example is given to demonstrate their use. This paper essentially supplements a previous paper (included in an appendix), treating in more detail topics that become important when state-of-the-art measurements are required.

## PERIOOICALS

JOURNAL OF RESEARCH reports National Burcau of Standards research and development in physics, mathematics. and chemistry. Conprehensive scientific papers give complete details of the work. including laboratory data, experimental procrdures. and theoretical and mathematical analveses. Illustrated with photographs, drawings, and charts. Includes listings of other NBS papers as issued.

Published in two sections, azailable separately:

## - Physics and Chemistry (Section A)

Papers of interest primarily to scientists working in these fields. This section covers a broad range of physical and chemical research, with major eniphanis on standards of physical measurement, fundamental constants, and propertics of matter. Issued six times a year. Annual subscription: Domestic, $\$ 17.00$; Foreign, $\$ 21.25$.

## - Mathematical Sciences (Section B)

Studies and compilations designed mainly for the mathematician and theoretical physicist. Topics in mathematical statistics, theory of experiment design. numerical analysis, theoretical physics and chemistry, logical design and programming of computers and computer systems. Short numerical tables. Issued quarterly. Annual subscription: Domestic, $\$ 9.00$; Foreign. \$11.25.

## TECHNICAL NEWS BULLETIN

The best single source of information concerning the Bureau's measurement, research, developmental, cooperative, and publication activities, this monthly publication is designed for the industry-oriented individual whose daily work involves intimate contact with science and technology-for engineers, chemists, physicists, research managers, product-development managers, and company executives. Includes listing of all NBS papers as issued. Annual subscription: Domestic, $\$ 6.50$; Foreign, $\$ 8.25$.

## hORPERIOOICALS

Applied Mathematics Series. Mathematical tables. manuals, and studics.
Building Science Series. Research results, test methods. and performance criteria of building matrials, components, systrms. and structures.
Handbooks. Recommendecl codes of engincering and industral prancice including safety codes) developed in conperation with interested industrics, professional organizations, and regulatory bodies.
Special Publications. Proccedings of NBS conferences, bibliographies, annual reports, wall charts, pamphlets, etc.
Monographs. Major contrihutions to the technical literature on various subjects related to the Burcau's scientific and technical activities.
National Standard Reference Data Series. NSRDS provides quantitative data on the physical and chemical properties of materials, compiled from the world's literature and critically evaluated.
Product Standards. Provide requirements for sizes, types, quality, and methods for testing various industrial products. These standards are developed cooperatively with interested Government and industry groups and provide the basis for common understanding of product characteristics for both buyers and sellers. Their use is voluntary.
Technical Notes. This series consists of communications and reports covering both other-agenc! and NBS-sponsorcd unok) of limited or transitory interest.

## Federal Information Processing Standards

 Publications. This series is the official puhlication within the Federal Government for information on standards adopted and promulgated under the Publir Law 89-306. and Bureau of the Budget Circular A-86 entitled, Standardization of Data Elements and Codes in Data Systems.Consumer Information Series. Practical information, hased on NBS research and experience. covering areas of interest to the consumer. Easily understandable language and illustrations provide useful background knowledge for shopping in today's technological marketplace.

## BIBLIOGRAPHIC SUBSCRIPTION SERVICES

## The following current-awareness and literature-survey bibliographies are issued periodically by the Bureau:

Cryogenic Data Center Current Awareness Service (Publications and Reports of Interest in Cryogenics) A literature survey issued weekly. Annual subscription: Domestic, $\$ 20.00$; foreign, $\$ 25.00$.

Liquefied Natural Gas. A literature survey issued quarterly. Annual subscription: $\$ 20.00$.
Superconducting Devices and Materials. A literature survey issued quatterly, Annual subscription: $\$ 2000$. Send subscription orders and remittances for the preceding bibliographic services to the U.S. Department of Commerce, National Technical Information Service, Springfield, Va. 22151.
Electromagnetic Metrology Current Awareness Service (Abstracts of Selected Articles on Mfeasurement Techniques and Standards of Electromagnetic Quantities from D-C to Millimeter-Wave Frequencies). Issued monthly. Annual subscription: $\$ 100.00$ (Special rates for multi-subscriptions . Send subscription order and remittance to the Electromagnetic Metrology Information Center. Electromagnetics Division, National Burcau of Standards, Boulder, Colo. 80302

Order NBS publications (cxecpt Bibliographic Subscription Services) from: Superintendent of Documents. Govermment Printing Office. Washington, D.C. 20402.

## U.S. DEPARTMENT OF COMMERCE National Bureau of Standards

[^0]:    ${ }^{2}$ Headquarters and Laboratories at Gaithersburg. Maryland, unless otherwise noted; mailing address Washinglon, D.C. 20234.

    ${ }^{3}$ Located at Boulder. Colorado 80302.

    - Part of the Center for Building Technology.

[^1]:    *Frequency coverage for the NBS 14 mm coaxial source is d.c. to 1.2 GHz , for WR284 is 2.60 to 3.95 GHz , for WR90 is 8.2 to 12.4 GHz , for WR62 is 11.9 to 18.0 GHz , and for WR15 is 50 to 75 GHz .

[^2]:    *From Cohn [4] average amplitude/saturation amplitude is approximately equal to 0.07 for $0.1 \%$ clipping in a square law detector. Bolometer-power bridges work accurately up to 10 mw of power so this suggests > 147 mw saturation level. This hard limiting model is not easy to interpret for real amplifiers. From our experience, 1 dB compression at 100 mw is adequate to keep clipping correction to less than $0.1 \%$. For other discussions of the effects of clipping see Deutsch and Hance [5], Bell [6], Van Vleck and Middleton [7].

[^3]:    *Copies of these papers are in Appendix E.

