Abstract

This Special Publication represents the work of researchers at professional conferences, as reported by NIST employees in Fiscal Year 2020 (October 1, 2019–September 30, 2020).

Keywords

NIST conference papers, NIST research, public access to NIST research.

Preface

NIST is committed to the idea that results of federally funded research are a valuable national resource and a strategic asset. To the extent feasible and consistent with law, agency mission, resource constraints, and U.S. national, homeland, and economic security, NIST will promote the deposit of scientific data arising from unclassified research and programs, funded wholly or in part by NIST, except for Standard Reference Data, free of charge in publicly accessible databases. Subject to the same conditions and constraints listed above, NIST also intends to make freely available to the public, in publicly accessible repositories, all peer-reviewed scholarly publications arising from unclassified research and programs funded wholly or in part by NIST.

This Special Publication represents the work of researchers at professional conferences, as reported in Fiscal Year 2020.

More information on public access to NIST research is available.

Table of Contents

Griffith, David W.; Ben Mosbah, Aziza. "On Upper Bounds for D2D Group Size." Paper presented at 2019 IEEE Global Communications Conference (GLOBECOM), Waikoloa, HI, US. December 09, 2019 - December 13, 2019. . . . . SP-1

Brubaker, Matthew; Spann, Bryan; Genter, Kristen; Roshko, Alexana; Blanchard, Paul; Harvey, Todd E.; Bertness, Kris A. "AlGaN/GaN core-shell heterostructures for nanowire UV LEDs." Paper presented at Nanowire Week, Hamilton, CA. June 11, 2018 - June 15, 2018. . . . . SP-7

Ng, Lisa; Kinser, Lindsey; Emmerich, Steven; Persily, Andrew K. "Estimating Interzonal Leakage in a Net-Zero Energy House." Paper presented at ASTM Symposium on Whole Building Air Leakage: Testing and Building Performance Impacts, San Diego, CA, US. April 08, 2018 - April 09, 2018. . . . . SP-8

Riddick, Frank H.; Wallace, Evan K.; Nieman, Scott; Tevis, Joe; Ferreyra, R. "Implementing Grain Traceability Standards: CART and Simulation." Paper presented at 2018 American Society of Agricultural and Biological Engineers (ASABE) Annual International Meeting, Detroit, MI, US. July 29, 2018 - August 01, 2018. . . . . SP-37

Kotsubo, Vincent; Ullom, Joel; Nam, Sae Woo. "Compact 1.7 K Cryocooler for Superconducting Nanowire Single-Photon Detectors." Paper presented at 20th International Cryocooler Conference, Burlington, VT, US. June 18, 2018 - June 21, 2018. . . . . SP-47

Butler, Kathryn; Johnsson, Erik L.; Tang, Wei. "Structure Vulnerability to Firebrands from Fences and Mulch." Paper presented at The Fire Continuum Conference, Missoula, MT, US. May 21, 2018 - May 24, 2018. . . . . SP-57

Obaton, Anne Francoise; Butsch, Bryan; McDonough, Stephen; Laroche, Nans; Gaillard, Yves; Tarr, Jared; Bouvet, Patrick; Cruz, Rodolfo; Donmez, Alkan. "Evaluation of Nondestructive Volumetric Testing Methods for Additively Manufactured Parts." Paper presented at ASTM Symposium on Structural Integrity of Additive Manufactured Parts, Washington, DC, US. November 06, 2018 - November 08, 2018. . . . . SP-70

Sahoo, Anirudha; El Ouni, Naceur; Shenoy, Vineet. "A Study of Timing Constraints and SAS Overload in the CBRS Band using SAS-CBSD Protocol." Paper presented at 2019 IEEE Global Communications Conference (GLOBECOM), Wikola, HI, US. December 09, 2019 - December 13, 2019. . . . . SP-133

Shankar Raman, Arvind; Harper, Dustin; Haapala, Karl; Linke, Barbara; Bernstein, William Z.; Morris, KC. "Challenges In Representing

Manufacturing Processes for Systematic Sustainability Assessments - Workshop On June 21, 2018." Paper presented at ASME 2019 International Manufacturing Science and Engineering Conference (MSEC2019), Erie, PA, US. June 10, 2019 - June 14, 2019. . . . . SP-139

Sauca, Ana; Zhang, Chao; Seif, Mina; Choe, Lisa. "Evaluating Critical Temperatures of Axially Loaded I-shaped Steel Members Using ANSI/ AISC-360 Appendix 4 and Finite Element Model." Paper presented at Annual Stability Conference, St. Louis, MO, US. April 02, 2019 - April 05, 2019. . . . . SP-148

Rhorer, Richard; Quinn, George; Mates, Steven P. "Dynamic Compression Tests of Alumina Dumbbells Using a Spherical Joint." Paper presented at Society for Experimental Mechanics 2019 Annual Meeting, Reno, NV, US. June 03, 2019 - June 06, 2019. . . . . SP-161

Novotny, David. "Reducing Effects of LO Cable Movement in Antenna and Long Distance VNA Measurements." Paper presented at 2019 Joint International Symposium on Electromagnetic Compatibility, Sapporo and Asia-Pacific International Symposium on Electromagnetic Compatibility (EMC Sapporo/APEMC), Sapporo, JP. June 03, 2019 - June 07, 2019. . . . . SP-169

Mell, Peter; Delaitre, Aurelien; de Vaulx, Frederic; Dessauw, Philippe. " Implementing a Protocol Native Managed Cryptocurrency." Paper presented at The Fourteenth International Conference on Software Engineering Advances (ICSEA 2019), Valencia, GA, ES. November 24, 2019 - November 28, 2019. . . . . SP-173

Kelsey, John M.; Dachman-Soled, Dana; Sonmez Turan, Meltem; Mishra, Sweta. "TMPS: Ticket-Mediated Password Strengthening." Paper presented at The Cryptographer's Track of the RSA Conference (CT-RSA 2020), San Francisco, CA, US. February 24, 2020 - February 28, 2020. . . . . SP-181

Hassan, Md.; Chen, Wangchun. "Optimization of a Magnetostatic Cavity for a 3He Spin Analyzer on the CANDOR Polychromatic Reflectometer." Paper presented at 12th International Conference on Polarised Neutrons for Condensed Matter Investigations, Milton Hill, GB. July 03, 2018 - July 06, 2018. . . . . SP-204

Hedberg Jr., Thomas; Barnard Feeney, Allison; Srinivasan, Vijay. "On Practice and Theory of Constructive Composite Geometry and Topology." Paper presented at ASME 2019 International Design Engineering Technical Conferences and Computers and Information in Engineering Conference, Anaheim, CA, US. August 18, 2019 - August 21, 2019. . . . . SP-215

Feng, Siyuan; Choi, Hyong-Ah; Griffith, David W.; Rouil, Richard A. "On

Selecting Channel Parameters for Public Safety Network Applications in LTE Direct." Paper presented at IEEE Consumer Communications & Networking Conference (CCNC), Las Vegas, NV. January 10, 2020 - January 13, 2020.. . . . . SP-227

Liu, Chunmei; Shen, Chen; Chuang, Jack; Rouil, Richard A.; Choi, Hyeong-Ah. "Throughput Analysis between Unicast and MBSFN from Link Level to System Level." Paper presented at 2019 IEEE 90th Vehicular Technology Conference: VTC2019-Fall, Honolulu, HI, US. September 23, 2019 - September 25, 2019.. . . . . SP-233

Wang, Jian; Rouil, Richard A.; Cintron, Fernando. "Distributed Resource Allocation Schemes for Out-of-Coverage D2D Communications." Paper presented at 2019 IEEE Global Communications Conference (GLOBECOM), Waikoloa, HI, US. December 09, 2019 - December 13, 2019.. . . . . SP-240

Hati, Archita; Nelson, Craig. "Multipath Mitigation from FM-AM Correlation." Paper presented at 2019 IEEE IFCS-EFTF, Orlando, FL, US. April 14, 2019 - April 18, 2019.. . . . . SP-250

Sheh, Raymond; Jacoff, Adam. "Best in Class: Leveraging Robot Performance Standards in Academic Competitions to Encourage Development and Dissemination." Paper presented at ASTM STP1614 on Symposium on Homeland Security and Public Safety: Research, Applications and Standards, San Diego, CA, US. June 28, 2018 - June 29, 2018.. . . . . SP-253

Leventon, Isaac; Bruns, Morgan. "Automated Fitting of Thermogravimetric Analysis Data." Paper presented at Interflam 2019, London, UK. July 01, 2019 - July 03, 2019.. . . . . SP-290

Leventon, Isaac; Bonny, Justin. "Influence of Dispositional and Situational Factors on Human Perceptions of Fire Risk." Paper presented at Interflam 2019, London, UK. July 01, 2019 - July 03, 2019.. . . . . SP-299

Sayrafian, Kamran; Krhac, Katjana; Noetscher, Gregory; Simunic, Dina. "A Simulation Platform to Study the Human Body Communication Channel." Paper presented at IEEE Engineering in Medicine and Biology Conference (EMBC 2019), Berlin, DE. July 23, 2019 - July 26, 2019.. . . . . SP-311

Tosado, Jacob; Chen, Wangchun; Rodriguez, Efrain E. "A Strategy for Handling Aberration in Spherical Neutron Polarimetry." Paper presented at 12th International Conference on Polarised Neutrons for Condensed Matter Investigations Journal of Physics: Conference Series, Abingdon, GB. July 03, 2018 - July 06, 2018. . . . . SP-315

Feng, Shaw C.; Lu, Yan; Jones, Albert T. "Data Registration for In-Situ Monitoring of Laser Powder Bed Fusion Processes." Paper presented at International Mechanical Engineering Congress and Exposition, Salt Lake City, UT, US. November 11, 2019 - November 14, 2019.. . . . . SP-325

Piliptchak, Pavlo; Aksu, Murat; Proctor, Frederick; Michaloski, John L. " Physics-based Simulation of Agile Robotic Systems." Paper presented at International Mechanical Engineering Congress & Exposition, Salt Lake City, UT, US. November 11, 2019 - November 14, 2019.. . . . . SP-335

Moges, Tesfaye; Witherell, Paul; Ameta, Gaurav. "On Characterizing Uncertainty Sources in Laser Powder Bed Fusion Additive Manufacturing Models." Paper presented at International Mechanical Engineering Congress and Exposition (IMECE2019), Salt Lake City, UT, US. November 11, 2019 - November 14, 2019. . . . . SP-343

Shao, Guodong; Jain, Sanjay; Laroque, Christoph; Lee, Loo Hay; Lendermann, Peter; Rose, Oliver. "Digital Twin for Smart Manufacturing: the Simulation Aspect." Paper presented at Winter Simulation Conference 2019, National Harbor, MD, US. December 08, 2019 - December 11, 2019.. . . . . SP-358

Tchoua, Roselyne; Ajith, Aswathy; Hong, Zhi; Ward, Logan; Chard, Kyle; Audus, Debra; Patel, Shrayesh; de Pablo, Juan. "Active Learning Yields Better Training Data for Scientific Named Entity Recognition." Paper presented at 2019 IEEE 15th International Conference on e-Science (e-Science), San Diego, CA, US. September 24, 2019 - September 27, 2019. . . . . SP-372

Shrestha, Som; Desjarlais, Andre; Dalgleish, Laverne; Ng, Lisa; Hun, Diana; Emmerich, Steven; Accawi, Gina. "Moisture Transfer in Commercial Buildings due to the Air Leakage: A New Feature in the Online Airtightness Savings Calculator." Paper presented at 2019 Buildings XIV International Conference, Clearwater, FL, US. December 09, 2019 - December 12, 2019.. . . . . SP-382

Jain, Sanjay; Narayanan, Anantha Narayanan; Lee, Yung-Tsun. " Infrastructure for Model Based Analytics for Manufacturing." Paper presented at 2019 Winter Simulation Conference, National Harbor, MD, US. December 08, 2019 - December 11, 2019.. . . . . SP-397

Souryal, Michael; Nguyen, Thao T. "Effect of Federal Incumbent Activity on CBRS Commercial Service." Paper presented at IEEE International Symposium on Dynamic Spectrum Access Networks, Newark, NJ, US. November 11, 2019 - November 14, 2019. . . . . SP-409

Vassilev, Apostol. "BowTie - a deep learning feedforward neural network for sentiment analysis." Paper presented at LOD 2019, Siena, IT. September 10, 2019 - September 13, 2019. . . . . SP-414

Schneider, Barry I.; Bartschat, Klaus; Zatsarinny, Oleg; Bray, Igor; Martin, Fernando; Scrinzi, Armin; Pamidighantam, Sudhakar; Tennyson, Jonathan; Gorfinkiel, Jimena; Klinker, Markus. "A Science Gateway for Atomic and Molecular Physics." Paper presented at Practice and Experience in Advanced Research Computing (PEARC), Chicago, IL, US. July 28, 2019 - August 01, 2019.. . . . . SP-426

Gao, Weichao; Sahoo, Anirudha. "Performance Study of a GAA-GAA Coexistence Scheme in the CBRS Band." Paper presented at IEEE Dynamic Spectrum Access Networks (DySPAN) Conference, Newark, NJ, US. November 11, 2019 - November 14, 2019.. . . . . SP-434

Potteiger, Bradley; Neema, Himanshu; Koutsoukos, Xenofon; Tang, CheeYee; Stouffer, Keith A. "Simulation Testbed for Railway Infrastructure Security and Resilience Evaluation." Paper presented at Hot Topics in the Science of Security (HotSoS) 2020, Lawrence, KS, US. April 07, 2020 - April 08, 2020. . . . . SP-444

Hall, Timothy; Caromi, Raied; Souryal, Michael; Wunderlich, Adam. " Reference Data Sets for Training and Evaluating RF Signal Detection and Classification Models." Paper presented at 2019 IEEE Global Communications Conference (GLOBECOM), Waikoloa, HI, US. December 09, 2019 - December 14, 2019.. . . . . SP-452

Jargon, Jeffrey; Long, Chris; Feldman, Ari; Martens, Jon. "Developing Models for a 0.8 mm Coaxial VNA Calibration Kit within the NIST Microwave Uncertainty Framework." Paper presented at 94th ARFTG Microwave Measurement Conference, San Antonio, TX, US. January 26, 2020 - January 29, 2020.. . . . . SP-457

Gamboa Quintiliani, Samantha; Moreaux, Alexandre; Griffith, David W.; Rouil, Richard A. "UE-to-Network Relay Discovery in ProSe-enabled LTE Networks." Paper presented at International Conference on Computing, Networking and Communications (ICNC 2020), Big Island, HI, US. February 17, 2020 - February 20, 2020.. . . . . SP-461

Phan, Long; Sadek, Fahim H.; Thonstad, Travis; Lew, Hai; Marcu, Sorin; Philip, Jacob. "Effects of Alkali-Silica Reaction on Mechanical Properties and Structural Capacities of Reinforced Concrete Structures." Paper presented at Structural Mechanics in Reactor Technology (SMiRT) 25, Charlotte, NC, US. August 04, 2019 - August 09, 2019.. . . . . SP-468

Quelennec, Aurore; Gorman, Jason J.; Reyes-Hernandez, Darwin. "Label-free surface acoustic wave-based embedded flow sensor." Paper presented at The 23rd International Conference on Miniaturized Systems for Chemistry and Life Sciences (µTAS 2019), Basel, CH. October 27, 2019 - October 31, 2019.. SP-477

Yuffa, Alex. "On Wacker•s Essential Equation in the Extrapolation Measurement Technique." Paper presented at Annual Symposium of the Antenna Measurement Techniques Association (AMTA), San Diego, CA, US. October 06, 2019 - October 11, 2019.. SP-479

Jargon, Jeffrey; Quimby, Jeanne; Remley, Kate; Koepke, Amanda; Williams, Dylan. "Verifying the Performance of a Correlation-Based Channel Sounder in the 3.5 GHz Band with a Calibrated Vector Network Analyzer." Paper presented at Asia-Pacific Microwave Conference (APMC) 2019, Singapore, SG. December 10, 2019 - December 13, 2019.. SP-484

Nguyen, Cuong; Roberts, Jeremy. "Green Button Data-Access Model for Smart Cities." Paper presented at The 2nd ACM/EIGSCC Symposium On Smart Cities and Communities, Portland, OR, US. September 10, 2019 - September 12, 2019.. SP-487

Sayrafian, Kamran; Roudneshin, Masoud; Aghdam, Amir. "Output Power Maximization of a Microgenerator Using Machine Learning Approach." Paper presented at The 7th Annual IEEE International Conference on Wireless for Space and Extreme Environments, Ottawa, CA. October 16, 2019 - October 18, 2019.. SP-493

Halba, Khalid; Griffor, Edward; Roth, Thomas; Kamongi, Patrick. "Using Statistical Methods and Co-Simulation to Evaluate ADS-Equipped Vehicle Trustworthiness." Paper presented at Electric Vehicles International Conference (EV) 2019, Bucharest, RO. October 03, 2019 - October 04, 2019.. SP-498

Persily, Andrew K.; Polidoro, Brian. "40th AIVC - 8th TightVent & 6th Venticool Conference, 2019 Residential Application of an Indoor Carbon Dioxide Metric." Paper presented at Conference 40th AIVC - 8th TightVent - 6th Venticool Conference in Ghent Belgium, Ghent, BE. October 15, 2019 - October 16, 2019.. SP-503

Mell, Peter. "Augmenting Fiat Currency with an Integrated Managed Cryptocurrency." Paper presented at The Fourteenth International Conference on Software Engineering Advances (ICSEA 2019), Valencia, ES. November 24, 2019 - November 28, 2019.. SP-516

Splett, Jolene D.; Jimenez, Felix; Koepke, Amanda. "Estimating the Parameters of Circles and Ellipses Using Orthogonal Distance Regression and Bayesian Errors-in-Variables Regression." Paper presented at 2019 Joint Statistical Meetings, Denver, CO, US. July 28, 2019 - August 01, 2019.. SP-524

Sieber, John. "How to Use and How Not to Use Certified Reference Materials in Industrial Chemical Metrology Laboratories." Paper presented at Denver X-Ray Conference, Lombard, IL, US. August 05, 2019 - August 09, 2019. SP-541

Persily, Andrew K. "40th AIVC - 8th Tight Vent & 6th Venticool Conference, 2019 Techniques to Estimate Commercial Building Infiltration Rates." Paper presented at 40th AIVC - 8th TightVent - 6th Venticool Conference, 2019, Ghent, BE. October 15, 2019 - October 16, 2019.. SP-558

Nablo, Brian; Ahn, Jungjoon; Bhadriraju, Kiran; Lee, Jong; Reyes-Hernandez, Darwin. "Live quantification of cell viability via neutral red uptake using lens-free imaging." Paper presented at The 23rd International Conference on Miniaturized Systems for Chemistry and Life Sciences (µTAS 2019), Basel, CH. October 27, 2019 - October 31, 2019. SP-567

Candell, Rick; Hany, Mohamed; Liu, Yongkang; Montgomery, Karl; Foufou, Sebti. "A Graph Database Approach to Wireless IIoT Work-cell Performance Evaluation." Paper presented at 2020 IEEE International Conference on Industrial Technology, Buenos Aires, AR. February 26, 2020 - February 28, 2020.. SP-569

Flowers-Jacobs, Nathan; Rufenacht, Alain; Fox, Anna; Waltman, Steven; Schwall, Robert; Brevik, Justus; Dresselhaus, Paul; Benz, Samuel P. " Development and Applications of a Four-Volt Josephson Arbitrary Waveform Synthesizer." Paper presented at 2019 IEEE International Superconductive Electronics Conference (ISEC), Riverside, CA, US. July 28, 2019 - August 01, 2019. SP-577

Fong, Jeffrey T.; Heckert, N. Alan; Filliben, James J.; Marcal, Pedro; Berweger, Samuel; Wallis, Thomas Mitchell (Mitch); Kabos, Pavel. " Design of an intelligent PYTHON code to run coupled and license-free finite-element and statistical analysis software for calibration of near-field scanning microwave microscopes." Paper presented at COMSOL Users Conference, Boston, MA, US. October 02, 2019 - October 04, 2019. SP-579

Wong, Vivian; Ferguson, Max; Law, Kincho; Lee, Yung-Tsun. "An Assistive Learning Workflow on Annotating Images for Object Detection." Paper presented at 2019 IEEE International Conference on Big Data, Los Angeles, CA, US. December 09, 2019 - December 12, 2019. SP-585

Falkenstein-Smith, Ryan; Sung, Kunhyuk; Chen, Jian; Hamins, Anthony. "

Chemical Structure of Medium-Scale Liquid Pool Fires." Paper presented at 13th International Symposium on Fire Safety Science, Waterloo, CA. April 27, 2020 - May 01, 2020.. . . . . SP-594

Persily, Andrew K.; Dols, William Stuart; Emmerich, Steven; Ng, Lisa. " The Role of Carbon Dioxide in Ventilation and IAQ Evaluation: 40 years of AIVC." Paper presented at 40th Air Infiltration and Ventilation Centre Conference, Ghent, BE. October 08, 2019 - October 09, 2019.. . . . . SP-610

Tam, Wai Cheong; Fu, Eugene Yujun; Mensch, Amy; Hamins, Anthony; You, Christina; Ngai, Grace; Leong, Hong va. "Prevention of Cooktop Ignition Using Detection and Multi-Step Machine Learning Algorithms." Paper presented at International Association of Fire Safety Science 2020, Waterloo, CA. April 27, 2020 - May 01, 2020.. . . . . SP-614

Huang, Siyuan; Hoskins, Brian; Daniels, Matthew; Stiles, Mark; Adam, Gina. "Streaming Batch Gradient Tracking for Neural Network Training." Paper presented at AAAI Conference on Artificial Intelligence, New York, NY, US. February 07, 2020 - February 12, 2020. . . . . . SP-637

Saidkhodjaev, Temur; Voas, Jeff; Kuhn, D. Richard; DeFranco, Joanna; Laplante, Phil. "Aggregating Atomic Clocks for Time-Stamping." Paper presented at 2020 IEEE International Conference on Service Oriented Systems Engineering (SOSE), Oxford, UK. August 03, 2020 - August 06, 2020.. . . . . SP-639

Koepke, Lucas; Splett, Jolene D.; Quinn, Timothy; Hrabe, Nik; Benzing, Jake; Frey, Michael. "Multiple Changepoint Analysis of Noisy Nonlinear Data with an Application to Modeling Crack Growth in Additively Manufactured Titanium." Paper presented at 2019 Joint Statistical Meetings, Denver, CO, US. July 28, 2019 - August 01, 2019.. . . . . SP-653

Sung, Kunhyuk; Chen, Jian; Bundy, Matthew; Hamins, Anthony. "The Characteristics of a 1 m Methanol Pool Fire." Paper presented at 13 International Symposium on Fire Safety Science (IAFSS 2020), Waterloo, CA. April 26, 2020 - May 01, 2020.. . . . . SP-664

Guo, Yang; Liu, Franklin; Wang, An; Liu, Hang. "AccuPIPE: Accurate Heavy Flow Detection in the Data Plane Using Programmable Switches." Paper presented at IEEE/IFIP Network Operations and Management, Budapest, HU. April 20, 2020 - April 24, 2020.. . . . . SP-682

McLinden, Mark O.; Kazakov, Andrei F.; Brown, J; Brignoli, Riccardo; Bell, Ian; Domanski, Piotr A. "Options for Low-GWP Refrigerants." Paper presented at Institute of Refrigeration, London, UK. November 06, 2019 - November 06, 2019.. . . . . SP-687

Zou, Qingtian; Singhal, Anoop; Sun, Xiaoyan; Liu, Peng. "Automatic Recognition of Advanced Persistent Threat Tactics for Enterprise Security." Paper presented at 6th ACM International Workshop on Security and Privacy Analytics 2020, New Orleans, LA, US. March 16, 2020 - March 18, 2020.. . . . . SP-705

Miller, Carl A. "The Impossibility of Efficient Quantum Weak Coin-Flipping." Paper presented at 52nd Annual ACM Symposium on Theory of Computing (STOC 2020), Chicago, IL, US. June 22, 2020 - June 26, 2020.. . . . . SP-717

Mosleh, Susanna; Ma, Yao; Rezac, Jake; Coder, Jason. "Dynamic Spectrum Access with Reinforcement Learning for Unlicensed Access in 5G and Beyond." Paper presented at 2020 IEEE 91st Vehicular Technology Conference: VTC2020-Spring, Antwerp, BE. May 25, 2020 - May 28, 2020. . . . . SP-741

Manzello, Samuel; Suzuki, Sayaka. "Influence of Angle Orientation on Firebrand Production from the Combustion of Materials Exposed to Applied Wind Fields." Paper presented at 57 Japanese Combustion Symposium, Hokkaido, JP. November 20, 2019 - November 22, 2019. . . . . SP-748

Manzello, Samuel; Suzuki, Sayaka. "Investigating coupled effect of radiative heat flux and firebrand showers on ignition of fuel beds." Paper presented at 57 Japanese Combustion Symposium, Sapporo (Hokkaido), JP. November 20, 2019 - November 22, 2019. . . . . SP-750

Liu, Changwei; Singhal, Anoop; Wijesekera, Duminda. "Forensic Analysis of Advanced Persistent Threat Attacks in Cloud Environments." Paper presented at Sixteenth IFIP 11.9 International Conference on Digital Forensics, New Delhi, IN. January 06, 2020 - January 08, 2020. . . . . SP-752

Park, Hyunseop; Ko, Hyunwoong; Lee, Yung-Tsun; Cho, Hyunbo; Witherell, Paul. "A Framework for Identifying and Prioritizing Data Analytics Opportunities in Additive Manufacturing." Paper presented at 5th International Workshop on Methodologies to Improve Managing Big Data projects in IEEE big data 2019, Los Angeles, CA, US. December 09, 2019 - December 12, 2019.. . . . . SP-773

Oe, Takehiko; Panna, Alireza; Elmquist, Randolph; Jarrett, Dean G.; Fukuyama, Yasuhiro; Kaneko, Nobu-Hisa. "Precise evaluation of the 129 kΩ and 1 MΩ quantum Hall array devices for a quantum Wheatstone bridge." Paper presented at Conference on Precision Electromagnetic Measurements (CPEM), Denver, CO, US. August 24, 2020 - August 28, 2020.. . . . . SP-783

Ganesan, Adarsh; Seshia, Ashwin; Gorman, Jason J. "Phononic

Frequency Combs For Engineering MEMS/NEMS Devices With Tunable Sensitivity." Paper presented at IEEE SENSORS 2019, Montreal, CA. October 27, 2019 - October 30, 2019.. . . . . SP-785

Ma, Yao; Mosleh, Susanna; Coder, Jason. "A Unified Analytical Approach to Multi-Cell LBT-Based Spectrum Sharing Systems." Paper presented at the 2020 IEEE 91st Vehicular Technology Conference: VTC2020-Spring, Antwerp, BE. May 25, 2020 - May 28, 2020.. . . . . SP-789

Jun, Sung Yun; Caudill, Derek; Chuang, Jack; Papazian, Peter; Bodi, Anuraag; Gentile, Camillo; Senic, Jelena; Golmie, Nada T. "Penetration Loss at 60 GHz for Indoor-to-Indoor and Outdoor-to-Indoor Mobile Scenarios." Paper presented at IEEE European Conference on Antennas and Propagation, Copenhagen, DK. March 15, 2020 - March 20, 2020.. . . . . SP-795

Cohl, Howard; Greiner Petter, Andre; Schubotz, Moritz; Breitinger, Corinna; Muller, Fabian; Aizawa, Akiko; Gipp, Bela. "Discovering Mathematical Objects of Interest - A Study of Mathematical Notations." Paper presented at The Web Conference 2020, Taipei, TW. April 20, 2020 - April 24, 2020. . . . . SP-800

Liu, Chunmei; Shen, Chen; Chuang, Jack; Rouil, Richard A.; Choi, Hyeong-Ah. "Evaluating Unicast and MBSFN in Public Safety Networks." Paper presented at IEEE International Symposium on Personal, Indoor and Mobile Radio Communications (PIMRC) 2020, London, UK. August 31, 2020 - September 03, 2020. . . . . SP-812

Williams, Dylan; Chamberlin, Richard; Cheron, Jerome; Chitwood, Sam; Willis, Ken; Butler, Brad; Yazdani, Farhang. "DARPA Organic Interconnect Characterization." Paper presented at DesignCon 2020, Santa Clara, CA, US. January 28, 2020 - January 30, 2020.. . . . . SP-819

Mouha, Nicky; Celi, Christopher. "Extending NIST's CAVP Testing of Cryptographic Hash Function Implementations." Paper presented at CT-RSA 2020: Cryptographers' Track at the RSA Conference, San Francisco, CA, US. February 24, 2020 - February 28, 2020. . . . . SP-841

Gordon, Josh; Battou, Abdella; Kilper, Dan. "Workshop on Machine Learning for Optical Communication Systems: a summary." Paper presented at The Optical Networking and Communication Conference & Exhibition OFC 2020, San Diego, CA, US. March 08, 2020 - March 12, 2020.. . . . . SP-858

Copeland, Craig R.; McGray, Craig; Ilic, Robert; Geist, Jon; Stavis, Samuel M. "Particle Tracking of a Complex Microsystem in Three Dimensions and Six Degrees of Freedom." Paper presented at 2020 IEEE

33rd International Conference on Micro Electro Mechanical Systems (MEMS), Vancouver, CA. January 18, 2020 - January 22, 2020.. SP-861

Tait, Alexander; Buckley, Sonia; Shainline, Jeff; McCaughan, Adam; Chiles, Jeff; Nam, Sae Woo; Mirin, Richard. "Microresonator enhanced, waveguide coupled emission from silicon defect centers for superconducting optoelectronic networks." Paper presented at Optical Fiber Conference, San Diego, CA, US. March 08, 2020 - March 12, 2020. SP-865

Shrestha, Pragya; Lyu, xiao; Si, Mengwei; Cheung, Kin (Charles); Ye, Pei. "First Direct Measurement of Sub-Nanosecond Polarization Switching in Ferroelectric Hafnium Zirconium Oxide." Paper presented at IEEE International Electron Devices Meeting (IEDM), SAn Francisco, CA, US. December 07, 2019 - December 11, 2019. SP-874

Vernica, Teodor; Hanke, Aaron; Bernstein, William Z. "Leveraging standard geospatial representations for industrial augmented reality." Paper presented at MBE 2020: Model-Based Enterprise Summit 2020, Gaithersburg, MD, US. March 30, 2020 - April 03, 2020. SP-878

Bhushan, Sumit; Slattery, Oliver T.; Tang, Xiao; Ma, Lijun. "Terahertz Electromagnetically Induced Transparency in Cesium Atoms." Paper presented at Frontier in Optics (FIO). September 14, 2020 - September 17, 2020. SP-885

Smith, Kassi; Bosworth, Bryan; Jungwirth, Nick; Cheron, Jerome; Orloff, Nate; Long, Chris; Williams, Dylan; Chamberlin, Richard; Quinlan, Franklyn; Fortier, Tara; Feldman, Ari. "On-Wafer Metrology of a Transmission Line Integrated Terahertz Source." Paper presented at CLEO: Laser Science to Photonic Applications, San Jose, CA, US. May 10, 2020 - May 15, 2020. SP-887

Xu, Hansong; Yu, Wei; Liu, Xing; Griffith, David W.; Golmie, Nada T. "On Data Integrity Attacks against Industrial Internet of Things." Paper presented at IEEE Cyber Science and Technology Congress (CyberSciTech 2020), Calgary, CA. August 17, 2020 - October 24, 2020.. SP-889

Wong, Vivian; Ferguson, Max; Law, Kincho; Lee, Yung-Tsun; Witherell, Paul. "Automatic Volumetric Segmentation of Additive Manufacturing Defects with 3D U-Net." Paper presented at SSS20 (VIRTUAL) AAAI Spring Symposium on AI in Manufacturing, Palo Alto, CA, US. March 23, 2020 - March 25, 2020.. SP-899

Diaz-Elsayed, Nancy; Hernandez, Luis; Rajamani, Ravi; Weiss, Brian A. " Asset Condition Management: A Framework for Smart, Health-Ready Manufacturing Systems." Paper presented at ASME 2020 15th

International Manufacturing Science and Engineering Conference (MSEC2020), Cincinnati, OH, US. June 22, 2020 - June 26, 2020. . . . . SP-906

Weiss, Brian A.; Kaplan, Jared. "Assessment of a Novel Position Verification Sensor to Identify and Isolate Robot Workcell Health Degradation." Paper presented at ASME 2020 15th International Manufacturing Science and Engineering Conference (MSEC2020), Cincinnati, OH, US. June 22, 2020 - June 26, 2020. . . . . SP-913

Dadfarnia, Mehdi; Sharp, Michael; Sprock, Timothy. "Understanding and Evaluating Naive Diagnostics Algorithms Applicable in Multistage Manufacturing from a Risk Management Perspective." Paper presented at ASME Manufacturing Science and Engineering Conference 2020 (MSEC 2020), Cincinnati, OH, US. June 22, 2020 - June 26, 2020. . . . . SP-922

Roth, Thomas; Nguyen, Cuong; Burns, Martin; Neema, Himanshu. " Integrating a Network Simulator with the High Level Architecture for the Co-Simulation of Cyber-Physical Systems." Paper presented at 2020 Simulation Innovation Workshop, Orlando, FL, US. February 10, 2020 - February 14, 2020.. . . . . SP-931

Wong, Kevin K F. "Identification of Geometric Nonlinearity Formulations and the Influences on Structural Dynamic Responses." Paper presented at 17th World Conference on Earthquake Engineering, Sendai, JP. September 13, 2020 - September 18, 2020.. . . . . SP-943

Moody, Dustin; Perlner, Ray; Smith-Tone, Daniel; Apon, Daniel; Verbel, Javier. "Combinatorial Rank Attacks Against the Rectangular Simple Matrix Encryption Scheme." Paper presented at PQCrypto 2020: The Eleventh International Conference on Post-Quantum Cryptography, Paris, FR. April 15, 2020 - April 17, 2020.. . . . . SP-955

Hatada, Mitsuhiro; Scholl, Matthew. "Method for Effective Measurement, Labeling, and Classification of Botnet C2s for Predicting Attacks." Paper presented at 27th Annual Network and Distributed System Security Symposium (NDSS), San Diego, CA, US. February 23, 2020 - February 26, 2020. . . . . SP-971

Dunkers, Joy; Da Silva, Sandra M.; Servetas, Stephanie; Filliben, James J.; Pinheiro, Guilherme; Lin, Nancy. "Key Considerations for Microbial Viability Measurements." Paper presented at Workshop on Ultraviolet Disinfection Technologies & Healthcare Associated Infections: Defining Standards and Metrology Needs, Gaithersburg, MD, US. January 14, 2020 - January 15, 2020.. . . . . SP-974

Kacker, Raghu N.; Kuhn, D. Richard. "CAgen: A fast combinatorial test generation tool with support for constraints and higher-index arrays." Paper presented at IEEE International Conference on Software Testing, Verification and Validation ICST 2020 Workshops, Porto, PT. March 23, 2020 - March 27, 2020.. SP-976

Sexton, Thurston; Brundage, Michael; Dima, Alden A.; Sharp, Michael. " MSEC: A Quantitative Retrospective." Paper presented at MSEC: Manufacturing Science and Engineering Conference, Cincinnati, OH, US. June 22, 2020 - June 26, 2020. SP-986

Amoah, Papa; Perez, Jesus; Obeng, Yaw S. "Application of Broadband RF Metrology to Integrated Circuit Interconnect Reliability Analyses: Monitoring Copper Interconnect Corrosion in 3D-ICs." Paper presented at 2020 International Conference on Microelectronic Test Structures, Edinburgh, UK. April 06, 2020 - April 09, 2020. SP-998

Nablo, Brian; Reyes-Hernandez, Darwin; Poster, Dianne L.; Postek, Michael; Obeng, Yaw S. "Standards, Metrology and Technology to Minimize Healthcare-Associated Infections: Novel approaches to measure efficacy." Paper presented at Workshop on Ultraviolet Disinfection Technologies & Healthcare Associated Infections: Defining Standards and Metrology Needs, Gaithersburg, MD, US. January 14, 2020 - January 15, 2020.. SP-1001

Haney, Julie; Furman, Susanne M.; Acar, Yasemin. "Smart Home Security and Privacy Mitigations: Consumer Perceptions, Practices, and Challenges." Paper presented at International Conference on Human-Computer Interaction, Copenhagen, DK. July 19, 2020 - July 24, 2020.. SP-1003

Wong, Kevin K F; McCabe, Steven. "Quantification of Seismic Energy Demand in Nonlinear Structures Through Analytical Derivations." Paper presented at 17th World Conference on Earthquake Engineering, Sendai, JP. September 13, 2020 - September 18, 2020. SP-1022

Sadjadi, Omid; Greenberg, Craig; Singer, Elliot; Reynolds, Douglas; Mason, Lisa; Hernandez-Cordero, Jaime. "The 2019 NIST Speaker Recognition Evaluation CTS Challenge." Paper presented at The Speaker and Language Recognition Workshop: Odyssey 2020, Tokyo, JP. November 01, 2020 - November 05, 2020. SP-1034

Artusio-Glimpse, Aly; Rogers, Kyle; Williams, Paul A.; Lehman, John H. " HALO - High Amplification Laser-pressure Optic." Paper presented at NEWRAD 2020, 14th International Conference on New Developments and Applications in Optical Radiometry, Boulder, CO, US. June 23, 2020 - June 26, 2020. SP-1041

Kant, Melis; Jaruga, Pawel; Coskun, Erdem; Ward, Samuel; Stark, Alexander; Becker, David; Adhikary, Amitav; Sevilla, Michael; Dizdar, Miral M. "Ion-beam radiation damage to DNA by investigation of free radical formation and base damage." Paper presented at DNA Damage, Mutation and Cancer; Gordon Research Conference, Ventura, CA, US. March 01, 2020 - March 06, 2020. . . . . SP-1043

Coskun, Erdem; Tuna, Gamze; Jaruga, Pawel; Tona, Alessandro; Erdem, Onur; Dizdar, Miral M. "Measurement of PARP1 in human tissues by liquid chromatography tandem mass spectrometry." Paper presented at DNA Damage, Mutation and Cancer, Gordon Research Conference, Ventura, CA, US. March 01, 2020 - March 06, 2020. . . . . SP-1044

Deisenroth, David; Mekhontsev, Sergey; Lane, Brandon. "Measurement of mass loss, absorbed energy, and time-resolved reflected power for laser powder bed fusion." Paper presented at SPIE Photonics West, San Francisco, CA, US. February 01, 2020 - February 06, 2020.. . . . . SP-1045

Cheung, Kin (Charles). "Anomalous accelerated negative-bias- instability (NBI) at low drain bias." Paper presented at 2020 International Reliability Physics Symposium, Virtual Dallas, TX, US. April 28, 2020 - May 30, 2020.. . . . . SP-1058

Sadjadi, Omid; Greenberg, Craig; Singer, Elliot; Reynolds, Douglas; Mason, Lisa; Hernandez-Cordero, Jaime. "The 2019 NIST Audio-Visual Speaker Recognition Evaluation." Paper presented at The Speaker and Language Recognition Workshop: Odyssey 2020, Tokyo, JP. November 01, 2020 - November 05, 2020.. . . . . SP-1061

Kacker, Raghu N.; Kuhn, D. Richard. "Effectiveness of dataset reduction in testing machine learning algorithms." Paper presented at IEEE International Conference on Artificial Intelligence Testing, Oxford, UK. April 13, 2020 - April 16, 2020.. . . . . SP-1068

Elmquist, Randolph; Kruskopf, Mattias; Patel, Dinesh; Hu, I Fan; Liu, Chieh-I; Rigosi, Albert; Panna, Alireza; Payagala, Shamith; Jarrett, Dean G. "AC and DC Quantized Hall Array Resistance Standards." Paper presented at 2020 Conference on Precision Electromagnetic Measurements(CPEM 2020), Denver, CO, US. August 24, 2020 - August 28, 2020. . . . . SP-1076

Segura, Christopher; Sattar, Siamak. "Uncertainty in the Seismic Response of Structural Components due to Material Variability." Paper presented at 17th World Conference on Earthquake Engineering, Sendai, JP. September 13, 2020 - September 18, 2020. . . . . SP-1078

Georgakopoulos, Dimitrios; Budovsky, Ilya; Benz, Samuel P. "Josephson Arbitrary Waveform Synthesizer as a Reference Standard for the Calibration of Lock-in Amplifiers." Paper presented at 2020 Conference on Precision Electromagnetic Measurements (CPEM), Denver, CO, US. August 24, 2020 - August 28, 2020. . . . . SP-1090

Paul, Jagannath; Wahlstrand, Jared; Bristow, Alan. "Polarization-dependent absolute-phase-corrected multidimensional coherent spectra of exciton-polaritons." Paper presented at Ultrafast Phenomena and Nanophotonics XXIV, San Francisco, CA, US. February 03, 2020 - February 06, 2020. . . . . SP-1092

Mell, Peter; Gueye, Assane. "A Suite of Metrics for Calculating the Most Significant Security Relevant Software Flaw Types." Paper presented at 2020 IEEE 44th Annual Computers, Software, and Applications Conference (COMPSAC), Madrid, ES. July 13, 2020 - July 17, 2020. . . . . SP-1098

Fung, Juan; Sattar, Siamak; Butry, David; McCabe, Steven. "Machine Learning Methods for Predicting Seismic Retrofit Costs." Paper presented at 17th World Conference on Earthquake Engineering, Sendai, JP. September 13, 2020 - September 18, 2020. . . . . SP-1104

Payagala, Shamith; Dee, Alana; Jarrett, Dean G. "Evaluation of an alternative null detector for adapted Wheatstone bridge." Paper presented at Conference on Precision Electromagnetic Measurements, Denver, CO, US. August 22, 2020 - August 28, 2020. . . . . SP-1114

Jun, Sung Yun; Caudill, Derek; Senic, Jelena; Gentile, Camillo; Chuang, Jack; Golmie, Nada T. "Over-The-Air Calibration of a Dual-Beam Dual-Polarized 28-GHz Phased-Array Channel Sounder." Paper presented at 2020 IEEE International Symposium on Antennas and Propagation and North American Radio Science Meeting, Montreal, CA. July 05, 2020 - July 10, 2020. . . . . SP-1116

Oe, Takehiko; Payagala, Shamith; Jarrett, Dean G.; Kaneko, Nobu-Hisa. "Evaluation of NMIJ Traveling Dual Source Bridge Using NIST Adapted Wheatstone Bridge." Paper presented at Conference on Precision Electromagnetic Measurements (CPEM), Denver, CO, US. August 24, 2020 - August 28, 2020. . . . . SP-1118

Yang, S.; Cular, Stefan; Rufenacht, Alain; Burroughs, Charles J.; Dresselhaus, Paul; Benz, Samuel P.; Ng, M. "Direct DC Voltages Comparison between two Programmable Josephson Voltage Standards at SCL." Paper presented at 2020 Conference on Precision Electromagnetic Measurements (CPEM), Denver, CO, US. August 24, 2020 - August 28, 2020. . . . . SP-1120

Bell, Ian. "Working Fluid Screening for Ocean Thermal Energy Conversion (OTEC) Applications." Paper presented at IIR International Rankine 2020 Conference - Heating, Cooling and Power Generation, Glasgow, UK, Glasgow, UK. July 26, 2020 - July 29, 2020. . . . . SP-1122

Bieler, Mark; Struszewski, Paul; Feldman, Ari; Jargon, Jeffrey; Hale, Paul D.; Gong, Pengwei; Xie, Wen; Yang, Chuntao; Feng, Zhigang; Zhao, Kejia; Yang, Zhijun. "Ultrafast waveform metrology: A first international comparison." Paper presented at Conference on Precision Electromagnetic Measurements, Denver, CO, US. August 24, 2020 - August 28, 2020. . . . . SP-1128

Feldman, Ari; Jargon, Jeffrey; Dennis, Tasshi; Hale, Paul D. "Photodiode Calibration Comparison between Electro-Optic Sampling and Heterodyne Measurements up to 75 GHz." Paper presented at Conference on Precision Electromagnetic Measurements, Denver, CO, US. August 24, 2020 - August 28, 2020. . . . . SP-1130

Kruskopf, Mattias; Patel, Dinesh; Liu, Chieh-I; Rigosi, Albert; Elmquist, Randolph; Wang, Yicheng; Bauer, Stefan; Yin, Yefei; Pierz, Klaus; Pesel, Eckard; Goetz, Martin; Schurr, Jurgen. "Graphene quantum Hall effect devices for AC and DC resistance metrology." Paper presented at 2020 Conference on Precision Electromagnetic Measurements(CPEM 2020), Denver, CO, US. August 24, 2020 - August 28, 2020. . . . . SP-1132

Zhang, Shanshan; Lane, Brandon; Chou, Kevin. "Powder Thermal Conductivity Measurements in L-PBF using Powder-Included Build Specimens: Internal Geometry Effect." Paper presented at Manufacturing Science and Engineering Conference (MSEC2020), Cincinnati, OH, US. June 22, 2020 - June 26, 2020. . . . . SP-1134

Rufenacht, Alain; Fox, Anna; Butler, Grace; Burroughs, Charles J.; Dresselhaus, Paul; Schwall, Robert; Cular, Stefan; Benz, Samuel P. " Compact DC Josephson Voltage Standard." Paper presented at 2020 Conference on Precision Electromagnetic Measurements, Denver, CO, US. August 24, 2020 - August 28, 2020. . . . . SP-1143

Geng, Jing; Li, Honglei; Hany, Mohamed; Liu, Yongkang; Candell, Rick; Bhattacharyya, Shuvra. "Integrating Field Measurements into a Model-Based Simulator for Industrial Communication Networks." Paper presented at 16th IEEE International Conference on Factory Communication Systems, Porto, PT. April 27, 2020 - April 29, 2020. . . . . SP-1145

Mates, Steven P.; Lopez-Hawa, Homar; Moscoso-Kingsley, Wilfredo;

Madhavan, Viswanathan. "Dynamic Flow Stress Measurements of 6061-T6 Aluminum under Rapid Heating for Machining Studies." Paper presented at Society for Experimental Mechanics 2020 Annual Meeting, Orlando, FL, US. June 08, 2020 - June 11, 2020.. . . . . . . SP-1153

Mosleh, Susanna; Ma, Yao; Rezac, Jake; Coder, Jason. "A Novel Machine Learning Approach to Estimating KPI and PoC for LTE-LAA-based Spectrum Sharing." Paper presented at IEEE International Conference on Communications (ICC) Workshop 2020, Dublin, IE. June 07, 2020 - June 11, 2020. . . . . . . SP-1159

Johnson, Ward L. "Contributions to Acoustic Loss in Langasite, Langatate, and Catangasite Resonators at High Temperatures." Paper presented at Sensor and Measurement Science International 2020, Nuremberg, DE. June 22, 2020 - June 25, 2020. . . . . . . SP-1165

Jarrett, Dean G.; Payagala, Shamith; Fitzgerald, Ryan P.; Bergeron, Denis E.; Cessna, Jeffrey T.; Waduwarage Perera, Charles; Zimmerman, Neil M. "Ohms Law Low-current Calibration System for Ionization Chambers." Paper presented at 2020 Conference on Precision Electromagnetic Measurements(CPEM 2020), Denver, CO, US. August 24, 2020 - August 28, 2020. . . . . . . SP-1167

Gharavi, Hamid. "Deterministic Intra-Vehicle Communications: Timing and Synchronization." Paper presented at IEEE International Conference on Communications (IEEE ICC), Dublin, IE. June 07, 2020 - June 11, 2020.. . . . . . . SP-1169

Giraldo, Jairo; Tang, CheeYee; Urbina, David; Cardenas, Alvaro. "The More the Merrier: Adding Hidden Measurements for Anomaly Detection and Mitigation in Industrial Control Systems." Paper presented at Hot Topics in the Science of Security (HotSoS) 2020, Lawrence, KS, US. April 07, 2020 - April 08, 2020.. . . . . . . SP-1175

Fahnestock, Larry; Shi, Shitao; Speicher, Matthew. "Seismic Stability Assessment of Steel Moment Frames and Implications for Design." Paper presented at 17th World Conference on Earthquake Engineering, Sendai, JP. September 13, 2020 - September 18, 2020. . . . . . . SP-1185

Maison, Bruce; Kasai, Kazuhiko; Speicher, Matthew. "Loading Protocols and Backbone Curves: U.S. and Japan Perspectives." Paper presented at 17th World Conference on Earthquake Engineering, Sendai, JP. September 13, 2020 - September 18, 2020. . . . . . . SP-1197

Veksler, Dmitry; bersuker, gennadi; Bushmaker, A; Mason, Maribeth; Shrestha, Pragya; Cheung, Kin (Charles); Campbell, Jason; Rueckes, T;

Clevlend, L; Luan, H; Gilmer, D. "Memory update characteristics of carbon nanotube memristors (NRAM) under circuitry-relevant operation conditions." Paper presented at 2020 International Reliability Physics Symposium, Dallas, TX, US. April 28, 2020 - May 30, 2020.. . . . . .SP-1209

Lecci, Mattia; Testolina, Paolo; Giordani, Marco; Polese, Michele; Ropitault, Tanguy; Gentile, Camillo; Varshney, Neeraj; Zorzi, Michele. " Simplified Ray Tracing for the Millimeter Wave Channel: A Performance Evaluation." Paper presented at 2020 Information Theory and Applications Workshop, San Diego, CA, US. February 02, 2020 - February 07, 2020.. . . . . .SP-1213