[^4]:    This paper is a contribution of the National Bureau of Standards not subjec: to copyright

[^5]:    - "Effective Input Noise Temperature, Average $T_{e}$ fof a multiport transducer with one port designated as the output port). The noise temperature ni degrees Kelven which, assigned simultaneously to the specified impedance terminations at all frequencies at all accessiole ports except the designated output port of a noisefree equivalent of the iransducer, would vield the same total noise power in a specified output band delivered to the output termination as that of the actual transoucer connected to noisefree equivalents of the terminations at all ports except the output port." 13
    * The noise temperature of a noise source is defined to be the physical temperature of a blackbody radiator which has the same available power density as the nolse sousce lat the frequency in question).

[^6]:    Manuscript received June 4, 1970.
    The author is with the National Bureau of Standards, Bouder, Colo.

[^7]:    ${ }^{1}$ If $S_{13}=0$, the term $S_{21}$ is only of interest in attempting to optimize the coupling between the amplifier and the system that
    follows it.

[^8]:    ${ }^{3}$ This transformation has the following properties: 1) $\Gamma_{0}{ }^{\prime}=0$ when the conditions for minvimum power (ransfer are satisfied $\left.\left(\Gamma_{a}=S_{1 t^{\prime \prime}}\right), 2\right)!\Gamma_{q^{\prime}} \mid=1$ when $\left|\Gamma_{q}\right|=1,3$ ) the value of $\left|\Gamma_{a^{\prime}}\right|$ is "invariant" to the chnice of terminal surface between generator and amplifier, provided that this choice is limited to a lusiless region. For a more complete discussion, see |6|.
    ${ }^{3}$ Although the functional for:n of this equation is equivalent to that obtained by a number of earlier authors, it is important to recognize the following distinctions. 1) The emphasis is on noise temperatures instead of nowe flurures. 2) In addum in "charac:terizing the rapidty with which $T_{0}$ oincreines; above $T_{o} G$ is $\Gamma_{0}{ }^{\prime}$ departs from $\beta$," the tern $b$ is ulsh the ratio belween the unise temperature of the input port and 7 a . 3) The complete dependence upon source impedance is contained in the smgle tern $\mathrm{I}^{\circ}{ }^{\circ} \cdot 4$, The behavior with either power matching or noise matching is immedis : • Iv evifent from inspection.

[^9]:    - This is the available noise power (per cycle of bandwidth) from the input terminals expressed as a temperature.
    - In obtaining this result it is helpful to note that

    $$
    \left(1-\left|\Gamma_{a}^{\prime}\right|^{2}\right)=\frac{\left(1-\left|\Gamma_{0}\right|^{2}\right)\left(1-\left.\left|S_{0}\right|\right|^{2}\right)}{\left|1-S_{11}\right| \Gamma_{\theta} \mid} .
    $$

[^10]:    - The point of view adopted here is that there are many situations in which the applications engineer might bs willing to adjust the impedance matching bat urwilling to tachle the more ambitious problem of also adding inverse feedhack. For a discusion of this more general probirm, sue (1); see also, J. S. Engberc. "Simultaneous input power natch and nove optimization using ieedback," M.S. thesis, Syracuse L'niveroity, Syracuse, ©. Y., July 1969.

[^11]:    ${ }^{7}$ For a discussion of this point, see [7].
    ${ }^{8}$ See, for exsmple, [6].

[^12]:    Manuscript received Februally 2, 1968; revised May 9. 1068. This research was supported by the Advanced Research Promects deency of
    

    The author is with the Notwial Buresu ol Standatls. Boulder. Colo. 80302
    ${ }^{1}$ The elfect of the lime deperadence of the mose on system semblivity is Ircated by [8].

[^13]:    ${ }^{2}$ The avaitable noise power speetral density is detined as the maximum nomse power spectral densily dat could be delaced to a load. The creait will delaer the maxmmen power when the lowd has the proper retlection coethemen. No mampulation of the rellechon cocibicient of any of the port genceators is implied.

[^14]:    ${ }^{2}$ The rigorous mathematical proof that the value $\kappa_{s j}$ is the sane for noise as the CW signals is beyond the scope of thes paper. The toundalions for such a proof are in Middleton [y]. however. the route to the proof may be more obvious from the appendices of the paper by the author [8].

[^15]:    0 The "generator" wave amplitude is defined as the amplitude the generator would deliver to a reflectionless load [15], [16]. Jn this paper. a basis has been chosen so that the characteristic impedance $Z_{i i}$ associated with a port $i$ will not be expressed explicitly. For those who wish an'explicit statement. each voltage such as $a_{i}$ should be replaced by $a_{1} / \sqrt{\ell_{0}}$, and each scattering matrix element $S_{3}$; should be replaced by $\sqrt{ } Z_{0,} S_{i j} / \sqrt{ } Z_{o,}$.

[^16]:    ${ }^{7}$ When actually writing out $D_{4,5, j}$. one should take advantage of the property that $D_{t i s, s}$ is unchanged when the jth row and column of the deterninant are deleted. This property is expressed by $D_{(1,5)\rangle}=D_{(i S \beta)(j,)}$.

[^17]:    ${ }^{3}$ One should remernher that zero correlation does not imply that the signals are unrelated. f or wample. For the relinted signals $n_{1}=r+y$
     - 'yy** iav zero when the power speciral density in $x$ equals $y$. If the spectral densinces of $x$ and 1 are weal at all Irequencies. then $n$ and $n$ are uncorrelated. This promiple is used in the Blum radioneter [1]. [2].

[^18]:    ${ }^{9}$ Mismatch factor is used here in accordance with Miller et al. [10].
     cient "looking" out of the nutliport and $[$ '. is the rellection coctliciont "looking" into the nultiport at reference plane $i$.