Marangoni, Rafael; El Haddad, Darine; Seifert, Frank; Chao, Leon; Newell, David B.; Schlamminger, Stephan. "Measurement of the magnet system for the QEMMS." Paper presented at 2020 Conference on Precision Electromagnetic Measurements (CPEM), Denver, CO, US. August 24, 2020 - August 28, 2020.. . . . . .SP-1219

Marangoni, Rafael; El Haddad, Darine; Seifert, Frank; Chao, Leon; Pratt, Jon R.; Newell, David B.; Schlamminger, Stephan. "Design of the Kibble balance for the QEMMS." Paper presented at 2020 Conference on Precision Electromagnetic Measurements (CPEM), Denver, CO, US. August 24, 2020 - August 28, 2020.. . . . . SP-1221

Flowers-Jacobs, Nathan; Rufenacht, Alain; Fox, Anna; Dresselhaus, Paul; Benz, Samuel P. "Calibration of an AC Voltage Source Using a Josephson Arbitrary Waveform Synthesizer at 4 V." Paper presented at Conference on Precision Electromagnetic Measurements, Denver, CO, US. August 24, 2020 - August 28, 2020.. . . . . .SP-1223

Qiao, Guixiu; Garner, Jonathan. "Advanced sensing development to support accuracy assessment for industrial robot systems." Paper presented at ASME International Manufacturing Science and Engineering Conference, Cincinnati, OH, US. June 22, 2020 - June 26, 2020.. . . . . .SP-1225

Dukes, Jazalyn; Sattar, Siamak. "Development of a Database of Experimental Tests on FRP Retrofitted Reinforced Concrete Shear Walls." Paper presented at 17th World Conference on Earthquake Engineering, Sendai, JP. September 13, 2020 - September 18, 2020. . . . . .SP-1232

Brevik, Justus; Soares Boaventura, Alirio De Jesus; Castellanos Beltran, Manuel; Donnelly, Christine; Flowers-Jacobs, Nathan; Fox, Anna; Hopkins, Pete; Dresselhaus, Paul; Williams, Dylan; Benz, Samuel P. "A Cryogenic Quantum-Based RF Source." Paper presented at 2020 95th

ARFTG Microwave Measurement Conference, Los Angeles, CA, US. August 04, 2020 - August 06, 2020.. . . . . SP-1241

Ayoade, Gbadebo; Akbar, Khandakar; Sahoo, Pracheta; Gao, Yang; Singhal, Anoop; Jee, Kangkook; Khan, Latifur; Agarwal, Anmol. " Evolving Advanced Persistent Threat Detection Using Provenance Graph and Metric Learning." Paper presented at IEEE International Conference on Communications and Network Security (CNS 2020), Avignon, FR. June 29, 2020 - July 01, 2020.. . . . . SP-1245

Sattar, Siamak; Johnson, Katherine. "Recommended Options for Improving the Functional Recovery of the Built Environment and Critical Infrastructure." Paper presented at 17 World Conference on Earthquake Engineering, Sendai, JP. September 13, 2020 - September 18, 2020. . . . . SP-1255

Flowers-Jacobs, Nathan; Babenko, Akim; Fox, Anna; Brevik, Justus; Dresselhaus, Paul; Benz, Samuel P. "Zero-Compensation Josephson Arbitrary Waveform Synthesizer at 1.33 V." Paper presented at 2020 Conference on Precision Electromagnetic Measurements (CPEM), Denver, CO, US. August 24, 2020 - August 28, 2020.. . . . . SP-1266

Manzello, Samuel. "Structure Ignition Mechanisms in Wildland-Urban Interface (WUI) Fire and Associated California State Fire Marshal Standard Test Methods." Paper presented at Japan Association for Fire Science and Engineering, Hirosaki, JP. May 28, 2020 - May 29, 2020.. . . . . SP-1268

Gopman, Daniel; Wang, Jian-Ping; Low, Tony; Wang, Weigang; Taylor, William. "Toward Ultra-fast and Ultra-low Power Switching in Perpendicular Magnetic Tunnel Junctions." Paper presented at GomacTech 2020 Conference, San Diego, CA, US. March 16, 2020 - March 20, 2020.. . . . . SP-1270

Hanke, Aaron; Vernica, Teodor; Bernstein, William Z. "Linking Performance Data and Geospatial Information of Manufacturing Assets through Standard Representations." Paper presented at ASME 2020 International Design Engineering Technical Conferences & Computers and Information in Engineering Conference (IDETC/CIE 2020), St. Louis, MO, US. August 16, 2020 - August 19, 2020.. . . . . SP-1275

Caplins, Benjamin; Blanchard, Paul; Chiaramonti Debay, Ann; Diercks, David; Miaja Avila, Luis; Sanford, Norman A. "Correcting Systematic Energy Deficits in the Laser-Pulsed Atom Probe Mass Spectrum of SiO2." Paper presented at Microscopy and Microanalysis 2020, Milwaukee, WI, US. August 02, 2020 - August 06, 2020. . . . . SP-1284

Moges, Tesfaye; Yang, Zhuo; Jones, Kevontrez; Feng, Shaw C.;

Witherell, Paul; Lu, Yan. "Hybrid Modeling Approach for Melt Pool Prediction in Laser Powder Bed Fusion Additive Manufacturing." Paper presented at ASME 2020 International Design Engineering Technical Conferences and Computers and Information in Engineering Conference (IDETC/CIE 2020), St. Louis, MO, US. August 16, 2020 - August 19, 2020. . . . . SP-1286

Marbukh, Vladimir; Sayrafian, Kamran; Rouzbehani, Behnam. "Utility Proportional Resource Allocation for Users with Diverse SLAs in Virtualized Radio Access Networks." Paper presented at IEEE International Black Sea Conference on Communications and Networking, Odesa, MD, US. May 26, 2020 - May 29, 2020. . . . . SP-1301

Feng, Shaw C.; Lu, Yan; Jones, Albert T. "Measured Data Alignments for Monitoring Metal Additive Manufacturing Processes Using Laser Powder Bed Fusion Methods." Paper presented at the ASME 2020 International Design Engineering Technical Conferences & Computers & Information in Engineering Conference, St. Louis, MO, US. August 16, 2020 - August 19, 2020. . . . . SP-1307

Remley, Kate; Bax, Clive; Mendivil, Edwin; Foegelle, Michael; Kvarnstrand, John; Skousen, Derek; Sanchez-Hernandez, David; Garcia-Fernandez, Miguel; Chang, Lorien; Yen, Elvis; Gutierrez, Johnny; Harbour, Justin. "Over-the-Air Testing of Cellular Large-Form-Factor Internet-of-Things Devices in Reverberation Chambers." Paper presented at 95th ARFTG Microwave Measurements Conference, Los Angeles, CA, US. June 26, 2020 - June 26, 2020. . . . . SP-1315

Manzello, Samuel; Suzuki, Sayaka. "Investigating Coupled Effect of Radiative Heat Flux and Firebrand Showers on Ignition of Fuel Beds - Structure vs Vegetative Firebrands." Paper presented at Japan Association for Fire Science and Engineering, Hirosaki, JP. May 28, 2020 - May 29, 2020. . . . . SP-1319

Curtis, Keith; Awad, George; Rajput, Shahzad; Soboroff, Ian. "HLVU: A new challenge to test deep understanding of movies the way humans do." Paper presented at ACM International Conference on Multimedia Retrieval (ICMR), Dublin, IE. June 08, 2020 - June 11, 2020. . . . . SP-1321

Landauer, Alexander; Van Blitterswyk, Jared; Riley, Michael A.; Forster, Aaron M. "Stress and Strain Heuristics for a Layered Elastomeric Foam at Medium Impact Rates." Paper presented at Society for Experimental Mechanics, Bethel, CT, US. September 14, 2020 - September 17, 2020. . . . . SP-1328

Barnes, Bryan; Henn, Mark-Alexander. "Contrasting Conventional and

Machine Learning Approaches to Optical Critical Dimension Measurements." Paper presented at Metrology, Inspection, and Process Control for Microlithography XXXIV, San Jose, CA, US. February 24, 2020 - February 27, 2020. . . . . SP-1333

On Upper Bounds for D2D Group Size

David Griffith and Aziza Ben Mosbah
National Institute of Standards & Technology

david.griffith@nist.gov

***Abstract*—In this paper, we derive upper bounds for the number of Device-to-Device (D2D)-capable out-of-coverage (OOC) User Equipments (UEs) that can share the Physical Sidelink Discovery Channel (PSDCH) while maintaining a minimum probability of discovery message decoding. We maximize these upper bounds with respect to the UEs' transmission probability threshold by exploiting the fact that the upper bound is nearly linear with respect to the number of resources in the discovery resource pool. The resulting simple approximate bound is accurate over a large range of parameter values. We validate our results using Monte Carlo simulations in MATLAB and the ns-3 simulation tool.**

I. Introduction

Device-to-device (D2D) communications offer a means for improving cellular network efficiency by reducing the load at the base station due to intra-cell traffic. The Proximity Services (ProSe) working group in the Third Generation Partnership Project (3GPP) has defined standards for D2D communications for UEs that are within a base station's coverage area and also for out-of-coverage (OOC) UEs, i.e., those that are outside any cellular coverage [1]. The latter case affects public safety users who may be deployed to remote areas or who may have to operate in regions where cellular service is offline due to a natural or other causes.

Each User Equipment (UE) in a group of UEs must discover the D2D applications hosted by other UEs in the group before it can establish D2D sessions with them. OOC UEs implement the discovery function by transmitting discovery messages over the Physical Sidelink Discovery Channel (PSDCH). The UEs randomly choose Physical Resource Block (PRB) pairs from a periodically recurring discovery resource pool whose dimensions are N_t, the number of subframe sets allocated for a transmission, by N_f, the number of PRB pairs in the frequency domain. There are $N_r = N_f N_t$ PRB pairs, i.e., PSDCH resources, in the discovery resource pool. Because they choose resources randomly, multiple UEs can select the same resource, which causes message collisions that reduce the PSDCH's throughput and delay UE discovery. The ProSe standard tries to fix this problem by incorporating a transmission probability threshold, θ, that UEs can use to throttle their transmissions; a UE will transmit on the PSDCH only if an internally randomly generated number in the unit interval $[0,1]$ is less than θ [2, Clause 5.15.1.1]. The value of θ determines how many UEs can participate in the D2D discovery process while maintaining a given level of performance, i.e., at least a minimum discovery message decoding probability.

Our previous work found the optimal value of θ that maximizes the probability of a successful discovery message transmission from one UE to another [3]. In this paper, we extend this work by deriving an expression for the maximum number of OOC UEs whose members' probability of decoding discovery messages is above a given minimum threshold. In Section II, we obtain an expression for the group size, N_u, as a function of other PSDCH parameters and use it to derive the maximum group size that supports at least a minimum discovery message decoding probability, $P_{\min}$. In Section III, we maximize the group size upper bound with respect to θ. Because direct methods are not tractable, we obtain approximate closed-form expressions for the critical value of θ, and use them to get the maximum group size upper bound. In Section IV, we validate our model using simulations and discuss the implications of the results, and in Section V, we summarize our results.

II. The Maximum Group Size

Let N_u be the number of OOC UEs. We assume that every UE can communicate with every other UE in its neighborhood, and that the UEs are using Model A discovery, i.e., they are continuously sending discovery announcement messages. In each discovery period, each UE generates a discovery message, selects a pool resource, and transmits its message with probability θ. We randomly select two UEs from their group and designate them as UE X and UE Y. From [3], $P_{Y\to X}$, the probability that UE X successfully decodes UE Y's discovery message during a given period, is

$$P_{Y\to X} = \theta\left(1-\frac{\theta}{N_t}\right)\left(1-\frac{\theta}{N_r}\right)^{N_u-2}. \qquad (1)$$

Solving Eq. (1) for N_u gives

$$N_u = \left\lfloor 2+\frac{\log\left(P_{Y\to X}/\theta\right)-\log\left(1-\theta/N_t\right)}{\log\left(1-\theta/N_r\right)}\right\rfloor, \qquad (2)$$

Since $P_{Y\to X} \leq 1$, $\theta \leq 1$, and both N_t and N_r are positive integers, it follows from Eq. (1) that $P_{Y\to X} < \theta$ and $\log\left(P_{Y\to X}/\theta\right) < 0$.

Let $P_{\min}$ be the minimum allowable value of $P_{Y\to X}$. We are interested in determining the largest number of UEs that the

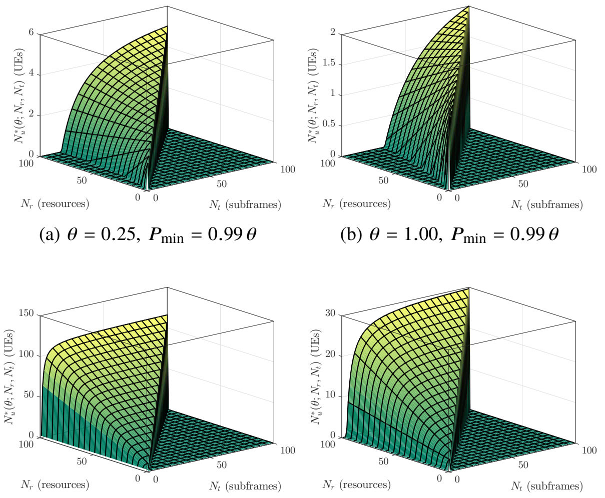
Griffith, David W.; Ben Mosbah, Aziza. "On Upper Bounds for D2D Group Size." Paper presented at 2019 IEEE Global Communications Conference (GLOBECOM), Waikoloa, HI, US. December 09, 2019 - December 13, 2019.



(a) $\theta = 0.25,\ P_{\min} = 0.99\,\theta$

(b) $\theta = 1.00,\ P_{\min} = 0.99\,\theta$

(c) $\theta = 0.25,\ P_{\min} = 0.75\,\theta$

(d) $\theta = 1.00,\ P_{\min} = 0.75\,\theta$

Fig. 1. Plots of $N_u^*(\theta; N_r, N_t)$ versus N_t and N_r, for various values of θ and $P_{\min}$.

discovery resource pool can support so that $P_{Y\to X} \ge P_{\min}$. The derivative of the argument of the floor function in Eq. (2) with respect to $P_{Y\to X}$ is $\left(P_{Y\to X}\log(1-\theta/N_r)\right)^{-1}$. Since $\log(1-\theta/N_r) < 0$, the argument of the floor function is monotonically decreasing with respect to $P_{Y\to X}$. Therefore the maximum value of N_u given $P_{Y\to X} \ge P_{\min}$ is

$$N_u^*(\theta; N_r, N_t) = \left\lfloor 2 + \frac{\log\left(P_{\min}/\theta\right) - \log\left(1-\theta/N_t\right)}{\log\left(1-\theta/N_r\right)} \right\rfloor. \quad (3)$$

Eq. (3) does not hold if $N_t > N_r$, since it is not possible for the number of subframes spanned by the resource pool to exceed the number of pool resources. Also, if $N_u^*(\theta; N_r, N_t) < 0$, then $P_{Y\to X} < P_{\min}$ for all values of N_u. This occurs when

$$N_t < \frac{\theta^2}{\theta - P_{\min}(1-\theta/N_r)^2} \le \frac{\theta^2}{\theta - P_{\min}}, \quad (4)$$

where the higher upper bound is the limit of the lower upper bound as $N_r \longrightarrow \infty$. Eq. (4) indicates that $P_{\min} > P_{Y\to X}$ for all values of N_u when N_t is sufficiently small, because of the half duplex effect.

Fig. 1 shows the effect of variations in θ and $P_{\min}$ on $N_u^*(\theta; N_r, N_t)$. In every subfigure in Fig. 1, we set $N_u^*(\theta; N_r, N_t) = 0$ when $N_t > N_r$, because the number of resources in the pool cannot be less than the number of subframes spanned by the pool. Also, when Eq. (4) holds, we set $N_u^*(\theta; N_r, N_t) = 0$, which produces the flat regions on the left side of each plot in Fig. 1a and Fig. 1b. Also, setting $P_{\min}$ close to θ reduces $N_u^*(\theta; N_r, N_t)$; for example, Fig. 1b shows that when $N_r = 100$ resources, at most two UEs can achieve $P_{Y\to X} \ge 0.99$ when $\theta = 1$.

Fig. 1 shows that the slope of the $N_u^*(\theta; N_r, N_t)$ surface is nearly linear in the N_r direction when N_r and N_t are large. The first and second order partial derivatives of $N_u^*(\theta; N_r, N_t)$ with respect to N_r are

$$\frac{\partial N_u^*(\theta; N_r, N_t)}{\partial N_r} = -\frac{\theta\big(\log(P_{\min}/\theta) - \log(1-\theta/N_t)\big)}{N_r(N_r-\theta)\log^2(1-\theta/N_r)} \quad (5)$$

and

$$\frac{\partial^2 N_u^*(\theta; N_r, N_t)}{\partial N_r^2} = \big(\log(P_{\min}/\theta) - \log(1-\theta/N_t)\big) \times \frac{2\theta^2 + (2\theta N_r - \theta^2)\log(1-\theta/N_r)}{N_r^2(N_r-\theta)^2\log^3(1-\theta/N_r)}. \quad (6)$$

From Eq. (5), when N_r is large the derivative approaches

$$\lim_{N_r\to\infty} \frac{\partial N_u^*(\theta; N_r, N_t)}{\partial N_r} = \frac{\log(1-\theta/N_t) - \log(P_{\min}/\theta)}{\theta}. \quad (7)$$

As N_t increases, the slope in Eq. (7) approaches a constant value: $\lim_{N_r\to\infty, N_t\to\infty} \partial N_u^*(\theta; N_r, N_t)/\partial N_r \approx -\log(P_{\min}/\theta)/\theta$. We confirm this by letting $N_r \longrightarrow \infty$ in Eq. (6), which gives $\lim_{N_r\to\infty} \partial^2 N_u^*(\theta; N_r, N_t)/(\partial N_r^2) = 0$.

Thus, for any value of N_t, we can approximate $N_u^*(\theta; N_r, N_t)$ as a linear function of N_r. We use a Taylor series expansion about the point $N_r = N_t$. If we retain only the constant and linear terms, we get

$$N_u^*(\theta; N_r, N_t) \approx \left(1 + \frac{\log(P_{\min}/\theta)}{\log(1-\theta/N_t)}\right) - \frac{\theta\left(\log(P_{\min}/\theta) - \log(1-\theta/N_t)\right)}{N_t(N_t-\theta)\log^2(1-\theta/N_t)}(N_r - N_t). \quad (8)$$

We want to find the maximum group size, given a pool of N_r resources, over the range of values for N_t. We define this upper bound as follows:

$$N_u^{\max}(\theta; N_r) = \max_{N_t} N_u^*(\theta; N_r, N_t). \quad (9)$$

We can use Eq. (3) to derive $N_u^{\max}(\theta; N_r)$. The derivative of the argument of the floor function in Eq. (3) with respect to N_t is $-\theta/[N_t(N_t-\theta)\log(1-\theta/N_r)]$. Since $\log(1-\theta/N_r) < 0$ and $\theta < N_t \le N_r$, the derivative is positive over the interval of interest, so that $N_u^*(\theta; N_r, N_t)$ is a non-decreasing function of N_t. Setting $N_t = N_r$ gives

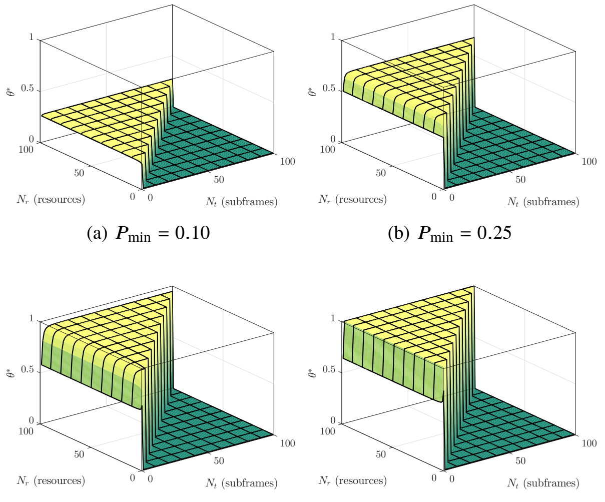
$$N_u^{\max}(\theta; N_r) = \left\lfloor 1 + \frac{\log\left(P_{\min}/\theta\right)}{\log\left(1-\theta/N_r\right)} \right\rfloor \ge N_u^*(\theta; N_r, N_t). \quad (10)$$

III. Maximum Group Size Bounds with Respect to θ

In this section, we maximize N_u^* in Eq. (3) and $N_u^{\max}$ in Eq. (10) with respect to θ. We assume that all N_u UEs use the same value for θ. We let θ^* be the value of θ that maximizes $N_u^*(\theta; N_r, N_t)$, and we let $\theta^{\max}$ be the value of θ that maximizes $N_u^{\max}(\theta; N_r)$.

We can simplify the problem by showing that θ^* is nearly constant with respect to N_r and N_t, and by showing that $\theta^* \approx \theta^{\max}$ unless N_t is small. Consider a set of pool dimensions where $N_r \le 100$ resources and $N_t \le N_r$ subframes. For each ordered pair (N_r, N_t), we use numerical methods to find θ^*,

Griffith, David W.; Ben Mosbah, Aziza. "On Upper Bounds for D2D Group Size." Paper presented at 2019 IEEE Global Communications Conference (GLOBECOM), Waikoloa, HI, US. December 09, 2019 - December 13, 2019.



(a) $P_{\min} = 0.10$ (b) $P_{\min} = 0.25$

(c) $P_{\min} = 0.35$ (d) $P_{\min} = 0.50$

Fig. 2. Plots of θ^*, which is the value of θ that minimizes Eq. (3), versus N_t and N_r, for various values of $P_{\min}$.

and we use the following values of $P_{\min}$: 0.10, 0.25, 0.35, and 0.50; the resulting plots of θ^* are shown in Fig. 2.

Fig. 2 shows that θ^* is insensitive to N_r and N_t, except when N_t is small (i.e., $N_t < 10$ subframes). Fig. 2a shows that when $P_{\min}$ is small, θ^* is nearly constant over all values of N_r and N_t, and Fig. 2d shows that θ^* varies with respect to N_t only when $N_t = 1$ subframe. Fig. 2b and Fig. 2c show more variation of θ^* with respect to N_t, but this occurs when $N_t < 10$ subframes.

The insensitivity of θ^* to N_r and N_t, and the fact that $\theta^* = \theta^{\max}$ when $N_r = N_t$, implies that $\theta^* \approx \theta^{\max}$ unless N_t is very small. Additional analysis shows that if $P_{\min} = 1/\mathsf{e}$, $\theta^* = 1$ over almost the entire set of values for N_t and N_r. Thus, we can obtain a good approximation for θ^* by finding $\theta^{\max}$.

As we will show, $N_u^{\max}(\theta; N_r)$ is linear with respect to the pool size, N_r. We expand $N_u^{\max}(\theta; N_r)$ in a Taylor series about $N_r = a$:

$$\begin{aligned} N_u^{\max}(\theta; N_r) = \Big\lfloor \Big(1 + \tfrac{\log(P_{\min}/\theta)}{\log(1-\theta/a))}\Big) - \tfrac{\theta \log(P_{\min}/\theta)}{a(a-\theta)\log^2(1-\theta/a))}(N_r - a) \\ + \tfrac{1}{2}\tfrac{\log(P_{\min}/\theta)\left[2\theta^2-(\theta^2-2a\theta)\log(1-\theta/a)\right]}{a^2(a-\theta)^2\log^3(1-\theta/a)}(N_r - a)^2 \\ + O\big((N_r - a)^3\big)\Big\rfloor. \end{aligned} \quad (11)$$

Derivatives of order two and higher in Eq. (11) vanish as a becomes very large, so the limit as $a \to \infty$ is

$$\begin{aligned} \lim_{a\to\infty} N_u^{\max}(\theta; N_r) &= \Big\lfloor \lim_{a\to\infty}\Big(1 + \tfrac{[\theta+(a-\theta)\log(1-\theta/a)]\log(P_{\min}/\theta)}{(a-\theta)\log^2(1-\theta/a)}\Big) \\ &\qquad - N_r \lim_{a\to\infty} \tfrac{\theta\log(P_{\min}/\theta)}{a(a-\theta)\log^2(1-\theta/a)}\Big\rfloor \\ &= \Big\lfloor 1 + \Big(\tfrac{1}{2} - \tfrac{N_r}{\theta}\Big)\log(P_{\min}/\theta)\Big\rfloor. \end{aligned} \quad (12)$$

To find our approximate value for $\theta^{\max}$, we take the derivative of the argument of the floor function with respect to θ:

$$\frac{\mathrm{d}}{\mathrm{d}\theta}\Big[1 + \Big(\tfrac{1}{2} - \tfrac{N_r}{\theta}\Big)\log\big(\tfrac{P_{\min}}{\theta}\big)\Big] = \frac{2N_r(1 + \log(P_{\min}/\theta)) - \theta}{2\theta^2}. \quad (13)$$

Setting the numerator in Eq. (13) equal to zero and rearranging the resulting expression gives:

$$\frac{\mathsf{e}P_{\min}}{2N_r} = \frac{\theta^{\max}}{2N_r}\mathsf{e}^{\theta^{\max}/(2N_r)}. \quad (14)$$

To solve Eq. (14) for $\theta^{\max}$, we use Lambert's W function, $\mathsf{W}(z)$, which is defined $\forall z \in \mathbb{C}$ as $z = \mathsf{W}(z)\exp\big(\mathsf{W}(z)\big)$ [4, Eq. (1.5)]. We match Eq. (14) to the W function's definition by letting $z = \mathsf{e}P_{\min}/(2N_r)$ and $\mathsf{W}(z) = \theta^{\max}/(2N_r)$, giving

$$\theta^{\max} = 2N_r\,\mathsf{W}(z) = 2N_r\,\mathsf{W}\big(\mathsf{e}P_{\min}/(2N_r)\big). \quad (15)$$

We also obtain a simple approximate value for $\theta^{\max}$ as follows. The Taylor series expansion of the W function about the point $x = 0$ has the form [4, Eq. (3.1)]

$$\mathsf{W}(x) = \sum_{n=1}^{\infty}\frac{(-n)^{n-1}}{n!}x^n, \quad (16)$$

and from this and Eq. (15), we get the series expansion for $\theta^{\max}$:

$$\theta^{\max} = \mathsf{e}P_{\min} - \frac{(\mathsf{e}P_{\min})^2}{2N_r} + O\left(\frac{(P_{\min})^3}{N_r^2}\right). \quad (17)$$

Since $P_{\min} > 0$ and $\mathsf{W}(0) = 0$, letting $N_r \to \infty$ gives

$$\lim_{N_r\to\infty}\theta^{\max} = \mathsf{e}P_{\min}\exp\big(-\mathsf{W}(0)\big) = \mathsf{e}P_{\min}, \quad (18)$$

Thus we have the following approximation for $\theta^{\max}$:

$$\theta^{\max} \approx \begin{cases} \mathsf{e}P_{\min}, & 0 < P_{\min} \le 1/\mathsf{e} \\ 1, & 1/\mathsf{e} < P_{\min} \le 1 \end{cases} \quad (19)$$

Using Eq. (19) with Eq. (10), we get the following approximate expression for the maximum group size:

$$N_u^{\max}(\theta; N_r) \approx \begin{cases} \left\lfloor 1 - \frac{1}{\log\left(1 - \frac{\mathsf{e}P_{\min}}{N_r}\right)}\right\rfloor, & 0 < P_{\min} \le 1/\mathsf{e} \\ \left\lfloor 1 + \frac{\log(P_{\min})}{\log\left(1 - \frac{1}{N_r}\right)}\right\rfloor, & 1/\mathsf{e} < P_{\min} \le 1 \end{cases} \quad (20)$$

If we expand the two terms in Eq. (20) as a pair of Taylor series about $N_r = a$ and then let $a \to \infty$, we get

$$1 - \frac{1}{\log\left(1 - \frac{\mathsf{e}P_{\min}}{N_r}\right)} = \frac{N_r}{\mathsf{e}P_{\min}} + \frac{1}{2} - \frac{\mathsf{e}P_{\min}}{12N_r} - \frac{\mathsf{e}^2P_{\min}^2}{24N_r^2} + O\left(\left(\frac{1}{N_r}\right)^3\right) \quad (21a)$$

$$\begin{aligned} 1 + \frac{\log(P_{\min})}{\log\left(1 - \frac{1}{N_r}\right)} &= -N_r\log(P_{\min}) + \left(1 + \frac{\log(P_{\min})}{2}\right) \\ &\quad + \frac{\log(P_{\min})}{12N_r} + \frac{\log(P_{\min})}{24N_r^2} + O\left(\left(\frac{1}{N_r}\right)^3\right). \end{aligned} \quad (21b)$$

If N_r is large, we can use Eq. (21) to get the following approximate expression for $N_u^{\max}(\theta; N_r)$:

$$N_u^{\max}(\theta; N_r) \approx \begin{cases} \left\lfloor \frac{1}{2} + N_r/(\mathrm{e}P_{\min}) \right\rfloor, & 0 < P_{\min} \leq 1/\mathrm{e} \\ \left\lfloor 1 - \left(N_r - \frac{1}{2}\right) \log(P_{\min}) \right\rfloor, & 1/\mathrm{e} < P_{\min} \leq 1 \end{cases} \tag{22}$$

The approximations are very close to the actual values. In Fig. 3 we plot the approximation error for $\theta^{\max}$ and $N_u^{\max}(\theta; N_r)$ versus N_r. First, in Fig. 3a, we plot the absolute error between the exact value of $\theta^{\max}$ and its approximate value from Eq. (19). The error decreases as N_r increases and $P_{\min}$ decreases. By increasing $P_{\min}$, the error increases to an asymptotic value associated with $P_{\min} = 1/\mathrm{e}$, for any N_r. Beyond $P_{\min} = 1/\mathrm{e}$, $\theta^{\max} = 1$, and the error remains at the level associated with $P_{\min} = 1/\mathrm{e}$. The error is significant for high values of $P_{\min}$ and small pool sizes; for example, it is greater than 0.1 for $N_r < 5$ resources when $P_{\min} \geq 1/\mathrm{e}$. However, discovery resource pools that are so small do not seem likely to be implemented in practical systems. For $N_r > 50$ resources, the greatest error in the value of $\theta^{\max}$ is less than 0.01, and the error is less than 0.001 for $N_r > 500$ resources.

We plot the absolute error in $N_u^{\max}(\theta; N_r)$ versus N_r in Fig. 3b, comparing the exact value from Eq. (10) with the approximation from Eq. (22). We use a different set of values for $P_{\min}$ to show the effect when $P_{\min} > 1/\mathrm{e}$. In this case, the error is less than $1/2$ over the full range of values of N_r. Thus, the approximation in Eq. (22) is accurate enough that it can be used in all cases.

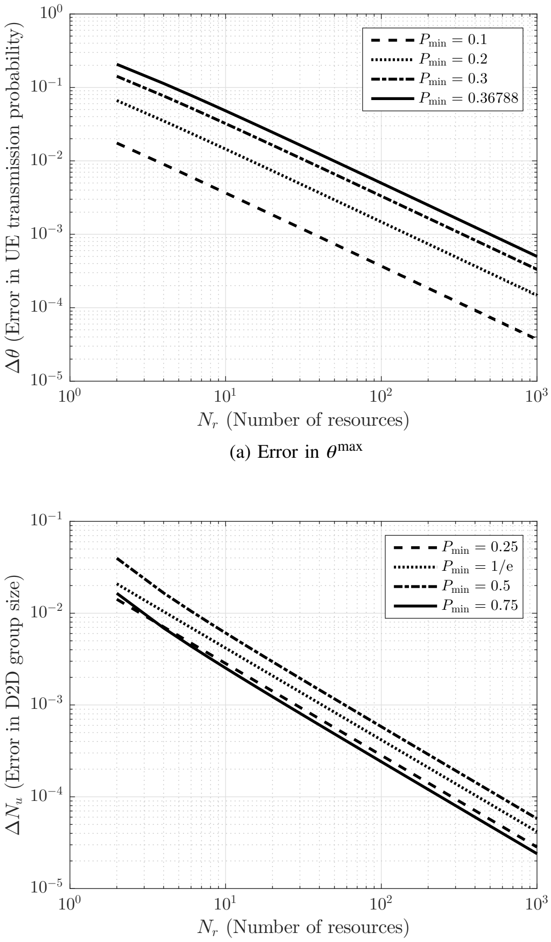
IV. Validation and Numerical Results

We validated our results from Section II and Section III by performing Monte Carlo simulations of discovery pool resource selection in MATLAB, and we compared the resulting maximum group size with what was predicted by Eqs. (3) and (10). We also examined the impact of the discovery pool dimensions on the group size upper bound by performing simulations in ns-3 of a group of OOC UEs exchanging discovery messages over the PSDCH, in which we obtained the maximum group size $N_u^*(\theta; N_r, N_t)$ versus $P_{\min}$, using the following four values for θ: 1/4, 1/2, 3/4, and 1.

A. Monte Carlo Simulations

We simulated the discovery resource selection process for a discovery pool size of $N_r = 40$ resources, using the parameters shown in Table I. As the extent of the resource pool in the time domain decreases, the half-duplex effect has a greater impact on the ability of UEs to decode discovery messages. This will reduce the maximum OOC group size that can achieve $P_{Y \to X} \geq P_{\min}$.

For each set of pool parameters, we used the following three values for $P_{\min}$: 0.2, 0.3, and 0.4. We used Eq. (19) to generate the following respective values of θ: 0.5437, 0.8155, and 1. We assigned the generated value of θ to each UE in the OOC group, and we computed $N_u^*(\theta; N_r, N_t)$ and $N_u^{\max}(\theta; N_r)$, which are listed in Table I.



(a) Error in $\theta^{\max}$

(b) Error in $N_u^{\max}(\theta; N_r)$

Fig. 3. Errors between approximate and exact values of $\theta^{\max}$ and $N_u^{\max}(\theta; N_r)$

TABLE I
Monte Carlo Simulation Parameters

N_f	N_t	$P_{\min}$	θ	N_u^*	$N_u^{\max}$
1	40	0.2	0.5437	74	74
		0.3	0.8155	49	49
		0.4	1.0000	37	37
4	10	0.2	0.5437	70	74
		0.3	0.8155	46	49
		0.4	1.0000	34	37
10	4	0.2	0.5437	64	74
		0.3	0.8155	39	49
		0.4	1.0000	26	37

For each set of pool parameters and value of $P_{\min}$, we simulated N_u UEs, where N_u varied from $N_u^* - 2$ to $N_u^{\max} + 2$, because we are interested in examining the behavior of $P_{Y \to X}$ in the vicinity of the theoretical upper bounds on N_u. For each value of N_u we performed $N_{\text{runs}} = 100$ runs, with $N_{\text{trials}} = 1000$ trials per run. For each trial, we designated a random UE as UE_0, the transmitter of interest, and we chose a second random UE to be the receiver. Each UE independently generated a random transmission decision variable, $p1$. If $p1 \leq \theta$, the UE transmitted; otherwise, it did not. UEs that decided to transmit discovery messages chose one of the N_r resources in the pool with uniform probability. Each UE's resource choice was independent of the choices of all other UEs. UEs kept track of which subframe set they were using to send their discovery messages. The trial was a success if UE_0 decided to transmit, no other UE chose UE_0's resource, and the receiver did not transmit in the same subframe set as UE_0. Any other outcome was a failure.

The estimated value of $P_{Y\to X}$ for each run is the ratio of the number of successful trials to the number of trials in the run. The output of each simulation was a set of N_{runs} estimates for $P_{Y\to X}$: $\{\widehat{P}_{Y\to X}(n)\}_{n=1}^{N_{\text{runs}}}$. The estimate of $P_{Y\to X}$ is

$$\widehat{P}_{Y\to X} = \frac{1}{N_{\text{runs}}} \sum_{n=1}^{N_{\text{runs}}} \widehat{P}_{Y\to X}(n) \qquad (23)$$

The standard deviation of the set of estimates of $P_{Y\to X}$ is:

$$\widehat{\sigma}_{\widehat{P}_{Y\to X}} = \sqrt{\frac{1}{N_{\text{runs}}-1} \sum_{n=1}^{N_{\text{runs}}} \left(\widehat{P}_{Y\to X}(n) - \widehat{P}_{Y\to X}\right)^2} \qquad (24)$$

Using Eqs. (23) and (24), we plot the 95 % confidence interval associated with the simulation result, whose limits are

$$\widehat{P}_{Y\to X} \pm 1.96\,\widehat{\sigma}_{\widehat{P}_{Y\to X}}/\sqrt{N_{\text{runs}}}. \qquad (25)$$

Fig. 4 shows the simulation results that we obtained using the parameters listed in Table I. In each subfigure, we plot $P_{Y\to X}$ versus N_u for a given set of pool parameters, with different markers for each of the three values of $P_{\min}$ that we used. We show the theoretical values of N_u^*, listed in Table I, in each subfigure with additional ticks on the N_u-axis. In each subfigure, $P_{Y\to X}$ decreases with respect to N_u, so that N_u^* is the largest value of N_u such that $P_{Y\to X} \geq P_{\min}$, which validates the model. The slope of $P_{Y\to X}$ decreases as $P_{\min}$ decreases, so that $P_{Y\to X}$ becomes less sensitive to N_u. Note that in Fig. 4a, $N_u^* = N_u^{\max}$. Also, the sensitivity of N_u^* to $P_{\min}$ increases as $P_{\min}$ becomes small.

Figs. 4b and 4c show the effect of modifying the discovery resource pool parameters while keeping N_r constant. For a pool with $N_f = 4$ PRB pairs and $N_t = 10$ subframe sets, N_u^* is below $N_u^{\max}$ by 5.71 %, 6.52 %, and 8.82 % for $P_{\min}$ values of 0.2, 0.3, and 0.4, respectively. The effect is greater when $N_f = 10$ PRBs and $N_t = 4$ subframe sets, where N_u^* is below $N_u^{\max}$ by 15.63 %, 25.64 %, and 42.31 % for $P_{\min}$ values of 0.2, 0.3, and 0.4, respectively.

B. Simulations using ns-3

Our ns-3 simulations examine the impact of the pool parameters on the group size upper bound. We examined four values of θ: 0.25, 0.50, 0.75, and 1.00. For each value of θ, we created groups of UEs whose sizes were multiples of 15, up to a maximum of 150 UEs, and we examined groups consisting of 2 UEs. All UEs used the same value of θ. For each combination of group size and θ, we considered the same three discovery resource pool configurations that we examined in Section IV-A, each of which has $N_r = 40$ resources.

For each set of parameters, we conducted 10 runs, with 10 trials per run. We obtained estimates of $P_{Y\to X}$ for each trial, and obtained estimates of the mean and standard deviation using Eqs. (23) and (24), and used Eq. (25) to obtain 95 % confidence intervals. Fig. 5 shows the results; we use connecting lines to make the graphs legible and to illustrate trends in the data.

We compared our results to the theoretical model and found excellent agreement; we do not show the theoretical results in Fig. 5 for the sake of clarity in the subfigures. The figures collectively show that the group size upper bounds are most sensitive to $P_{\min}$ when θ is large, since increasing each UE's transmission rate increases the offered load, which increases the collision rate. Also, the effect of the pool parameters on the upper bound is more pronounced when $P_{\min}$ is small and when θ is large. The plots show that if we want $P_{\min}$ to be close to θ (e.g., within 90 %), N_u must be small. For example, when $\theta = 0.25$, we can satisfy $P_{\min} \approx 0.9\,\theta$ with a group that comprises at most about 15 UEs. Larger upper bounds for the group size are achievable only with a larger resource pool, preferably one where $N_t > N_f$.

V. Summary

In this paper, we derived an upper bound for the size of a group of OOC UEs whose members' probability of decoding discovery messages is at least $P_{\min}$. We showed that the value of θ that maximizes the group size upper bound is insensitive to the discovery pool dimensions. By using a linear approximation for the upper bound, we developed a closed-form expression for the optimal value of θ. We then showed that the optimal value of θ is proportional to $P_{\min}$, which yields a simple expression for the maximum group size. We validated our results using both Monte Carlo simulations in MATLAB and simulations of the PSDCH used by OOC UEs in the ns-3 network simulation tool.

Keywords: GaN nanowires, UV LEDs, core-shell

Nanowire-based ultraviolet (UV) LEDs hold great promise as nanoscale light sources, potentially enabling advanced scanning microscopy probes capable of optoelectronic sensing and near-field scanning photolithography. In this work, we report on the synthesis of core-shell nanowire LEDs, including characterization of *p-i-n* junctions and AlGaN/GaN heterostructures for enhanced injection and confinement of minority carriers.

Ordered nanowire arrays were grown on silicon substrates via an N-polar selective area nanowire growth process.[1] These silicon-doped nanowire cores were then overcoated with a conformal Mg:GaN shell layer to produce nanowires arrays with *p-i-n* structure. As shown in Figure 1a, the nanowire LEDs produce electroluminescence under forward bias with emission at 380 nm, corresponding to donor-acceptor-pair (DAP) recombination in the *p*-type shell layer. For extending the LED emission towards shorter wavelengths, nanowire arrays with AlGaN shell layers were also grown using conditions identical to those used for the Mg:GaN shells. The AlGaN overcoats were found to exhibit thickness and compositional gradients that depended on the nanowire diameter. As shown in Figure 1b, the thickness of the axial segment of the AlGaN shell was larger in small-diameter nanowires. The Al mole fraction was also observed to decrease for small-diameter nanowires, as determined by photoluminescence measurements (Figure 1c). These observations are consistent with diffusion-induced transport of Ga (but not Al) to the nanowire tip during growth, which effectively increased the axial growth rate and diluted the alloy concentration at the tip.

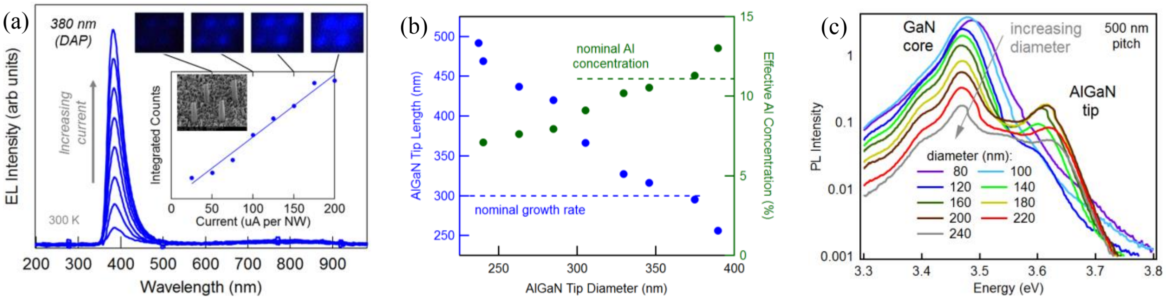

Figure 1. *(a) Core-shell p-i-n GaN nanowire LEDs emitting at 380 nm and (b) dimensional and (c) photoluminescence measurements of AlGaN/GaN core-shell heterostructures. The dotted lines in (b) indicate equivalent planar values for the nominal growth rate and Al mole fraction.*

Estimating Interzonal Leakage in a Net-Zero Energy House

Lisa Ng[1], Lindsey Kinser[2], Steven Emmerich[1], Andrew Persily[1]

[1] Indoor Air Quality and Ventilation Group, Engineering Laboratory, National Institute of Standards and Technology, Gaithersburg MD

ABSTRACT

The Net-Zero Energy Residential Test Facility (NZERTF) was constructed at the National Institute of Standards and Technology (NIST) to support the development and adoption of cost-effective net-zero energy designs and technologies. The 250 m^2 two-story, unoccupied NZERTF, built in 2012, had among its design goals an airtight and highly insulated building enclosure designed for heat, air and moisture control. The airtightness goal was achieved through detailed envelope design, and careful construction, as well as during and after construction commissioning. When it was built, the NZERTF was one of the tightest residential buildings in North America with a whole building pressurization test result of roughly 0.6 h^{-1} at 50 Pa measured per ASTM E779-19, *Standard Test Method for Determining Air Leakage Rate by Fan Pressurization*. No special attention was given to the airtightness of the interior floors and other interior partitions. To support airflow modeling efforts, this interior leakage was quantified through a series of interzonal pressurization tests. Both the basement and attic were considered to be conditioned spaces because the thermal and air-moisture barriers encompass the basement walls and attic roof. Transfer grilles and other openings linked the living space to these two zones. A series of fan and partition configurations were used to quantify the leakage values of the various interzone airflow paths. Test results showed that the interior floors were more than 10 times leakier than the exterior building envelope and that the leakage associated with the transfer grilles between levels was less than the floor leakage. This paper describes the design of the interzonal tests and the challenges in

Ng, Lisa; Kinser, Lindsey; Emmerich, Steven; Persily, Andrew K. "Estimating Interzonal Leakage in a Net-Zero Energy House." Paper presented at ASTM Symposium on Whole Building Air Leakage: Testing and Building Performance Impacts, San Diego, CA, US. April 08, 2018 - April 09, 2018.

performing them, which included isolating zones, controlling multiple blower doors, and access for installing pressurization fans. The results of these tests were inputs to a multizone airflow (CONTAM) model of the building for use in evaluating the effects of different ventilation strategies and other airflow-related technologies on energy consumption and indoor air quality.

airtightness, interzonal leakage, net-zero house, ASTM E779-10, pressurization tests

INTRODUCTION

In 2017, buildings were associated with 39 % of all energy used in the United States, with residential buildings and commercial buildings accounting for 20 % and 19 %, respectively [1]. Based on estimates by the U. S. Department of Energy (DOE), infiltration alone accounts for 14 % and 6 % of the energy used by residential and commercial buildings, respectively [2]. To reduce these energy impacts, tighter building envelopes are being required by codes and standards [2-5]. There are no standards related to the leakiness of interior floors and walls based on energy and indoor air quality considerations (though some fire codes address the issue), even though interzonal airflow through these surfaces can be important for contaminant transport and thus occupant exposure [6].

The literature on interzonal airflow experiments includes analyses of two-zone test cases [7-9]. Determining interzonal airflow is more difficult than whole building testing, either requiring a series of pressurization tests or multiple tracer gas tests. Emmerich et al. [7] conducted interzonal pressurization tests in five homes with attached garages to determine the leakiness of the house-garage interface. The tests involved placing one or two fans in different exterior doorways and altering the positions of the door connecting the two zones, as well as of the garage door to the outside. They found that the house-garage interface (normalized by the house-garage surface area) was two and half times to nearly eleven times leakier than the house exterior envelope (normalized by the house exterior surface area), which has implications for the transfer of contaminants from garages into houses. Hult et al. [9] compared the results of various single-fan and two-fan tests of the leakiness of house-garage interfaces. They also compared single-pressure difference to multiple-pressure difference tests. They found that a method using one fan in two configurations provided results with the smallest uncertainty among the single-fan tests. In general, the single-pressure tests led to less reliable results than the multiple-pressure tests. Though requiring an extra configuration, the "one-fan, three configurations" test performed by Emmerich et al. [7] also resulted in low uncertainty.

Tracer gas tests have also been used to determine interzonal airflow rates, as opposed to the interzone partition leakiness determined by the previously-described fan pressurization tests [10-15]. Du et al. [16] conducted constant-concentration tracer tests in several homes using two tracer gases. The steady-state concentrations of the tracer gases were used to estimate the airflow rates between a bedroom and the rest of the home. They found that most of the air entering the bedrooms came from somewhere else in the house and not from outside. Conversely, most of the air entering the rest of the house came from outside and not from the bedroom. They also found that homes that relied more on central heating and cooling systems had relatively higher interzonal airflows than homes in which occupants opened windows for ventilation.

This paper examines the use of blower door tests to determine the effective leakage area (ELA) of various house components (exterior envelope, interior floor leakage, leakage of transfer grilles) for input into a multizone airflow model. The results of such simulations can be used to evaluate different ventilation strategies and other airflow-related technologies to study the effects of weather, indoor conditions, and system operation on interzonal airflow and contaminant transport. This paper describes the test house, the design of the interzonal tests and the challenges in performing these tests, as well as the performance of a multizone airflow model (i.e., CONTAM) using measured values of interior leakages to predict contaminant concentrations. Interzonal tracer decay tests also were performed, and their analyses are saved for future work.

TEST HOUSE

The Net-Zero Energy Residential Test Facility (NZERTF) was built on the campus of the National Institute of Standards and Technology (NIST) in 2012 to demonstrate low-energy residential technologies with the goal of net-zero energy use on an annual basis (FIG. 1). The NZERTF is a 250 m^2 two-story, unoccupied house located in Gaithersburg, MD with an unfinished basement and an attic, both within the conditioned space. As reflected in TABLE 1, which summarizes the physical characteristics of the house, the basement is mostly below-grade, with a window well providing egress. A two-story foyer with a staircase connects the first and second floor, which has a horizontal area of approximately 17 m^2 (12 % of the first floor area). Given the open connection between these two floors, they were considered a single zone in these tests.

The detached garage contains the controls and data acquisition systems of the instruments and sensors in the NZERTF, so that their heat load is not introduced into the home. Lighting, appliances, plug loads, and sensible and latent heat loads of the simulated occupants are controlled by the data acquisition system [17]. A virtual family consisting of two adults and two children are simulated in the house, with their electrical and water usage varying over a seven-day schedule [18].

TABLE 1. Physical characteristics of NZERTF

Building characteristic	**Value**
Roof area	184 m^2
Basement wall area (above-grade)	2 m^2
First floor/second floor exterior wall area	314 m^2
Attic floor	130 m^2
Basement ceiling	151 m^2
Total exterior surface area	500 m^2
Total volume (basement, first floor, second floor, attic)	1300 m^3

The main design goal of the NZERTF was to achieve net-zero energy use over the course of a year, which was achieved from July 2013 to June 2014. One of the ways to reduce energy use in homes is to reduce heating and cooling loads because Since infiltration can account for 14 % of the total energy use of a home, the NZERTF was designed and constructed to be airtight. The building envelope airtightness of the NZERTF was tested to be 0.63 h^{-1} at 50 Pa [19], which is tighter than the requirements in LEED v4 [20] and ENERGY STAR v3.1 [21], and only slightly leakier than the Passive House U. S. requirement [22]. The normalized leakage (NL) value for the house equals 0.06, which is tighter than 99 % of U.S. homes based on statistical analysis of the Lawrence Berkeley National Laboratory Residential Diagnostics Database [23]. The NL value is defined in the ASHRAE Fundamentals Handbook [24] as follows:

$$NL = 1000 \left(\frac{ELA_4}{Area}\right)\left(\frac{H}{2.5\ m}\right)^{0.3} \tag{1}$$

where ELA_4 (m^2) is the ELA at 4 Pa, Area (m^2) is the floor area, and H (m) is the house height.

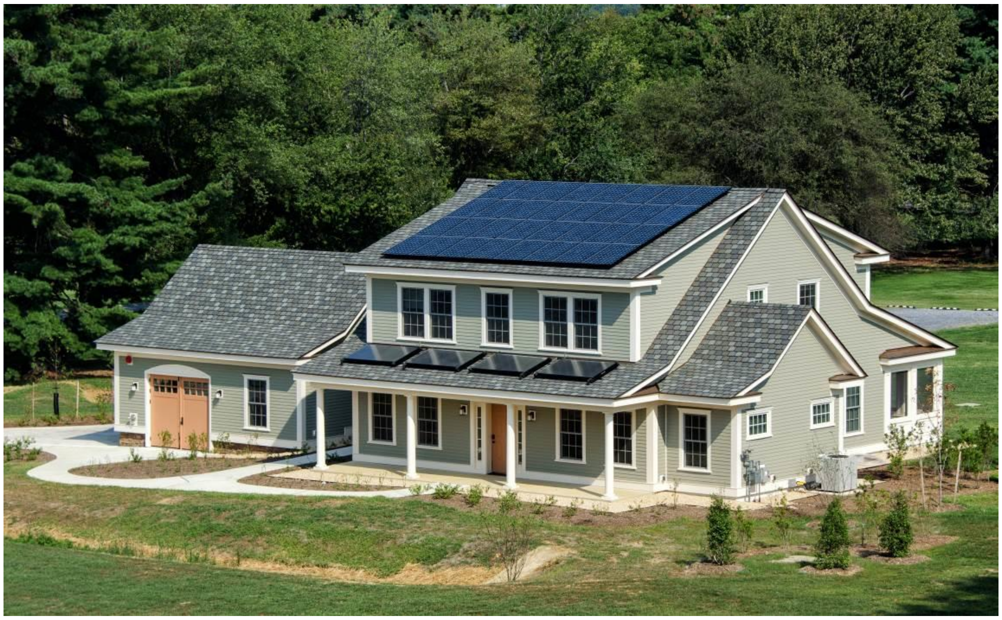

FIG. 1. NZERTF at NIST facing south.

The basement, first floor, and second floor were actively conditioned by a central, air-source heat pump. The central heat pump had supplies in the basement, first floor, and second floor. Two returns were on the first floor and two returns were on the second floor. The heat pump has no outdoor air intake. Three transfer grilles were located on the floor of the first level to allow airflow between the basement and the house (referred to as the first floor transfer grilles). Two transfer grilles were located on the ceiling of the second floor to allow airflow between the attic and the house (FIG. 2a) referred to as the attic transfer grilles. Because the attic is within the thermal envelope, the attic transfer grilles were installed to provide the attic with conditioned air without requiring air distribution ductwork in the attic [25]. All the transfer grilles contain a damper that would close in case of a fire. The basement door and the attic hatch were closed during normal operation of the house. The basement door had an undercut that was approximately 0.9 m wide by

Ng, Lisa; Kinser, Lindsey; Emmerich, Steven; Persily, Andrew K. "Estimating Interzonal Leakage in a Net-Zero Energy House." Paper presented at ASTM Symposium on Whole Building Air Leakage: Testing and Building Performance Impacts, San Diego, CA, US. April 08, 2018 - April 09, 2018.

2.5 cm high, and the attic hatch door had a gap around it that was approximately 0.3 cm wide and 5.5 m long around its perimeter. Under depressurization, smoke tests were performed around interior airflow paths, such as the transfer grilles and around the basement door (FIG. 2) to better understand the airflow through these building elements. Smoke tests were also used to identify airflow paths that should be sealed during pressurization testing, such as the access panels in a bathroom used for signal and control wire (FIG. 2c) to isolate and determine leakage associated with the construction of the floors, basement door, and attic door. Other interior airflow paths that were sealed during testing included the supplies and returns of the central heat pump and the independently ducted mechanical ventilation system, the heat recovery ventilator (HRV). The HRV was balanced, with supplies on the first and second floors and exhausts in the bathrooms on the first and second floors. Both systems were turned off during all of the pressurization tests. The kitchen exhaust fan and dryer also were turned off, and their exterior vents were sealed.

(a) Floor transfer grille (b) Basement door (c) Access panel

FIG. 2 Photographs of smoke tests performed at NZERTF at the (a) floor transfer grilles, (b) basement door, and (c) access panel while depressurizing. Arrows indicate direction of airflow.

Because the NZERTF is airtight, the designers wanted to prevent the house from depressurizing when either the kitchen exhaust fan or dryer were turned on. Thus, a 15-cm round duct was installed in the attic, penetrating the exterior attic wall on the west side, with motorized and barometric dampers installed in the duct. The motorized damper was activated when either the kitchen exhaust fan or dryer was turned on. The barometric damper would open if the motorized damper was open and if the inside pressure was 10 Pa less than the outside pressure.

METHODOLOGY

The testing and data analysis methodologies as follows:

(1) Five house configurations were tested under various blower door arrangements.

(2) Each test configuration was expressed in mathematical form following the analogy of an electrical circuit with pressure corresponding to voltage and airflow corresponding to current. The airflow Q and pressure difference ΔP across a surface were represented by the equation $Q = C\Delta P^{n}$, where C is the flow coefficient ($m^3/s{\bullet}Pa$) and n is the pressure exponent. Both C and n were determined from the test data. These expressions formed the system of the equations needed to solve for the ELAs of the following building surfaces: roof (L_{R}), basement wall (L_{BW}), living area (first floor/second floor) walls (L_{W}), attic floor (L_{AF}), and basement ceiling leakage (L_{BC}) (illustrated in FIG. 3).

(3) The simultaneous solution of this system of equations resulted in values of C for each of the list building surfaces. C was converted to effective leakage, L, using the following equation

[24]:

$$L\ (\text{cm}^2)\ \text{at}\ \Delta P_{\text{ref}} = C \bullet (\rho/2)^{0.5} \bullet (\Delta P_{\text{ref}})^{\text{n-0.5}} \bullet 100^2 \qquad (2)$$

where ΔP_{ref} is the reference differential pressure (Pa) and ρ is the density of air (kg/m^3).

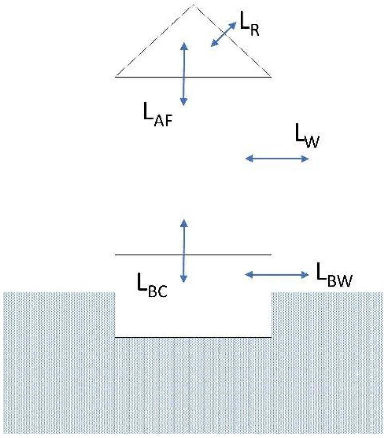

FIG. 3. Building surface leakages in NZERTF.

(4) The effective leakage of the basement door undercut and transfer grilles were determined by subtracting the result of the comparable "sealed" test configuration from the "unsealed" test result.

(1) Test Setup

Two blower doors, which complied with the requirements of ASTM E779-19, *Standard Test Method for Determining Air Leakage Rate by Fan Pressurization,* were used in the tests. Pressures were measured using a multichannel pressure measurement and fan control apparatus from the same manufacturer as the blower doors. Baseline pressures were recorded when the fan was turned off before and after each blower door test. These values were then averaged and subtracted from each measured pressure recorded during the test, as outlined in ASTM E779. The data logging and control software allowed for the simultaneous measurement of differential pressures across the fan and at three locations throughout the house. The software was setup to record differential pressures and fan flow rates between 10 Pa and 60 Pa in increments of 5 Pa, in both pressurization and depressurization modes. The software also provided the ability to take 100 pressure differential readings at each incremental differential pressure value and report the average. All tests were conducted over two weeks in November 2016, during which time the average indoor temperature was 21 °C, outdoor temperature was 7 °C and wind speed was 4 m/s.

(2) Test Configurations

Five house configurations were tested, varying the placement of the fan and open/closed status of exterior and interior doors (FIG. 4). All tests were successfully executed except for Test #3, which required the attic pressure to be at the same as the outside pressure. The existing opening in the attic (makeup-air duct) was not large enough to neutralize the attic-outdoor pressure. Details of each test and the mathematical expressions used to represent each test are described in the following sections.

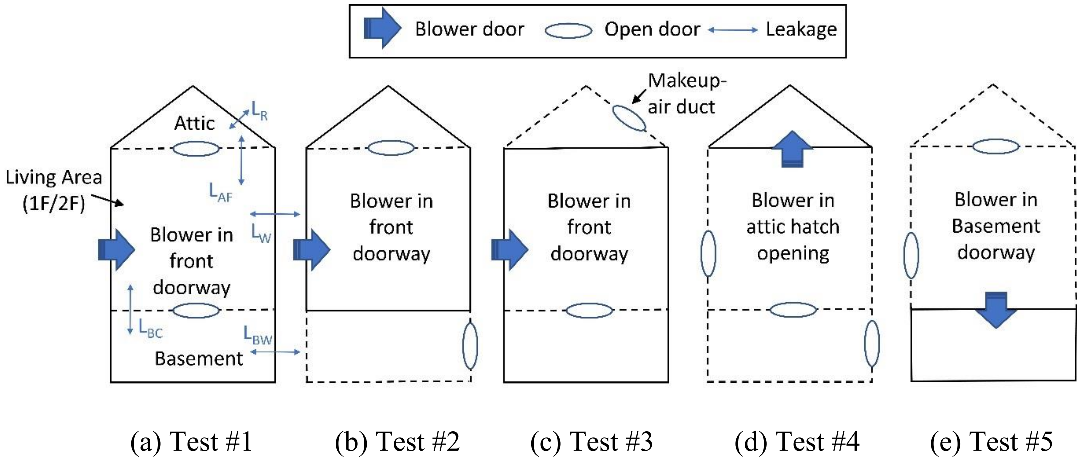

FIG. 4. Five house configurations for determining external and interzonal leakage.

Test #1

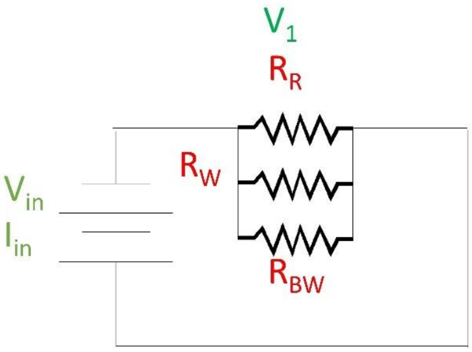
For this test configuration, the blower door was placed in the front doorway of the house, and both the basement door and attic hatch remained open. Pressure differentials with respect to the outdoors were measured in the basement, attic, and living room to ensure that the induced pressure across the building envelope was uniform across the entire house. Two subconfigurations ("A" and "B") were also tested: in Test #1A the exterior dryer and kitchen exhaust vents were unsealed and in Test #1B, these vents were sealed.

Test #1 was represented as an electrical circuit with three "resistances" (analogous to the flow coefficient C) in parallel (FIG. 5). The sum of the flow through each branch of the "circuit" is equal to Q_1, which was the measured airflow delivered by the blower door fan test to yield values of C_1 and n_1:

$$Q_1 = C_1 \Delta P_1^{n_1} = C_R \Delta P_{R_1}^{n_1} + C_W \Delta P_{W_1}^{n_1} + C_{BW} \Delta P_{BW_1}^{n_1} \tag{3}$$

Note that the value of n_1 is assumed to be the same for all surfaces in Eq. (3). No tests were performed to determine these values of n individually as part of Test #1. The subscript 1 denotes Test #1, and subscripts R, BW, and W denote the building surfaces (roof, basement wall and walls, respectively). On the basis of consideration of the similarity in airtightness of the exterior surfaces throughout the house, and the inability to measure them separately, we assumed that the following relationship:

$$C_{\mathrm{R}}/A_{\mathrm{roof}} = C_{\mathrm{BW}}/A_{\mathrm{basement\ wall}} = C_{\mathrm{W}}/A_{\mathrm{walls}} \tag{4}$$



I_{in}: current in (analogous to ΔP of test)
V_{in}: voltage in (analogous to Q of test)
V_1: voltage through parallel resistances R_{R}, R_{BW} and R_{W}
R_{R}: resistance through roof (analogous to C_{R})
R_{BW}: resistance through basement wall (analogous to C_{BW})
R_{W}: resistance through walls (analogous to C_{W})

FIG. 5. Electrical circuit equivalent of Test #1

Test #2

For this test configuration, the blower door was placed in the front doorway. The basement door was closed and the attic hatch was opened. Four subconfigurations (A, B, C, and D) were tested, varying the sealing and unsealing of the first floor transfer grilles (between the first floor and the basement) and the sealing and unsealing of the basement door undercut as summarized in Table 2.

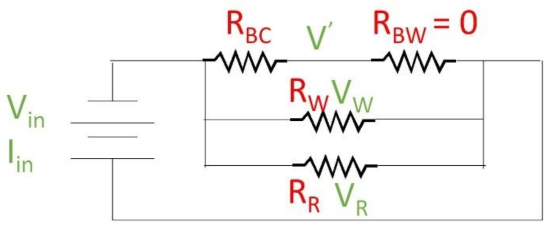
TABLE 2. Summary of subconfigurations for Test #2

Test #2 subconfigurations	First floor transfer grilles	Basement door undercut
A	Unsealed	Unsealed
B	Sealed	Unsealed
C	Unsealed	Sealed
D	Sealed	Sealed

Test #2 also has three resistances in parallel (C_R, C_W, C_2), with one of the resistances ($C^{'}$) composed of two resistances in series (C_{BW}, C_{BC}) (FIG. 6). Because the basement window is open for Test #2, the resistance R_B is essentially zero. The sum of the airflow through each branch of the "circuit" is equal to Q_2, which was measured during the blower door tests and yielded values of C_2 and n_2. The airflow-pressure expressions are as follows, where the subscript 2 refers to Test #2. Note that the value of n_2 is assumed to be the same for all surfaces in Eqs. (5) and (6).

$$Q_2 = C_2 \Delta P_2^{n_2} = C^{'} (\Delta P^{'})^{n^{'}} + C_W \Delta P_{W_2}^{n_2} + C_R \Delta P_{R_2}^{n_2}, \text{ and} \tag{5}$$

$$C'(\Delta P')^{n'} = C_{BC} \Delta P_{BC_2}^{n_2} \tag{6}$$



I_{in}: current in (analogous to ΔP of test)
V_{in}: voltage in (analogous to Q of test)
V_{R}: voltage through R_{R}
V_{W}: voltage through R_{W}
V': voltage through combined R_{BW} and R_{BC}

R_{R}: resistance through roof (analogous to C_{R})
R_{BW}: resistance through basement wall (analogous to C_{BW})
R_{W}: resistance through walls (analogous to C_{W})
R_{BC}: resistance through basement ceiling (analogous to C_{BC})

FIG. 6. Electrical circuit equivalent of Test #2.

Test #3

In Test #3, the blower door was placed in the front doorway. The basement door was open and the attic hatch was closed. Two subconfigurations (A and B) were tested: in Test #3A the attic transfer grilles (between the second floor and attic) were unsealed and in Test #3B, these transfer grilles were sealed. The airflow-pressure expressions are as follows:

$$Q_3 = C_3 \Delta P_3^{n_3} = C^{'}\left(\Delta P^{'}\right)^{n^{'}} + C_W \Delta P_{W_3}^{n_3} + C_{BW} \Delta P_{BW_3}^{n_3} \tag{7}$$

$$C'(\Delta P')^{n'} = C_R \Delta P_{R_3}^{n_3} = C_{AF} \Delta P_{AF_3}^{n_3} \tag{8}$$

Note that the value of n_3 is assumed to be the same for all surfaces in Eqs. (7) and (8).

Test #4

In Test #4, a smaller fan designed for duct leakage tests was connected to the attic hatch opening using a plywood mount and flexible duct (FIG. 7), and the front door of the house was open. Four subconfigurations (A, B, C, and D) were tested, alternating sealing and unsealing of the attic transfer grilles (between the second floor and the attic) and makeup-air duct in the attic (Table 3).

The airflow-pressure expression is as follows:

$$Q_4 = C_4 \Delta P_4^{n_4} = C_R \Delta P_{R_4}^{n_4} + C_{AF} \Delta P_{AF_4}^{n_4} \tag{9}$$

Note that the value of n_4 is assumed to be the same for all surfaces in Eq. (9).

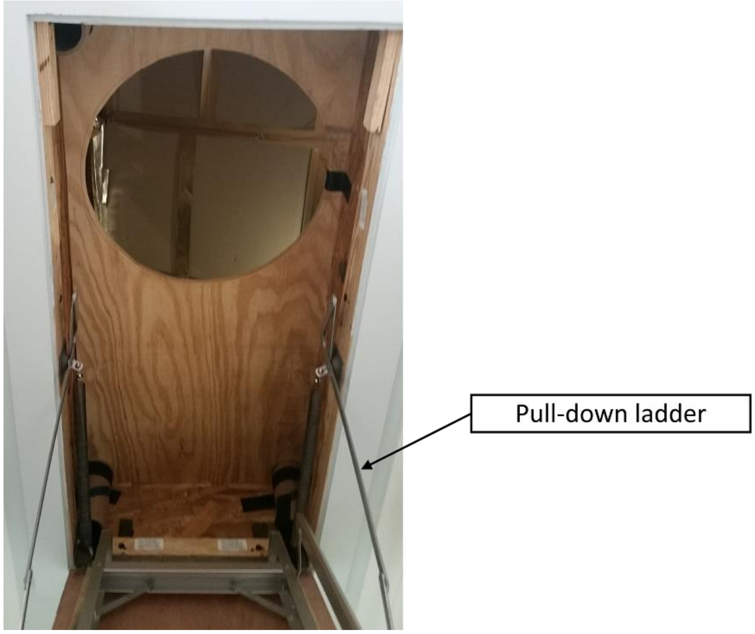


FIG. 7. Plywood mount for smaller fan in attic hatch opening.

TABLE 3. Summary of subconfigurations for Test #4.

Test #4 subconfigurations	Attic transfer grilles	Makeup-air duct
A	Sealed	Unsealed
B	Unsealed	Unsealed
C	Sealed	Sealed
D	Unsealed	Sealed

Test #5

For Test #5, the blower door was placed in the basement doorway and the front door of the house was open. Two subconfigurations (A and B) were tested: in Test #5A the first floor transfer grilles were sealed and in Test #5B, these transfer grilles were unsealed. The airflow-pressure expression is as follows:

$$Q_5 = C_5 \Delta P_5^{n_5} = C_{BW} \Delta P_{BW_5}^{n_5} + C_{BC} \Delta P_{BC_5}^{n_5} \tag{10}$$

Note that the value of n_5 is assumed to be the same for all surfaces in Eq. (10).

(3) Determining Leakage Values of Building Surfaces

This section describes the determination of the individual leakage values from the results of the tests that were just described, solving for C_{R}, C_{BW}, C_{W}, C_{AF}, and C_{BC}. Using the assumption expressed in Eq. (4), the only unknowns were C_{AF} and C_{BC}. They were solved, respectively, using Eq. (9) for Test #4C and Eq. (10) for Test #5A. These test numbers were the subconfigurations in which the interior leakage paths (basement door undercut and transfer grilles) were sealed. The values of C_{R}, C_{BW}, C_{W}, C_{AF} and C_{BW} were then converted to effective leakages L using Eq. (2).

The values of L_{AF} and L_{BC} determined using C_{AF} and C_{BC}, respectively, were compared with values calculated by subtracting the result of the comparable "sealed" test configuration from the "unsealed" test result. The ELA of Test #5A (first floor transfer grilles sealed) minus the leakage area of the basement wall (L_{BW}) equals the leakage area of the basement ceiling (L_{BC}). The ELA of Test #4C (attic transfer grilles sealed) minus the leakage area of the roof (L_{R}) equals the leakage area of the attic floor (L_{AF}).

(4) Determining Leakage Values of Basement Door Undercut and Transfer Grilles

The leakages of the basement door undercut and transfer grilles were determined by subtracting the result of the comparable "sealed" test configuration from the "unsealed" test result. The solution process for each building component is described below:

The effective leakage of the basement door undercut was calculated two ways:

(1) ELA Test #2 with first floor transfer grilles unsealed: $\mathrm{ELA}_{2\mathrm{A}}$ (door undercut unsealed) minus $\mathrm{ELA}_{2\mathrm{C}}$ (door undercut sealed)

(2) ELA Test #2 with first floor transfer grilles sealed: $\mathrm{ELA}_{2\mathrm{B}}$ (door undercut unsealed) minus $\mathrm{ELA}_{2\mathrm{D}}$ (door undercut sealed).

The effective leakage of the first floor transfer grilles was calculated three ways:

(1) ELA Test #2 basement door undercut unsealed: $\mathrm{ELA}_{2\mathrm{A}}$ (transfer grilles unsealed) minus $\mathrm{ELA}_{2\mathrm{B}}$ (transfer grilled sealed)

(2) ELA Test #2 basement door undercut sealed: $\mathrm{ELA}_{2\mathrm{C}}$ (transfer grilles unsealed) minus $\mathrm{ELA}_{2\mathrm{D}}$ (transfer grilled sealed)

(3) $\mathrm{ELA}_{5\mathrm{A}}$ (transfer grilles unsealed) minus $\mathrm{ELA}_{5\mathrm{B}}$ (transfer grilles sealed)

The effective leakage of the attic transfer grilles was calculated two ways:

(1) ELA Test #4 makeup-air duct sealed: $\mathrm{ELA}_{4\mathrm{A}}$ (transfer grilles unsealed) minus $\mathrm{ELA}_{4\mathrm{B}}$ (transfer grilled sealed)

(2) ELA Test #4 makeup-air duct unsealed: $\mathrm{ELA}_{4\mathrm{C}}$ (transfer grilles unsealed) minus $\mathrm{ELA}_{4\mathrm{D}}$

(transfer grilled sealed).

RESULTS

This section summarizes the ELAs obtained from the 14 blower door tests. These ELAs are used to calculate the leakiness of the roof, first and second floor walls, basement walls, basement ceiling, and attic floor using derived flow coefficients. The test ELAs also are used to calculate the effective leakages of the basement door undercut and transfer grilles. Lastly, results from multizone airflow simulations of the NZERTF, using the calculated leakages as inputs, are presented.

Effective leakages

The ELA at 50 Pa for all 14 tests were calculated using the procedures outlined in ASTM E779 (TABLE 4). The results are listed by test configuration (Test #1 to Test #5) and subconfiguration denoting whether vents and other openings were sealed or unsealed. Because of the attic-outdoor pressure not being able to be neutralized, the results of Tests #3A and #3B actually captured the leakage of the basement wall, first and second floor walls, and the combined leakage of the attic floor and roof. With the attic floor being so leaky relative to the attic roof (see TABLE 5 and subsequent explanation), Test #3 results closely matched the results of Test #1B, which captured the combined leakage of basement wall, first and second floor walls, and attic roof. (The exterior dryer and kitchen exhaust vents were sealed during these three tests.) For Tests #1 and #3, $n = 0.65$ on average, ranging from $n = 0.64$ to $n = 0.67$.

As expected, the ELAs of Tests #2, #4, and #5 (which include the combined leakage of exterior and interior leakages) are greater than the ELAs of Test #1 (exterior envelope only) because attention was paid to minimizing the leakiness of the exterior envelope. No attention was paid to the leakiness of the basement ceiling or attic floor, which is reasonable because both the basement and attic are within the conditioned volume. The ELAs of Test #4 were the highest of the tests, which indicated that the attic floor was leakier than the basement ceiling. This was also verified by further analysis presented below. For Tests #2, #4, and #5, $n = 0.61$ on average (ranging from $n = 0.58$ to $n = 0.68$), which was smaller than the average of the n values for Tests #1 and #3 (tests of the exterior envelope leakage).

TABLE 4. Summary of ELA at 50 Pa for five test configurations and their subconfigurations.

Test number	Leakage determined	ELA at 50 Pa (cm^2)	95 % confidence interval (+/- cm^2)
1A	L_R+L_{BW}+L_W (vents unsealed)	**237**	7
1B	L_R+L_{BW}+L_W (vents sealed)	**200**	3
2A	L_R+L_W + (L_{BW} + L_{BC})[1]	**898**	12
2B	L_R+L_W + (L_{BW} + L_{BC})[1]	**676**	9
2C	L_R+L_W + (L_{BW} + L_{BC})[1]	**765**	8
2D	L_R+L_W + (L_{BW} + L_{BC})[1]	**539**	9
3A	L_{BW}+L_W + (L_R + L_{AF})[1]	**202**	4
3B	L_{BW}+L_W + (L_R + L_{AF})[1]	**204**	3
4A	L_R + L_{AF}[1]	**696**	16
4B	L_R + L_{AF}[1]	**914**	51
4C	L_R + L_{AF}[1]	**694**	17
4D	L_R + L_{AF}[1]	**941**	30
5A	L_{BW} + L_{BC} (first floor grilles sealed)	**611**	4
5B	L_{BW} + L_{BC} (first floor grilles unsealed)	**836**	6

1. See the section, "Test Configurations", for descriptions of the various subconfigurations.

As discussed in the section, "Methodology", the ELAs of the tests are used to calculate C and L of the various building components (i.e., roof, walls, floor). The values of C_R, C_{BW}, and C_W were converted to effective leakages, L, using Eq. (1) and then normalized by their respective surface areas in TABLE 1. The assumption in Eq. (4), $L'_R = L'_W = L'_{BW}$, where the prime notation indicating

L is normalized by surface area, is given in TABLE 5. TABLE 5 also shows the results of calculating L_{AF} and L_{BC} two ways, (1) by determining C_{AF} and C_{BW} and then converting to L and (2) by subtracting the result of the comparable "sealed" test configuration from the "unsealed" test result. TABLE 5 shows the average calculated $L_{\mathrm{AF}} = 618$ cm^2 at 50 Pa (95 % confidence interval (CI) 567 cm^2 to 655 cm^2) when calculated using C_{AF} and shows that the average calculated $L_{\mathrm{AF}} =$ 606 cm^2 at 50 Pa (95 % CI 596 cm^2 to 620 cm^2) when calculated using ELA$_{4C}$ – L_{R}. There was only a 2 % difference in L_{AF} calculated by these two methods.

TABLE 5 shows the average calculated $L_{\mathrm{BC}} = 614$ cm^2 at 50 Pa (95 % CI 594 cm^2 to 634 cm^2) when calculated using C_{BC} and shows the average calculated $L_{\mathrm{BC}} = 611$ cm^2 at 50 Pa (95 % CI 596 cm^2 to 620 cm^2) when calculated using ELA$_{5A}$ – L_{BW} (< 1 % difference). The last column of TABLE 5 shows the effective leakages normalized by their respective surface area or per item. The attic floor (4.66 cm^2/m^2 at 50 Pa) is about 15 % leakier than the basement ceiling (4.01 cm^2/m^2 at 50 Pa) The attic floor and basement ceiling are also about 10 times leakier than the exterior envelope (0.48 cm^2/m^2 at 50 Pa). The leakage area of the attic floor (606 cm^2 at 50 Pa) is greater than the leakage of the attic transfer grilles (233 cm^2 at 50 Pa). The leakage of the basement ceiling (611 cm^2 at 50 Pa) is greater than the leakage of the first floor transfer grilles (224 cm^2 at 50 Pa).

TABLE 5. Flow coefficient and calculated leakages of building components.

	C (m^3/s•Pa)	**L from Eq. (2) (cm^2)**	**L using ELA$_{\mathrm{Test\#}}$ (cm^2)**	**L' (cm^2/m^2 or per item)**
Roof	C_{R}=0.006	L_{R}=88	N/A	0.48 cm^2/m^2
Basement wall	C_{BW}=0.00005	L_{BW}=1		0.48 cm^2/m^2
First and second floor walls	C_{W}=0.010	L_{W}=150		0.48 cm^2/m^2
Attic floor	C_{AF}=0.041	L_{AF}=618	L_{AF}=ELA$_{4C}$ – L_{R} = 606	4.66 cm^2/m^2
Basement ceiling	C_{BC}=0.049	L_{BC}=614	L_{BC}=ELA$_{5A}$ – L_{BW} = 611	4.05 cm^2/m^2

Basement door undercut	N/A	N/A	ELA$_{2A}$ – ELA$_{2C}$ = 132 ELA$_{2B}$ – ELA$_{2D}$ = 137	135 cm^2
First floor transfer grilles (qty = 3)	N/A	N/A	ELA$_{2A}$ – ELA$_{2B}$ = 221 ELA$_{2C}$ – ELA$_{2D}$ = 226 ELA$_{5A}$ – ELA$_{5B}$ = 225	75 cm^2 per transfer grille
Attic transfer grilles (qty = 2)	N/A	N/A	ELA$_{4A}$ – ELA$_{4B}$ = 218 ELA$_{4C}$ – ELA$_{4D}$ = 248	116 cm^2 per transfer grille

SIMULATIONS

To evaluate the effects of different ventilation strategies on airflows and contaminant concentrations in the NZERTF, the *L*' at 50 Pa (cm^2/m^2 or per item) in TABLE 5 were input into a multizone airflow model of the house developed using CONTAM [26]. This CONTAM model was also coupled with EnergyPlus, a whole-building energy analysis tool, to study the energy implications of these airflows [27]. In a previous modeling study, preliminary estimates of the interzone leakage values were used to predict formaldehyde and acetaldehyde concentrations [28].

The CONTAM model considers the interaction between external forces driving airflow (inside-outside temperature difference and wind) and building heating, ventilating, and air conditioning (HVAC) system airflow rates to determine pressures and airflows across internal partitions and the building envelope. CONTAM also accounts for external and internal contaminant sources and removal mechanisms to calculate contaminant transport associated with the airflows. EnergyPlus implements a multizone heat transfer model that accounts for conductive, convective and radiant heat transfer associated with building materials; interzone and envelope airflows; and HVAC systems. During cosimulation using the coupled model, indoor air temperatures and HVAC system airflow rates are passed from EnergyPlus to CONTAM, and airflow rates across the building envelope and between internal zones are passed from CONTAM to EnergyPlus [29, 30]. Details on the model and simulated concentrations of formaldehyde and acetaldehyde in the NZERTF are given in .

Simulations were performed using preliminary estimates for the interzonal leakages that were based on engineering judgement for the floor leakage and manufacturer's catalogs (for the transfer grilles), before the measurements reported on in this paper were performed. The preliminary floor leakage value underestimated the measured value by about half, and the effective leakage value of the transfer grilles had been overestimated by a factor of about three (TABLE 6). Simulations were then repeated using the measured interzonal leakage values. Annual simulations were performed using the Typical Meteorological Year 3 (TMY3) weather file for Baltimore, MD [31], with a time step of 1.0 min and with the heat pump fan controlled by the thermostat (set to 21.1 °C in the heating season and 23.9 °C in the cooling season) and the HRV running continuously at 0.05 m^3/s. Simulations were also performed with both the heat pump fan and HRV off.

TABLE 6. Preliminary and measured leakages of building components.

	Preliminary leakage	***Measured leakage***
Attic floor	2 cm^2/m^2 at 50 Pa	4.66 cm^2/m^2 at 50 Pa
Basement ceiling	2 cm^2/m^2 at 50 Pa	4.05 cm^2/m^2 at 50 Pa
Attic transfer grilles (qty=2)	418 cm^2 /each	116 cm^2/each
First floor transfer grilles (qty=3)	232 cm^2 /each	75 cm^2/each
Basement door undercut	229 cm^2	135 cm^2

TABLE 7 shows that there were significant differences in the predicted airflow rates of the individual paths (averaged over the annual simulation). On average, the predicted flow through the basement ceiling and attic floor using the measured leakage was higher than the value using the preliminary leakage. In contrast, the predicted flow through attic, first floor transfer grilles, and basement door undercut using the measured leakage were lower using the preliminary leakage. Note that the total airflow from the basement to the first floor, and from the second floor to the attic, were the same for the preliminary and measured leakage when averaged over a year (differences < 0.5 %). It may be that no change was observed in the average interzonal airflow because the exterior building leakage was comparatively airtight (ten times more airtight) and changes to the interzonal leakage were not great enough to affect the overall airflow pattern within the house.

The heat pump system was 100 % recirculating and the HRV was balanced. Although there were only heat pump supplies in the basement (no returns), whether the systems were on or off, the total infiltration was the same. With the systems off (details not shown for brevity), the airflow from the basement to the first floor decreased by 4 % because the heat pump was no longer supplying air to the basement. The only outside air supplied to the basement, when the heat pump and HRV was off, would have been through the basement wall, which had an ELA of 1 cm^2 at 50 Pa (0.48 cm^2/m^2 multiplied by the wall area of 2 m^2). With the systems off, the airflow from the second floor to the attic increased by 25 % to balance the decrease of air from the basement to the first floor.

TABLE 7. Predicted interzonal airflow rates using preliminary and measured leakage averaged over a year

Interzonal airflow rates (systems on)	**Average flow using preliminary leakage (m^3/s)**	**Average flow using measured leakage (m^3/s)**	**Percentage difference**
Attic transfer grilles	3.4E-03	9.7E-04	-72 %
Attic floor	1.8E-03	4.2E-03	139 %
First floor transfer grilles	5.3E-05	2.2E-05	-58 %
Basement ceiling	8.2E-06	4.2E-05	415 %
Basement door undercut	3.7E-05	3.4E-05	-9 %
Airflow from second floor to attic	5.2E-03	5.2E-03	-0.11%
Airflow from basement to first floor	9.9E-05	9.9E-05	0.06%

The average simulated concentrations of formaldehyde were not significantly different between using the preliminary and measured interzonal leakage. The differences in the average annual concentrations were < 0.05 % in the basement, combined first and second floor, and attic. This was because the total interzonal airflow between the basement and first floor, and between the second floor and the attic, averaged over a year, did not change whether using the preliminary or measured leakage. The similarity in the simulated formaldehyde concentrations also could have been due to the nature of the entire house being within the conditioned space. In a house with typical-construction, a leaky attic floor (coupled with a vented attic that is not part of the conditioned space) may create a greater stack effect within the house and may redistribute contaminants differently than in the NZERTF. The fact that the interzonal leakage did not affect the distribution of formaldehyde in the NZERTF could have been attributed to the heat pump system recirculating air from the house and delivering it to the basement and the house.

DISCUSSION

One challenge during this series of blower door tests was not being able to neutralize the pressure across the attic roof. Unsuccessful attempts were made to conduct a two-blower test by manually adjusting the speed of the blower door in the front doorway and smaller fan in the attic hatch opening. The authors will attempt a two-blower test using additional fan control devices in the future.

Blower door test results showed that the interior floors were approximately 10 times leakier than the exterior building envelope and that the leakage associated with the transfer grilles between levels was less than the total floor leakage. Considering that all the levels of the NZERTF were all within the conditioned space, the leaky interior floors do not pose an energy penalty (i.e., cold air from the basement flowing up to house, and conditioned air from house flowing out through the roof) when paired with a tight exterior envelope. In a home of more typical construction, however, in which the attic is not within the conditioned space and the exterior walls are not as tight, there could be a significant energy penalty as conditioned air escapes to the attic and out the roof vents.

There were no significant differences in the total interzonal airflows between the levels of the NZERTF, and no significant differences in the simulated formaldehyde concentrations, using preliminary and measured interzonal leakage in the NZERTF (both averaged over a year). Reasons for this lack of difference in the annual averages may include the fact that the zones within the NZERTF were all within the conditioned envelope. Thus cold basements and hot attics did not create as great a stack effect as created in homes with only living areas within the conditioned space. Also, the heat pump in the NZERTF recirculated air between the basement, first floor, and second floor, which may not be the case in all homes. Last, as noted, no change was observed in the average interzonal airflow because the exterior building leakage was comparatively airtight (10 times more airtight) and changes to the interzonal leakage were not great enough to affect the overall airflow pattern within the house. Nevertheless, improved knowledge of interzonal leakage could improve estimates of contaminant transport in other homes, especially when considering transient effects. These findings will be compared with the results of interzonal tracer decay tests, which have been performed in the NZERTF but not yet analyzed.

CONCLUSION

The NZERTF is a 250 m^2 two-story, unoccupied test home located at NIST in Gaithersburg, MD. It is airtight (0.6 h^{-1} at 50 Pa) and has a highly insulated building enclosure designed for heat, air and moisture control. Because the basement, first floor, second floor, and attic levels are all within the conditioned space, no special attention has been given to the airtightness of the interior floors; however, to support airflow modeling efforts, this leakage was quantified through a series of interzonal pressurization tests. It was found that the interior floors were 10 times leakier than the exterior building envelope, and that the leakage associated with the transfer grilles between levels was less than the total floor leakage. This paper described the design of the interzonal tests and the challenges to perform them. Having more accurate estimates of interzonal leakage could be advantageous in understanding the transport of air and contaminants in multizone structures, especially with respect to transient effects.

ABSTRACT. ***To ensure food safety, food manufacturers need the ability to quickly identify and trace food products to all equipment and processes throughout the entire associated food supply, production, and transportation network. Government and industry have recognized that supply chain traceability is the key to keeping the public safe, but new information standards are needed to enable such traceability. This paper describes several efforts being undertaken by industry, government, and academic organizations to develop and standardize traceability technology, focusing on grain traceability, and how modeling, simulation, and analysis technology are being used to support these projects. Noteworthy among these efforts is AgGateway's Commodity Automation by Rail and Truck (CART) project, which sought to understand the business processes and data exchanges required, all the way from farm operations through grain elevators to receiving at a feed manufacturer; exploring solutions through small proof-of-concept (PoC) projects; and enhancing and implementing existing standards, primarily the ISO 11783 standard for farm machinery electronics, and the AgXML standard for grain data exchange. The paper also presents ongoing work on using agent-based simulation to validate proposed traceability standards.***

Keywords. agent-based simulation, food traceability, standardization, supply chain analysis.

Introduction

Negative impacts to the food supply chains can be extremely costly, having caused over $22 billion in losses due to food recalls and related expenses (Hussain and Dawson, 2013). They can also be dangerous, having caused over 8.9 million illnesses, 53,245 hospitalizations, and over 2300 deaths (Flynn, 2014; ERS, 2017). Managing the supply chain for complex products such as cars or airplanes is difficult and might involve millions of parts from dozens of suppliers. Managing the supply/production chain in the food manufacturing domain adds a unique characteristic of both the input materials and the final product: they are biologically-based and thus perishable; they are usable during a limited timespan. This requires special procedures for gathering, storing, handling, and transporting materials and end-products, making the logistics for input sourcing and end-product distribution complex, costly, and susceptible to a myriad of disturbances including adverse weather

Riddick, Frank H.; Wallace, Evan K.; Nieman, Scott; Tevis, Joe; Ferreyra, R. "Implementing Grain Traceability Standards: CART and Simulation." Paper presented at 2018 American Society of Agricultural and Biological Engineers (ASABE) Annual International Meeting, Detroit, MI, US. July 29, 2018 - August 01, 2018.

conditions and transportation worker strikes.

There is constant variability in the characteristics of food production input materials. In addition, vast differences can be observed in the material characteristics of a product across lots, even from the same year. This forces manufacturers to constantly test, monitor, and find alternate sources for their input materials and then modify their products' manufacturing processes based on the characteristics of the materials that they were able to source.

To help manage the complexity of the food supply production chain and to deal with adverse events when they occur, most participants in the supply production chain have traceability-enabling systems. Briefly, traceability is "the ability to track any food through all stages of production, processing and distribution" (European Commission, 2017). Unfortunately, there is no standard for traceability systems or their information content that covers the complete food production chain. Furthermore, at many points in the supply chain, traceability information is collected and recorded manually and maintained on physical records, severely limiting the speed with which the information can be accessed when needed.

A system providing end-to-end traceability would enable the discovery and use of synergies in the food production chain; this would lead to a more efficient and cost-effective supply and production system; and would enable that problems be addressed quickly and with a minimum effort. The need for such a system has been recognized; many companies work to improve traceability within their organizations (Church, 2015; Dow, 2018) and academic researchers are studying various aspects of the traceability problem (Thakur and Hurburgh, 2009). Through the passage of the Food Safety Modernization Act (FSMA; US FDA, 2018) the U.S. government has mandated basic procedures that stakeholders in the food production and supply chain must follow, but because a standard system to support traceability does not exist, dates for strict compliance with FSMA have been delayed (Schultz, 2018).

To move towards the goal of a standards-based system supporting end-to-end traceability, several organizations have efforts underway to address traceability related deficiencies in the current food supply production chain. This paper describes several of these efforts, emphasizing how modeling, simulation, and analysis technology can help reach the desired goals. The technical developments needed to support end-to-end traceability are also discussed, as well as how the results of current traceability research efforts will be coordinated to support future efforts.

Key Notions of Traceability

The UN definition of traceability, "The ability to identify and trace the history, distribution, location and application of products, parts and materials…", points to a key function of traceability systems: *trace back* (UN, 2014). Trace back is the ability to assemble, for a given product, information about the input materials, processes, and human or machine resources that were directly used to create the product, and then to recursively repeat that process for each of the materials, processes, and/or human and machine resources discovered. This process is extremely important when trying to uncover the time, location, and nature of the adverse event in the production chain that caused a product defect.

A complement to the trace back function of traceability systems is the ability to *trace forward*. This function seeks to, given a specific material and/or piece of equipment at a specific point in the production chain, identify the materials at the next step in the production chain that used the previous materials as inputs or used the associated equipment in its processing, repeating this process recursively until all end products that are directly or indirectly related to the initial material or equipment have been identified. The trace forward function is necessary to identify the scope of potential end-products affected once the root cause and origin of a product defect has been determined.

One problem that makes traceability difficult is that different partners in the supply/production chain might use different management and/or computer systems to carry out their operations, and these systems might use different information to identify or describe the same product or material. Some kinds of traceability analyses only look at information describing how products move between partners; others focus on each traceability-related activity that happens within a partner's organizational boundary. Issues, information, and analysis focused on the inter-partner production chain activities are referred to as being a part of *external traceability* while issues, information, and analysis focused on what happens within a partner's organizational boundary are referred to as being a part of *internal traceability*.

The information necessary to support a traceability system is complex, interrelated, and vast; making sense of it can be very challenging. Even though a clear goal of a traceability system is to be able to associate a product with its inputs, the current approach most widely used to organize traceability information focuses on the events that occur within a production chain that will enable product inputs and outputs to be traced. With this approach, *Critical Tracking Events* (or CTEs) are defined to contain data about the input and output materials, processes, locations, and human or machine resources associated with each event in the production chain that is necessary to support the trace forward and trace back functions of a traceability system (Badia-Melis et al., 2015).

Using CTEs as the basis for recording, managing, and analyzing production chain data has been shown to enable supporting traceability analyses related to external traceability, internal traceability, and analyses which include both internal

Riddick, Frank H.; Wallace, Evan K.; Nieman, Scott; Tevis, Joe; Ferreyra, R. "Implementing Grain Traceability Standards: CART and Simulation." Paper presented at 2018 American Society of Agricultural and Biological Engineers (ASABE) Annual International Meeting, Detroit, MI, US. July 29, 2018 - August 01, 2018.

and external elements.

Barriers to the Development of Traceability Systems for Bulk Grain

The continued occurrence of food safety incidents has only underscored the need for traceability systems that can quickly perform trace back and trace forward functions to limit the exposure of consumers to serious illnesses and possible death. Developing and deploying such systems present a variety of problems. Developing systems to support production chains that have bulk grain as one of its materials add to those problems; some specific challenges are detailed below.

Difficulties in conceptualizing an end-to-end traceability system

Since no end-to-end traceability system currently exists, it is difficult to even discuss the concept of such a system with many production chain partners. Partners may have only focused on the internal traceability issues of their organizations and much of that information may only be maintained as tribal knowledge within the organization. Also, efforts to support external traceability may be limited to providing “one-up, one-down” traceability for themselves and their direct production chain partners (Bhatt et al., 2013).

No standard promoting consistency in the representation and interpretation of traceability information

In general, each participant in a production chain has their own unique enterprise and operational infrastructure. Traceability system components will need to be built upon the different infrastructural components of each partner, and mechanisms are needed to provide consistency and reduce or eliminate ambiguity in the information created and exchanged within the production chain. First, there is a need to standardize how to represent the data describing traceability concepts like events, materials, resources, and processes. Second, there is a need to provide context given that the same term may be interpreted differently by different production chain participants. This becomes evident by observing that the term “lot” could refer to a bag of grain, a truckload of grain, a rail car full of grain, of even a portion of land on which grain is grown.

Lack of methods for assessing relationships between input and output grain lots passing through grain storage bins

In production chains involving grains such as wheat or corn, the grain is often stored in large containers referred to as *bins* or *silos*. In general, these bins operate like queues: grain enters through the top and comes out of the bottom. Unfortunately, due to many factors (e.g., bin geometry, type of grain, grain moisture content, and extraction method) problems such as doming and rat-holing cause the grain movement through the bin to diverge from a strict first-in, first-out material movement pattern. In order to assess which bin outputs are connected with specific bin inputs, methods need to be developed to characterize how movement through a bin is affected by bin geometry and/or bin environmental conditions.

No methods for evaluating proposed solutions for defining, exchanging, and analyzing traceability information

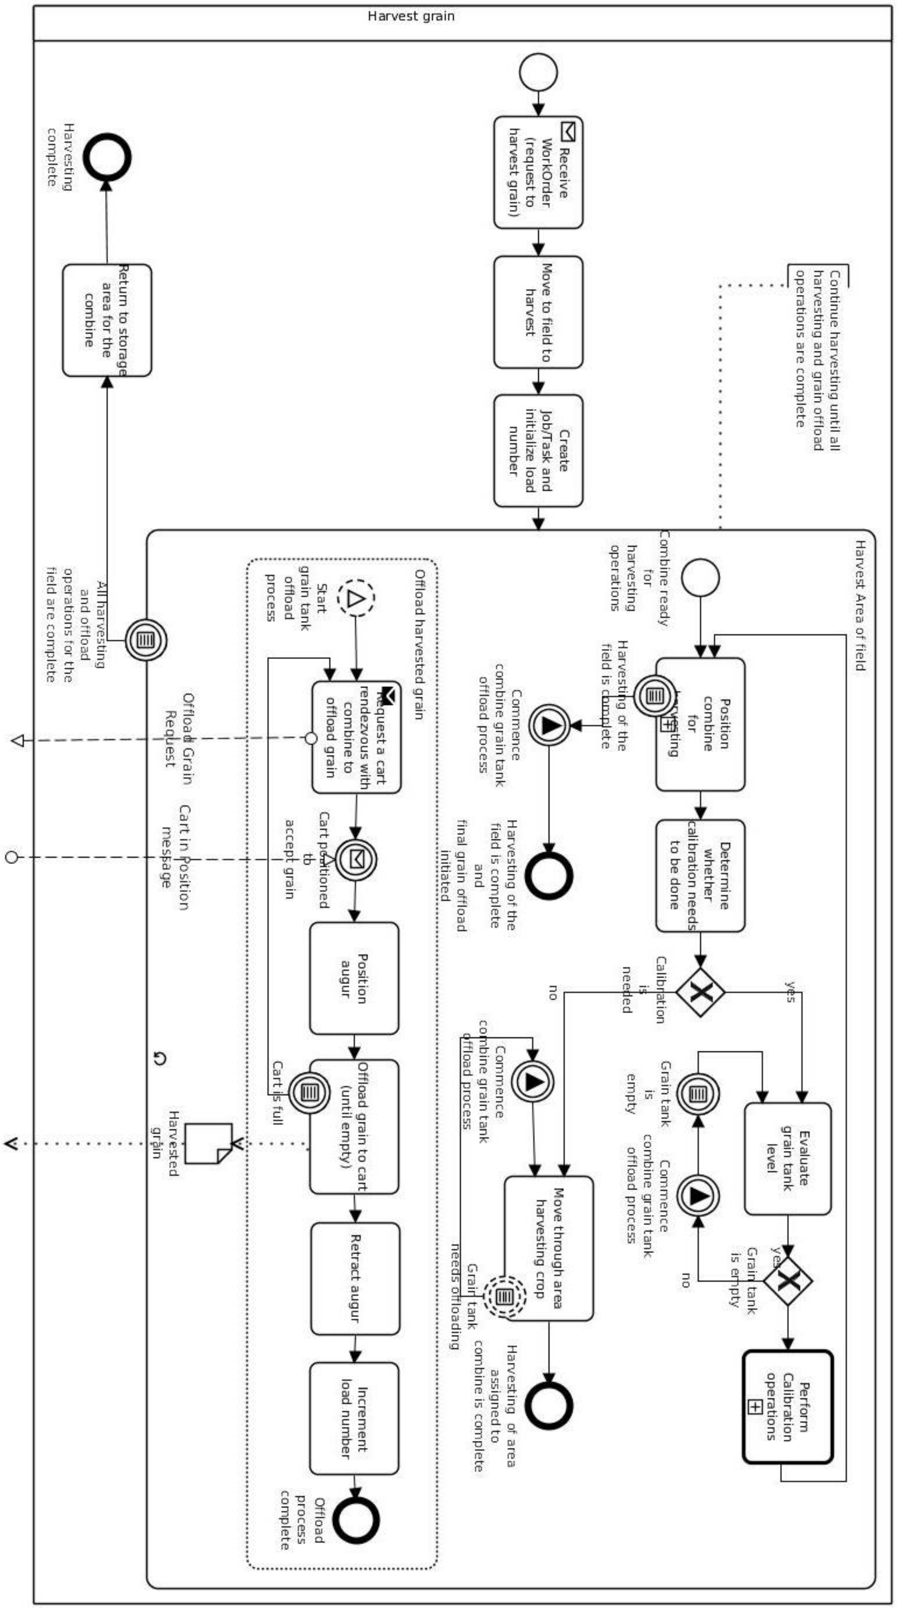
As candidate solutions for the aforementioned problems are developed, methods must be developed to assess whether traceability system based on these solutions would operate acceptably before the solutions are deployed.

Addressing Traceability Needs for Production Chains Involving Bulk Grains

The need for systems, methods, and standards to enable the deployment of traceability systems has been recognized by government, academic organizations, and the stakeholders in the food production chain, both in the U.S. and abroad (Donnelly and Thakur, 2010; Thakur et al., 2009; Opara, 2003). The motivation for feasible, economical, standards-based solutions for traceability has recently increased due to the lack of solutions that stakeholders in the U.S food production chain can use to comply with the precepts of FSMA. Several academic, government, and industry organizations, which were individually working on different aspects of the problem for production chains involving bulk grains, have recently begun to work together to develop methods and information specifications for traceability systems that might lead to standardized traceability solutions. While this is not an official “project”, these organizations hope that collaborating will result in synergy and lead to deployable results for each of their efforts. Several of these efforts are described below.

Modeling processes and their data: BPMN and Transfer Event modeling

Enabling all stakeholders to understand the complexities of an extensive production chain is a difficult but necessary task. Often, information about a process early in the chain must be collected and maintained to enable the ability to trace back from a downstream process. To illustrate how each production chain stakeholder’s processes interact, participants in the AgGateway industry consortium’s interoperability projects have been using Business Process Model and Notation (BPMN; Silver, 2011) to model the production chain (AgGateway, 2017). They were joined in this effort by researchers from the Open Applications Group Quality Content work group and from the NIST Agri-food Manufacturing System and Supply Chain Integration project, who have been doing similar modeling for supply and production chains in other domains. This collaboration involved modeling the overall production chain and key processes along it (OAGi, 2016; NIST 2017). As an example, Figure 1 presents a BPMN diagram that illustrates the harvesting process for bulk grain, created using a web-based BPMN modeling tool (Trisotech, 2018).



Harvest grain
Receive WorkOrder (request to harvest grain)
Move to field to harvest
Create Job/Task and initialize load number
Continue harvesting until all harvesting and grain offload operations are complete
Harvest Area of field
Combine ready for harvesting operations
Position combine for harvesting
Harvesting of the field is complete
Commence combine grain tank offload process
Harvesting of the field is complete and final grain offload initiated
Determine whether calibration needs to be done
Calibration is needed
yes
no
Evaluate grain tank level
Grain tank is empty
Commence combine grain tank offload process
yes
no
Perform Calibration operations
Commence combine grain tank offload process
Move through area harvesting crop
Grain tank needs offloading
Harvesting of area assigned to combine is complete
Offload harvested grain
Start grain tank offload process
Request a cart rendezvous with combine to offload grain
Offload Grain Request
Cart positioned to accept grain
Cart in position message
Position augur
Offload grain to cart (until empty)
Cart is full
Harvested grain
Retract augur
Increment load number
Offload process complete
All harvesting and offload operations for the field are complete
Return to storage area for the combine
Harvesting complete

Figure 1: BPMN process model of a grain harvest, including subprocesses for harvesting an area of the field and

offloading grain to a cart.

The data elements that describe the depicted processes were established and documented using BPMN diagrams of key production chain processes as a guide. With respect to support for traceability, it was decided that the focus should be on the critical tracking events and supporting data elements that document the transfer of quantities of grain from one container to another. Figure 2 shows how such a CTE named *TransferEvent* could be represented as an extension of the AgXML standard (AgXML, 2009) which defines information entities that can be used to exchange data between grain production chain partners.

AgGateway Commodity Automation for Rail & Truck (CART) Project Proof of Concept (POC)

To overcome deficiencies in the hardware, software, and data storage and exchange systems available to support production chain traceability and information exchange automation, AgGateway, an industry consortium with 200+ members, dedicated to enabling digital agriculture, started a project called the Commodity Automation for Rail & Truck (CART) project. The stated goal of CART is to facilitate “grain traceability from combine to grain cart, to truck, to elevator, to food processor” (AgGateway, 2018). To reach that goal, CART is conducting a number of technology, or proof of concept (POC) demonstrations, to evaluate the feasibility of proposed solutions for traceability. These demonstrations are in fact live simulations as defined by the live, virtual, constructive simulation taxonomy (US DoD, 1998). The POCs involve both modified and unmodified hardware and software, integrated together to collect, store, and exchange traceability information collected during the execution of real grain harvest events. Participants in CART include: farm operators, hardware and software vendors (some of which modified their products to participate in the POC), grain elevator operators, and processors (manufacturers of end-products that use grain as an input). The key processes of the harvest event were illustrated by diagrams such as Figure 1, and the transfer event data was exchanged as specified by the representation depicted in Figure 2. The points in the production chain where TransferEvents are exchanged are depicted in Figure 3.

The POC enabled participants to evaluate many different aspects of the proposed traceability solution, including overall approach feasibility, existing sensor adequacy for raw data collection, proposed hardware and software modification feasibility, and cloud-based solution feasibility for data storage and exchange. Some of the results of the initial POC are:

- The overall approach is feasible;
- TransferEvent data should be adequate to support traceability needs, and;

Riddick, Frank H.; Wallace, Evan K.; Nieman, Scott; Tevis, Joe; Ferreyra, R. ”Implementing Grain Traceability Standards: CART and Simulation.” Paper presented at 2018 American Society of Agricultural and Biological Engineers (ASABE) Annual International Meeting, Detroit, MI, US. July 29, 2018 - August 01, 2018.

- Hardware may need to be enhanced with additional automation capabilities and additional hardening to withstand environmental conditions.

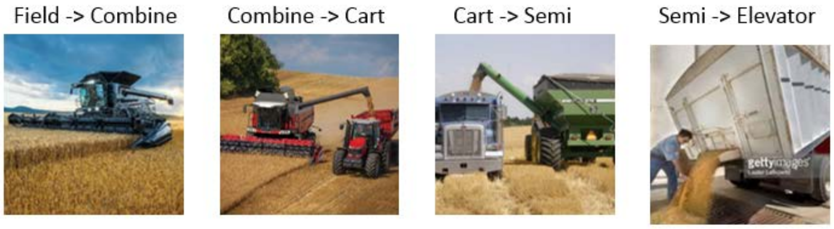

Figure 3: Points in the process where TransferEvents are exchanged

More information about the initial POC can be found in AgGateway (2017A). An additional POC is planned for Fall 2018.

Traceability Through Facilities Typified as Multi-Storage-Bin Environments

Facilities such as grain elevators typically have multiple storage bins to hold grain until dispensed for downstream partners in the production chain. With respect to traceability, two challenges commonly occur due to standard operating procedures at such facilities. First, delivered grain may be distributed to multiple bins and typically records documenting which bins received grain and the amount of grain received may not be kept permanently and in a searchable form. Second, there are no methods for tying grain inputs to outputs based on expected bin flow conditions, taking into account environmental (temperature, humidity, etc.), material (grain type, particle size, moisture content, etc.) and bin shape, material, etc.

To address these issues, NIST is funding research at Iowa State University to look into the traceability issues affecting bulk grains. Part of that effort involves analysis of past and current efforts in defining and using CTEs as the basis for supporting traceability. The output of this research has provided input to the efforts for CTE modeling and standardization described in the previous sections. In addition, part of this effort involves analyzing methods for bin flow characterization towards the goal of developing a mathematical model that can tie bin input to outputs. These efforts are in the early stages, the goal is to be able to use the output of this research to enhance capabilities of tools that support bulk grain traceability.

Simulating Production Chain Traceability for Illustration and Analysis

As previously mentioned, current research suggests traceability in production chains would be best supported by defining and maintaining CTE data about the important events that took place due to production chain operations. As with the live simulation events described previously, efforts to verify the feasibility of proposed solutions for traceability need to take place before standardization and deployment of those solutions. To support this type of analysis, data sets need to be constructed containing realistic collections of CTEs covering the operations of all stakeholders in the production chain and adhering to the format and content proposed by those solutions. To verify that a solution could support traceability analysis, CTE data associated with a specific production chain operation could be modified to indicate the occurrence of an adverse event, and then propagated through the production chain until a set of affected end products is identified. Then, trace back and trace forward analysis could be attempted to determine if all affected products, with few false positives, could be identified from the CTE data defined according to the proposed solution.

To be able to evaluate different proposed content specifications for CTE data, researchers at NIST have created a simulation of a bulk grain production chain that can generate CTE data sets. The primary goal is to generate a realistic collection of TransferEvent data, covering all transfers of grain from the field to the processor, to determine the extent to which traceability analysis can identify end-products affected by adverse events in the production chain. Secondary goals are to illustrate how individual stakeholders interact to perform production chain operations, and to provide a means to evaluate how different models of grain flows through storage bins might affect a proposed solution's traceability capabilities.

The simulated scenario is the same as that covered by the POC live simulation presented above: combines harvest grain from a field; when full, each combine offloads its grain to a cart; when a cart is full, it offloads to a truck; when full, a truck will deliver to an elevator where the grain is transferred to a storage bin; when a processor needs grain, it will send a truck to an elevator where grain is offloaded from a storage bin to the truck; this will then deliver to the processor, where grain will be offloaded to the processor's storage bin. Each time grain is moved from one container to another, a TransferEvent record should be created. In this scenario, not only will grain movement between obvious containers generate a TransferEvent (e.g., grain transfer from a combine's storage compartment to a cart's storage compartment) but a combine's harvesting of grain will also generate a TransferEvent – the area of a field from which the grain is harvested is considered a container for traceability purposes. This matches the TransferEvent generation points described in Figure 3. As was the case in the POC, the content for TransferEvents is based on the proposed specification described in Figure 2, although in both cases data for most of the optional fields was not generated. The behavior for the part of the simulation that covers operations from the field up to the loading of the semi-truck adheres to that specified by the diagram in Figure 1.

In addition to gathering information directly from participants in the POC and others involved in production chain operations, preparation for creating the simulation involved analyzing equipment specifications to determine appropriate value ranges for the key equipment characteristics that would be needed to simulate production chain operations. Information about typical farm crop characteristics was gathered from www.usda.gov.

The simulation was created using the AnyLogic software program (AnyLogic, 2018). This software enables the creation of multimethod simulations; the simulation described here was created as a hybrid agent-based and discrete-event simulation. Agents are constructed to represent the behavior of key entities in the scenario being simulated. The current simulation covers harvesting operations from the field to the dispatching of a Truck to an elevator. Agents to cover operation at the elevator and at the processor are currently under development. Details about several of the currently implemented agents can be found in Table 1.

Table 1: Agents and their responsibilities

Agent	Responsibilities	Key attributes
FieldMgr	Based on initialization data: • Create **Combine, Cart, Truck,** and **CropZone** agents • Assign/reassign **Combines** to **CropZones** • Manage how **Trucks** are filled with grain from **Carts** • Provide visualization of the state of harvesting operations	name id myFarm myGrower
CropZone	• A part of a field that is to be harvested by a **Combine** • CropZone is further subdivided into Areas • Areas enable crop conditions (e.g., moisture, quality, or yield potential) to be varied at a sub-**CropZone** level • Area size can be varied depending on the fidelity need for traceability analysis at the field level • Provide a specific location in a **CropZone** where an adverse field condition can be introduced	name id myFarm myGrower myField AreaList: List [0..n] of Area assignedCombine

The execution of the simulation takes place by agents carrying out their defined behaviors and through agent interaction. Agent behavior may be defined by a network of interconnected process modeling blocks (e.g., source, sink, or delay). This is typical for discrete-event simulation software. In addition, agent behavior can be defined by timed, message-based, or condition-based transitions between states in a state chart defined for the agent. In this case, specific behaviors are defined in functions written in the Java language-based coding framework of the AnyLogic software package. These functions are executed based on transitions firing or with entering or exiting a state. Figure 4 shows the state chart associated with a Truck agent.

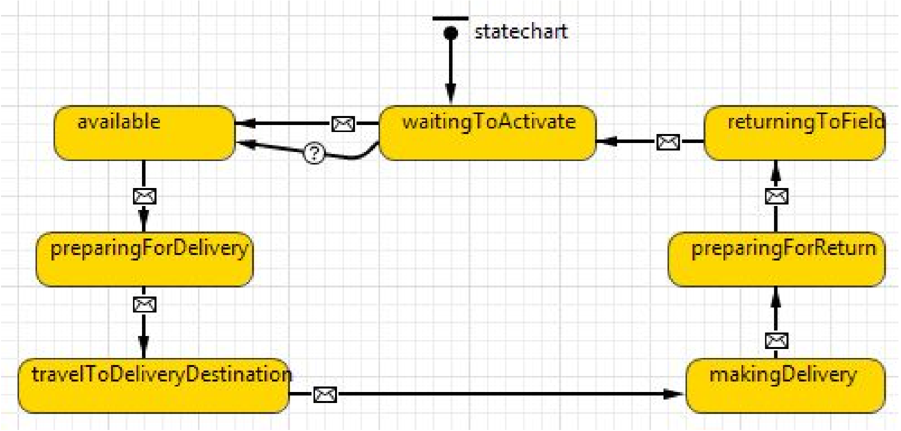

Figure 4: Chart showing the various states for a Truck agent in the simulation. Transitions between states are driven by messages. The truck is initially in a waiting to activate state and then transitions sequentially through the steps required to pick up material to the farm, travel to an elevator, deliver at the elevator and return to the original state to start the cycle again.

This simulation is not intended to provide a realistic emulation of the actual movement of individual vehicles in a harvesting operation. It is based on stochastic variation for the key events, including TransferEvents, that take place during harvesting and operation of the rest of the production chain. This approach: (1) provides a means to produce TransferEvent data sets that enable traceability analysis of the grain movement events in a complex production chain with many participants, and; (2) makes it easier to create simulations of different production chains by just changing the number and initialization data for the agents.

Figure 5 provides a snapshot of a simulation execution with two combines, two carts, three trucks, and four crop zones. The logic that governs a part of the behavior of Combine and Cart agents is presented at the top of the figure. Illustrations for the current states for the Combine, Cart, and Truck agents are provided below that. On the left, the current status for harvesting operations on each CropZone is provided. CropZones for which harvesting has not started, is underway, or has completed are color-coded in light green, medium green, or yellow, respectively. Note that since only two Combines are available, some will have to harvest more than one CropZone. In this case, the combine *Combine_1* was assigned to and finished harvesting cropzone *Zone_2* and is currently harvesting cropzone *Zone_4*.

Summary and Future Work

In this paper, the nature and goals of several projects that are addressing traceability issues have been described. The projects seek to gain synergy through inter-project collaborations, which should both increase the quality and confidence in the outputs of the individual projects. The participants plan to continue to collaborate on areas of common interest. Future activities may include: identification of new stakeholders that can contribute to the different efforts; continued evaluation of the data needs to support traceability; identification and evaluation of existing standards to assess how they might be used to construct systems that support traceability; exploration of whether the development of a cross domain ontology for traceability is feasible, and; finishing work on the modeling of grain flow through a bin.

Analysis of the results of the POC continue, and at least one additional live simulation of the grain production chain is planned, with many new participants showing interest. The target for this effort is Fall 2018.

Riddick, Frank H.; Wallace, Evan K.; Nieman, Scott; Tevis, Joe; Ferreyra, R. ”Implementing Grain Traceability Standards: CART and Simulation.” Paper presented at 2018 American Society of Agricultural and Biological Engineers (ASABE) Annual International Meeting, Detroit, MI, US. July 29, 2018 - August 01, 2018.

Immediate plans are to extend the production chain simulation to cover all production chain participants from the farm to the processor. This will enable it to generate a data set of transfer events that can be analyzed that covers the same parts of the production chain as covered by the POC. Future extensions of the simulation include: reading initialization data from and storing results in a database to make it easier to analyze the data; creating a form based front end for the creation of initialization data to reduce the effort to create different production chain scenarios to simulate, and; integrating the result of the bin flow modeling effort once they are available.

Compact 1.7 K Cryocooler for Superconducting Nanowire Single-Photon Detectors

V. Kotsubo, J.N. Ullom, and S.W. Nam

National Institute of Standards and Technology
Boulder, CO 80305, USA

ABSTRACT

State-of-the-art superconductor-based cryogenic detector systems are being installed at numerous research facilities worldwide and are achieving world-record sensitivities in a variety of applications. Implementation has been greatly facilitated by closed-cycle refrigeration. However, in many cases, cooling capacities of the refrigerators exceed requirements, at times by orders of magnitude, resulting in excessively large and cumbersome systems. The availability of more compact and lower power consumption systems should greatly facilitate further user acceptance. Toward this end, we are developing a compact 1.7 K closed-cycle pulse tube/Joule-Thomson hybrid cryocooler for superconducting nanowire single-photon detectors. A laboratory prototype consisting of the pulse tube cooler and the Joule-Thomson coldhead has demonstrated over 1.4 mW of cooling at 1.7 K. The Joule-Thomson compressor is under development and remains the single largest risk item in terms of reliability. The system, designed for low manufacturing costs, is projected to consume on the order of 250 W total power, including power for cooling fans, thermometry, and detector electronics, and to be mountable within a standard equipment rack.

INTRODUCTION

Applications for superconductor-based sensors and electronics have been steadily increasing over the past several years in diverse areas such as astrophysics/cosmology,[1] X-ray spectroscopy,[2] gamma-ray spectroscopy,[2] quantum information,[3] and photon science.[3] These systems operate at temperatures ranging from above 4 K to lower than 50 mK. Although these systems are developed by scientists with low-temperature expertise, end users typically have minimal cryogenic experience, and therefore acceptance has been greatly facilitated by push-button, closed-cycle cryocoolers. The majority of these systems depend on precooling with commercial Gifford-McMahon or valved pulse tube coolers, which were originally developed for applications requiring relatively large cooling capacities such as shield cooling in magnetic resonance imagers or cryopumping. As a result, for many, if not most of these systems, the size and power consumption of the system are orders of magnitude larger than necessary. For example, many transition edge sensor (TES) systems are cooled using adiabatic demagnetization refrigerators (ADRs) with cooling capacities of hundreds of nanowatts at temperatures below 100 mK. At the 4 K reject temperature for the ADR, the heat rejected is on the order of a milliwatt, yet precoolers with capacities on the order of a watt with a power draw of several kilowatts are used.

Kotsubo, Vincent; Ullom, Joel; Nam, Sae Woo. "Compact 1.7 K Cryocooler for Superconducting Nanowire Single-Photon Detectors." Paper presented at 20th International Cryocooler Conference, Burlington, VT, US. June 18, 2018 - June 21, 2018.

While there are advantages for using excessively large coolers such as rapid cooldown times and flexibility in cryostat design, future widescale applications of these types of systems will be greatly enhanced by reducing their size and power. Such applications include secure quantum encrypted communication links[3] that utilize superconducting nanowire single-photon detectors (SNSPD), and superconducting transition-edge sensor microcalorimeters for electron microscope microanalysis.[2]

Based on these considerations, we initiated the development of a compact cooler for an SNSPD detector system that will result in a form factor and low power draw of a standard rack- mountable electronics instrument. The cooler is a pulse tube/Joule-Thomson (PT/JT) hybrid, with the JT stage achieving 1.4 mW of cooling at 1.7 K, and the three-stage pulse tube providing cooling at 80 K, 25 K, and 10 K. To date we have successfully developed the pulse tube cooler and JT coldhead, whereas the JT compressor and associated gas decontamination is still under development.

We have previously published results on an early version of this cooler.[4] In this paper we present further details, plus improvements, including a modification of the pulse tube 10 K stage regenerator that increased the cooling capacity at 10 K by 35 % and reduced the minimum temperature from 7.8 K to 6.4 K; and a modification of the JT stage, which dropped the minimum temperature from 2.2 K to 1.7 K.

CRYOCOOLER DESCRIPTION

Design Goals

As discussed in a previous publication[4] the target application is a four-channel tungsten-silicide (WSi) SNSPD.[5] Estimated cooling loads on each of the cooler stages are presented in Table 1 along with the design goals. The cooling load on the JT stage arises primarily from low thermal conductance bias/readout coaxial cables, since SNSPD's dissipate negligible power and photons are coupled in through optical fiber. Our targeted cooling capacities included design margin on each stage. The 80 K stage radiation load estimate has considerable uncertainty due to unknown ambient temperature since the cryocooler will be enclosed in an equipment rack-mounted box, and because of the uncertain surface emissivity of the radiation shield.

The WSi SNSPD detectors require cooling to 1.25 K for maximum quantum efficiency, but this temperature is difficult to achieve with a ^{4}He JT refrigerator that utilizes a low power, compact compressor. A ^{3}He JT would reach this temperature and will be used for future units, but to facilitate development, we used ^{4}He and targeted 2.0 K since the identical vapor pressure if ^{3}He is used would result in 1.25 K. Operation at temperatures up to 2.5 K is acceptable if maximum quantum efficiency is not required.

The 10 K for the precooling temperature for the JT stage is a lower temperature than the thermodynamic optimum for this hybrid, but we opted for as low as reasonable precooling temperatures to reduce the high-pressure requirement for the JT loop, which in turn reduces stress on the JT compressor. We chose this approach because the JT compressor is the largest risk to reliability. Final test results shown below show that the actual operating temperature of this stage was below 7.7 K

Table 1. Estimated heat loads and design goals for a four channel SNSPD detector cooler.

Stage	Radiation (mW)	JT Precooling (mW)	Conduction (mW)	Total (mW)	Design Target (mW)
80 K	1000-2350	400	150	1550-2900	3000
25 K	5-12	28	7	40-47	100
10 K	0.2	2	1	3.2	5
2.0K	0	N/A	0.28	0.28	0.5

.

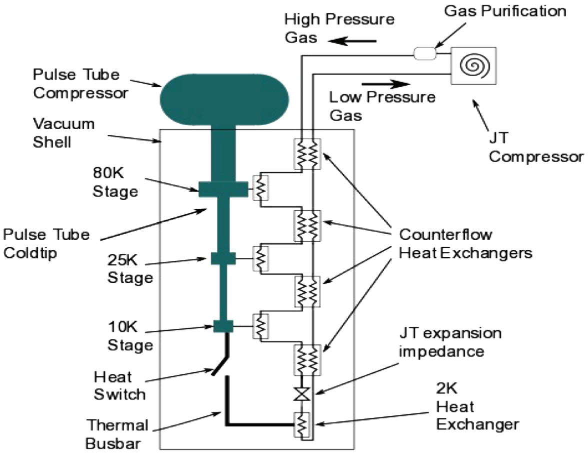

Figure 1. Operational schematic of the cryocooler.

Cooler Description

The cooler is shown schematically in Figure 1. The pulse tube is a three-stage, cooled inertance tube[6] configuration driven by a commercial resonant piston compressor at 35 Hz. Each stage is a U-tube configuration, resulting in an easy-to-integrate coldhead. Because the objective of the project is a producible, low cost cooler, the mechanical design sacrificed performance to reduce costs. The most impactful tradeoff was the use of standard sized stainless-steel tubing for the regenerator and pulse tube walls, rather than machined titanium, which is commonly used in aerospace coolers. Replacing the stainless-steel tubes with titanium tubes would result in 1.8 W, 0.07 W, and 0.001 W of additional cooling on the 80 K, 25 K, and 10 K stages, respectively.

The upper two-stage inertance tubes were dual diameters, whereas the third stage used only a single diameter because modeling indicated minimal improvement in performance with dual diameters. Regenerators used standard materials; the first stage used die-punched stainless-steel screens, with #150 mesh, 66 um wire diameter in the warm side and #400 mesh, 25.4 um wire diameter in the cold side. The second stage used #400 mesh, 25.4 um wire diameter stainless steel screens in the warm side and #400 mesh, 25.4 um wire diameter phosphor bronzes screens, flattened to produce 0.55 porosity, in the cold side. The third stage used high heat capacity microspheres. In the previous work reported in Ref. 4, 100 um diameter 50-50 erbium-praseodymium (ErPr) alloy spheres[7] were used. We have since replaced the lower half of the regenerator with 100 um diameter erbium-nickel (ErNi) spheres to improve cooling capacity below 10 K, and comparative tests results are presented below.

A critical mechanical design objective is geometries that minimize the effects of secondary flows within the pulse tube and regenerator, because these flows can seriously degrade performance. Most well-known are turbulence/convection in the pulse tube and streaming in regenerators.[8] Somewhat less appreciated are secondary flows in the displacer gap in Stirling coolers. A net circulation can flow through the displacer gap and return through the regenerator partially unregenerated and cause cooling loss unless there is sufficient lateral thermal conduction. Alternatively, because the displacer gap is dynamic, the local gap dimensions can vary during the operating cycle, causing local oscillating flows to not exactly reverse motion, again leading to unregenerated flow and cooling loss.

While it is well documented that, in large diameter regenerators, net circulation can lead to significant degradation in coolers,[8] we were concerned that even in small diameter regenerators, some level of circulation can exist, causing measurable cooling loss. In multi-stage coolers, circulation can be generated in the regenerators near the junctions between stages, where the phasing of the flows between the upper stage regenerator, lower stage regenerator, and buffer tube will necessarily lead to circulation in the regenerators if the upper and lower stage regenerators are in-line with each other because flows entering the regenerator can come from either the adjacent regenerator or the flow channel from the buffer tube. To mitigate this, we located the second stage regenerator such that the warm entrance was in the connecting channel between the first stage regenerator and first stage pulse tube rather than directly in-line with the first stage regenerator. Thus, the flow entering the cold end of the first stage regenerator always came from the channel. This arrangement was not possible for the junction between the second stage and third stage regenerators because the second stage regenerator packing access was through an attachment flange for the third stage regenerator, which was directly in line with the second stage regenerator. However, the small diameters of the second and third stages likely mitigated any effects of circulation. We have not validated whether this design feature improves cooling, but because the cooler performs as predicted by the model, it does not appear that there are any detrimental effects.

For the JT system, the very low cooling capacity requirement allowed a design driven by ease of fabrication rather than by thermodynamics. The stage nominally operates between a high pressure of 200 kPa and a low pressure of 3.2 kPa, with a flow rate of 0.6 mg/s. The thermodynamic power required to recompress the gas is only a few watts, which is such a small fraction of the total power budget that a highly thermodynamically efficient design is not required.

All four JT counterflow heat exchangers were simple tube-in-tube designs, with high-pressure gas flowing in the narrow annular space between the two tubes and the low-pressure gas flowing through the inner tube. This configuration simplifies fabrication, plus has a large internal surface area on the high-pressure return side to allow condensable contaminants to freeze out without plugging the flow passage. The expansion impedance was a 2 m long, 50 μm inner-diameter stainless steel capillary.

At the cold ends of the warmer three counterflow heat exchangers, a small heat exchanger consisting of fine mesh copper screen diffusion bonded to a copper body was used to heat sink the incoming gas to the pulse tube. The 1.7 K coldstage also had a small copper screen mesh heat exchanger for thermal contact to the load.

To mitigate particulate contamination, sintered stainless steel particulate filters were inserted in the high-pressure line prior to entering the cryostat, at the end of the heat exchanger at 80 K and just upstream of the JT expansion impedance. In addition, a small capsule of activated charcoal was placed in the high-pressure stream on the 80 K stage to adsorb any condensable contaminants.

To expedite cooldown of the JT coldstage from room temperature, a heat switch consisting of a small bar that clamped down on a small copper tab attached to the JT coldhead was used. The clamp was heat-sunk to the pulse tube 10 K stage and was actuated by pulling on a fine stainless-steel wire attached to the bar. The far end of the wire was fed through a bellows feedthrough through the room temperature vacuum flange to allow actuation of the heat switch.

In the original system,[4] both the inlet and outlet of the JT expansion capillary were housed in the same copper block and therefore at the same temperature. In this version, we separated the warm and cold ends of the capillary, and the result, presented below, was a lower base temperature of 1.7 K in comparison to the 2.2 K base temperature previously reported.

The JT compressor under development is a scroll compressor, selected because of the ability to achieve low suction pressures, compact size, and low per-unit cost.

MODELING RESULTS

Pulse Tube

The pulse tube was modeled using a widely used commercial Stirling and pulse tube software design package.[9] We relied heavily on the built-in numerical optimizing algorithm to design the cooler so, at least on paper, this is a highly efficient design. In this section we present modeling results, and although most of these model outputs are not easily measurable, we present them as an illustration of cooler behavior.

Table 2 presents top-level parameters of the pulse tube: frequency, charge pressure, oscillatory pressure amplitude P_1, compressor power, and cooling powers. The cooling powers identically match the design goals because those were set as constraints in the optimizer. The compressor power was the result of the optimization process that required its minimization.

Table 2. Modeled Top Level Pulse Tube Parameters

Frequency (Hz)	35
Charge Pressure (MPa)	1.5
Pressure Amplitude P_1 (MPa)	0.13
Compressor Power (W)	148
$\dot{Q}$ 1st stage @ 80 K (W)	3.00
$\dot{Q}$ 2nd stage @ 25 K (W)	0.10
$\dot{Q}$ 3rd stage @ 10 K (W)	5.0×10−3

Table 3. Modeled Compressor Loss

Total Compressor Power (W)	148
Delivered Acoustic Power (W)	117.5
Ohmic Loss (W)	17
Friction/Eddy Current Damping (W)	8.5
Compression Space Heat Transfer (W)	2.5
Seal Blowby (W)	2.5

The charge pressure of 1.5 MPa was driven by the limited regenerator heat capacity below 10 K, and this lower pressure sacrificed thermodynamic efficiency at the higher stages for increased thermodynamic efficiency at the lowest stage.

Table 3 lists the modeled losses for the pulse tube compressor, where the analysis used compressor parameters provided by the vendor. The ohmic loss is particularly small for this type of cooler because the compressor was significantly larger than necessary, with the capability of 600 W of input power.

Table 4 shows regenerator energetics. $\dot{E}_2$ is the second-order acoustic power, defined within the thermoacoustic framework[10] as:

$$\dot{E}_2 = \langle P_1 U_1 \rangle \tag{1}$$

where P_1 is the first order pressure amplitude and U_1 is the first order volume flow rate defined as:

$$U_1 = A_c v \tag{2}$$

where A_c is the cross-sectional flow area, v is the local spatial averaged velocity, and the brackets denote time averaging. The modeling includes higher harmonics, but the acoustic power associated with the fourth-order term is negligible so only the second-order acoustic power is presented. $\dot{H}_{\text{cold}}$, $\dot{Q}_{\text{screen}}$ and $\dot{Q}_{\text{tube}}$ are the enthalpy, screen conduction, and tube wall conduction losses. The enthalpy and screen conduction loss were taken at the cold end of the regenerator because the model couples these two losses internally within the regenerator. As a figure-of-merit, we define the acoustic power loss ratio as:

$$\varepsilon_{\dot{W}_2} = \left(\frac{\dot{E}_{2,cold}}{\dot{E}_{2,hot}}\right) \Bigg/ \left(\frac{\dot{E}_{2,cold,ideal}}{\dot{E}_{2,hot,ideal}}\right) = \left(\frac{\dot{E}_{2,cold}}{\dot{E}_{2,hot}}\right) \times \left(\frac{T_{hot}}{T_{cold}}\right) \tag{3}$$

where, for an ideal lossless regenerator using an ideal gas, the ratio of the acoustic powers at the ends of the regenerator scale as the ratio of the temperatures. The subscripts *hot* and *cold* refer the hot and cold ends of the regenerator. The acoustic power loss ratio therefore indicates the remaining fraction of the ideal acoustic power not consumed by irreversibilities such as viscous loss, within the regenerator.

The second figure-of-merit is the ratio:

$$\varepsilon_{\dot{H}} = \frac{\dot{E}_{2,cold} - \dot{H}_{cold}}{\dot{E}_{2,cold}} \tag{4}$$

which represents the fraction of the gross cooling power remaining after subtracting the enthalpy flow loss. The results of Table 4 indicate that acoustic power loss and enthalpy loss dominate, with

Table 4. Modeled Regenerator Energetics.

	$\dot{E}_{2,\text{hot}}$ (W)	$\dot{E}_{2,\text{cold}}$ (W)	$\dot{H}_{\text{cold}}$ (W)	$\dot{Q}_{\text{screen}}$ (W)	$\dot{Q}_{\text{tube}}$ (W)	ε_{W_1}	$\varepsilon_{\dot{H}}$
1st stage	111.6	19.0	5.80	0.53	1.32	0.66	0.69
2nd stage	3.46	0.97	0.50	0.026	0.048	0.90	0.48
3rd stage	0.086	0.031	0.01	8.0×10−5	0.0013	0.90	0.68

sizable acoustic power loss occurring in the first stage regenerator, while enthalpy losses occur in all three regenerators but is the largest in the second stage. Part of the reason for high second stage enthalpy loss is that it is operating near its minimum temperature of about 21 K. The high acoustic power efficiencies of the second and third stages in comparison to the first stage suggests that, by using commercially available screen meshes, the hydraulic diameters are larger than optimum, resulting in higher enthalpy losses but lower acoustic losses.

Table 5 shows the energetics of the thermal buffer tubes. The efficiency is:

$$\varepsilon_{TBT} = \frac{\dot{H}_{cold}}{\dot{E}_{2,cold}} \tag{5}$$

In the model, the enthalpy loss and tube wall thermal conduction loss are coupled so that the losses shift between the two along the length of the tube, so the enthalpy and tube conduction are taken at the cold end of the tube. The efficiencies are reasonably high, with one of the contributing factors being the low fluid displacement amplitudes, in the range of 10 % of the total length.

Joule-Thomson Modeling

Because of the very low flow rates and low thermodynamic compression power, the JT loop did not require a high degree of optimization, so counterflow heat exchangers were designed for ease of fabrication. They were modeled using a simple NTU analysis[11] using temperature-averaged fluid properties, along with a separate calculation of thermal conduction down the heat exchanger tubes. There was considerable leeway in the design, allowing heat exchanger lengths to vary by a factor of two without significantly affecting performance. The main consideration was minimizing the demand on the JT compressor, so the system was designed for the lowest reasonable high-side pressure to minimize stresses on bearings and backleakage through seals. Final flow and pressure requirements for the compressor were determined from test data.

TEST RESULTS

Pulse Tube Results

Prior to integration with the JT stage, the pulse tube was tested as a stand-alone unit. It was installed in a laboratory test dewar, with the warm-end temperature controlled to 310 K using temperature-regulated circulating water to simulate the anticipated higher temperature environment when the unit is installed within a fan-cooled equipment rack. The test dewar was not temperature controlled; its temperature varied considerably because the laboratory temperature was unregulated. As a result, there was significant run-to-run variability in the radiation load on the 80 K stage. The PT compressor and first-stage inertance tube were also not temperature regulated, which also led to some first-stage performance variability.

Modeling of the inertance tubes is generally not expected to be accurate because of turbulence, sensitivity to tube diameter, and uncertainty in the heat sink temperature, so an initial tuning of the inertance tube was required. Because inertance tubes for small capacity coolers are effectively low-*Q* quarter-wavelength acoustic resonators, the tubes were tuned by sweeping the drive frequency of the compressor and searching for the frequency of the maximum cooling capacity of each stage. The lengths of the inertance tubes where trimmed or extended by the ratio of this frequency to the resonant frequency of the compressor. The tubes were designed with as low a Q as possible to reduce sensitivity to length and temperature.

Upon completion of this tuning, the first characterization test was to simply measure the

Table 5. Energetics of the thermal buffer tube.

	$\dot{E}_{2,\mathrm{cold}}$ (W)	$\dot{H}_{\mathrm{cold}}$ (W)	ε_{TBT}	$\dot{Q}_{\mathrm{tube}}$ (W)
1st stage	14.2	10.4	0.73	0.42
2nd stage	0.82	0.68	0.83	0.043
3rd stage	0.021	0.017	0.81	7.4×10−4

cooling powers for each stage at their nominal design temperatures of 80 K, 25 K, and 10 K with 150 W compressor power. The results are tabulated in Table ww, with a drive frequency of 35 Hz and charge pressure of 1.5 MPa. The 10 K stage regenerator for this test consisted of all ErPr spheres. The measured loads are in addition to an unknown amount of radiation loading so the actual cooling capacity is somewhat higher on the 80 K and 25 K stages than shown in the table. Reasonable estimates of the radiation load suggest that the cooling power of the 80 K stage is in excess of the design point goal of 3.0 W.

Figures 2a and 2b show the cooling capacities of the 80 K stage and 25 K stage as a function of temperature. Each load curve was taken while holding the other two stages at constant temperature. These plots illustrate that the 80 K stage handles loads on the order of watts, while the 25 K stage handles loads on the order of tenths of watts.

Figure 3 show load curves for the 10 K stage and compares the performance of the all ErPr regenerator and the regenerator with ErPr in the warm half and ErNi in the cold half, with data for ErPr/ErNi regenerator combination shown at three different charge pressures. In all cases the ErPr/ErNi regenerator outperforms the all-ErPr regenerator, except at temperature above 10 K with 1.25 MPa charge pressure for the ErPr/ErNi regenerator. The ErPr/ErNi combination also consistently reached a minimum temperature in the 6.3 K to 6.5 K range while the minimum temperature of the all ErPr regenerator reached a minimum temperature slightly below 8 K. These lower temperatures were expected because of the lower heat capacity of ErPr compared to ErNi at lower temperatures. These data were taken with no applied load to the upper two stages such that the upper stages ran colder than the data in Table 6, which resulted in higher 10 K cooling capacity.

Joule Thomson Results

Because the JT compressor is still under development, final tests on the integrated JT-pulse tube coldhead was conducted open loop using a regulated compressed gas storage bottle as a supply and a vacuum pump vented to atmosphere on the return. The low side pressure was controlled by adjusting a valve in front of the vacuum pump.

Figure 4 shows load curves at high side pressures of 0.2 MPa, 0.15 MPa, 0.125 MPa, and 0.1 MPa. A maximum of 1.4 mW was produced at the minimum temperature of about 1.7 K. The cooling capacity increase at lower temperatures is from increased mass flow through the capillary from higher gas density. Operating at 0.1 MPa does not provide sufficient cooling to cool down the JT stage from the initial temperature of around 7 K.

Table 6. Simultaneously measured cooling capacities at all three stages with 150 W compressor power.

Stage	Temperature (K)	Capacity (W)
1	80	2.77
2	25	0.080
3	10	5.0×10−3

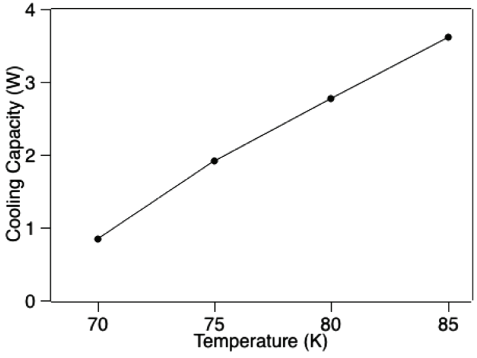

Figure 2a. Load curve for the 80 K stage

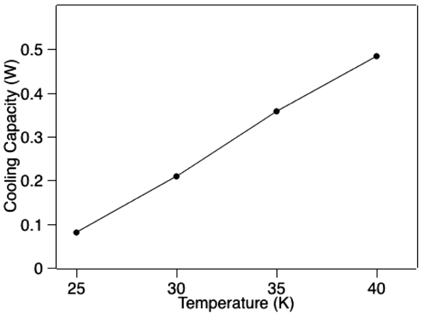

Figure 2b. Load curve for the 25 K stage

In the previous publication we reported instability at the lowest temperatures.[4] In the present setup, the instability occurs only when the temperature of the upstream side of the capillary drops below the liquefaction temperature corresponding to high side pressure. We attribute this to liquid in the low-pressure pumping line reaching the cold end of the JT counterflow heat exchanger, which then liquefies the fluid entering the capillary. Although we do not specifically know why this causes the instability, if we temperature-regulate the coldstage slightly above the minimum temperature, no liquid accumulates, which stabilizes the cold stage temperature.

The return pressure in these tests was as low as 650 Pa. The return pressure does not affect the load curves except that lower temperatures are reached with lower return pressures as expected from the saturation curve.

During these tests, the load on the pulse tube from circulating ^{4}He would cause the third stage temperature to rise slightly. However, in all situations the temperature remained below 7.7 K, indicating that Nb-Ti wire can be used for electrical leads between the 10 K stage and the JT stage.

Cooldown Time

The system cooled to base temperature within 24 h. The 80 K pulse tube stage reached close to its minimum temperature in about 4 h, but both the 25 K and 10 K stages took significantly longer because of their low cooling capacities and large thermal mass loads associated with the compliance tanks and JT components. Once the PT reached its bottom temperature, the JT stage would cool rapidly to its base temperature, within a few minutes if 0.2 MPa high-side pressure was used.

TOTAL POWER PROJECTION

Test data described above show that the design point cooling powers for the pulse tube require a nominal 150 W of compressor power. We have tested a variety of commercial off-the-shelf power electronic modules for driving the compressor and they generally had conversion efficiencies of better than 90 % power so the pulse tube will require a total power draw of about 165 W. Although the JT compressor is still under development, preliminary tests indicate that the power draw by the compressor and drive electronics will be about 50 W. If the power for cooling fans and thermometry/diagnostic instrumentation is included, the final total power draw may be well less than 250 W. We also evaluated power consumption if we used a smaller, commercially available, pulse tube compressor to reduce system weight, with the result that another 30 W of compressor power will be required.

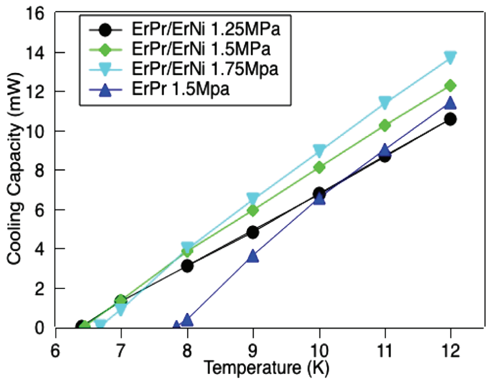

Figure 3. Load curves for the 10 K stage comparing the all ErPr regenerator to the ErPr/ErNi regenerator at pressures of 1.25 MPa, 1.5 MPa, and 1.75 MPa.

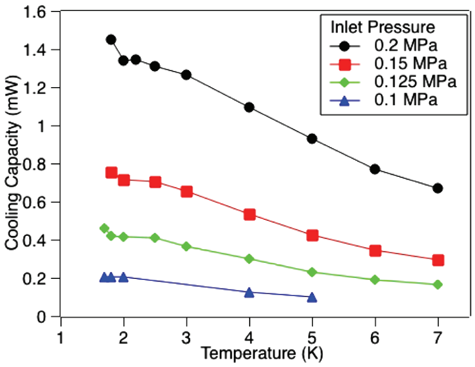

Figure 4. Load curves for the JT stage at high side pressures of 0.1 MPa, 0.125 MPa, 0.15 MPa, and 2 MPa.

EXPANDABILITY

These test results are for one operating condition for the pulse tube and one flow impedance for the JT stage. For low heat load applications, the flow impedance can be increased, reducing the mass flow, which would both reduce the power required for both the JT compressor and pulse tube compressor. Conversely, there is substantial upside in the cooling power capability of the JT stage. The JT impedance can be reduced, which would result in higher mass flow rates and higher cooling powers. The pulse tube has sufficient capacity to accommodate higher JT mass flow rates, so capacities approaching 5mW are possible, although this will require development of a larger capacity JT compressor.

Lower temperatures using ^{4}He are possible but will require a combination of reworking the JT counterflow heat exchanges to reduce pressure drop, a JT compressor with lower suction pressure, and superfluid film creep mitigation. Direct substitution with ^{3}He should result in temperatures below 1 K.

CONCLUSION

We have demonstrated a compact, low power pulse tube/JT hybrid cooler that reaches a base temperature of 1.7 K with up to 1.4 mW of cooling. We project that an SNSPD system using this cooler will have a total power draw of about 250 W and the entire unit will be rack mountable in a standard equipment rack. The component with the highest risk to reliable operation, the JT compressor, is presently under development.

Structure Vulnerability to Firebrands from Fences and Mulch

Kathryn M. Butler, **Erik L. Johnsson**, and **Wei Tang**,
National Institute of Standards and Technology, Gaithersburg, Maryland

Abstract—Fences and mulch contribute to the spread of wildland-urban interface fires, acting both as ignition targets and as sources that may ignite nearby objects through direct flame contact and firebrand generation.

This paper presents the findings from outdoor experiments that investigated the spread of fire through firebrand spotting from fences and mulch beds near a structure in a wind field. A fence section, mulch bed, or combination was arranged perpendicular to a small structure, with a large fan directing wind toward the structure. After ignition, data were collected on firebrand spotting time, time for the spot fire to reach the wall, and flame spread rate over the fence and mulch bed.

Fence type, wind speed, and type of mulch were found to affect firebrand spotting. For fence and mulch combinations, spotting usually occurred within 7 minutes. Time to spotting generally decreased with increasing wind speed. Two parallel fence panels burned significantly more intensely, and spotted more quickly, than a single fence panel. In the absence of mulch, spotting from fences often occurred more slowly or not at all. The combination of a fence and a mulch bed decreased the time to spotting over either the mulch bed or the fence alone.

Keywords: fence, firebrand, mulch, structure vulnerability, wildland-urban interface (WUI) fire

INTRODUCTION

Wildland-urban interface (WUI) fires threaten an estimated 70,000 communities, 46 million homes, and 120 million people within the United States (ICC and NARCD Councils 2013). In recent years, the United States has been losing on the order of 3,000 homes per year, and the costs are rising, with $14 billion spent in 2009 alone on fire suppression and damages.

Firebrands generated by a wildfire are carried by the wind and may ignite fires in a community far downstream of the fire front. After the fire has reached the community, firebrands generated from burning combustible objects near a structure contribute to the firebrand assault. Postfire investigations have demonstrated that firebrands are a major contributor to structure losses in WUI fires.

Fences and mulch are common contributors to the spread of WUI fires within WUI communities. They act both as ignition targets and as sources that may themselves ignite nearby objects through direct flame contact and firebrand generation. The linear nature of fences gives them the capability of spreading fire over long distances. In a study of the 2011 Tanglewood Complex Fire near Amarillo, Texas performed by the National Institute of Standards and Technology (NIST) (Maranghides and McNamara 2016), 2.4 km of fences within a community of 25 homes were found to be damaged or destroyed. Combustible fences also contributed to fire spread in the 2012 Waldo Canyon Fire in Colorado (Maranghides et al. 2015). Firefighters were documented removing fences as part of their defensive strategy to contain this fire, reducing resources allocated to suppression.

The goal of this work is to improve our understanding of the mechanisms by which fences and other combustible landscaping elements can transport fire to a home, including exposure to wind-driven firebrands. The results will be used to improve codes and standards, which in turn will provide guidance to homeowners and firefighters.

EXPERIMENTAL DESIGN

Setup

To investigate the spread of fire through firebrand spotting, a series of field experiments are being performed on fences, mulch beds, woodpiles, and other combustible landscaping elements arranged in front of a structure in a wind field.

Figure 1 shows a schematic of the experimental setup for fences and mulch beds. A wind machine, consisting of an airboat fan mounted on a trailer, was aimed toward a small structure. A flow straightener directed the wind downward slightly so the wind field would reach the ground and the base of any combustible object being tested. A fence section, with or without a mulch bed beneath, was arranged perpendicular to the wall of the structure. The fence section was 2.44 m long and 1.83 m high for privacy fences or 1.22 m high for lattice fences, attached to 0.09 m × 0.09 m pine (*Pinus* spp.) posts at each end. The fence or mulch bed was placed in contact with the wall of the structure or separated from it by some fixed distance.

To study the ability of firebrands to threaten a house, a target pan of hardwood mulch that was 0.46 m wide was arranged at the base of the structure wall. This mulch bed served as a surrogate for any combustible material next to a house. Because of its rough texture, any firebrands landing on this surface tended to stay in place.

Before being arranged in steel pans, the mulch was dried to a moisture content between 6 and 7 percent, as measured by a moisture analyzer. The mulch beds were prepared by filling the pans with an even layer of mulch and compressing it lightly by foot. The mulch beds were 0.05 m thick except for cases in which the mulch beds were reduced to half thickness (0.025 m).

The wind field was monitored by a set of bidirectional probes just upwind of the end of the fence. The ambient wind speed and direction were measured by

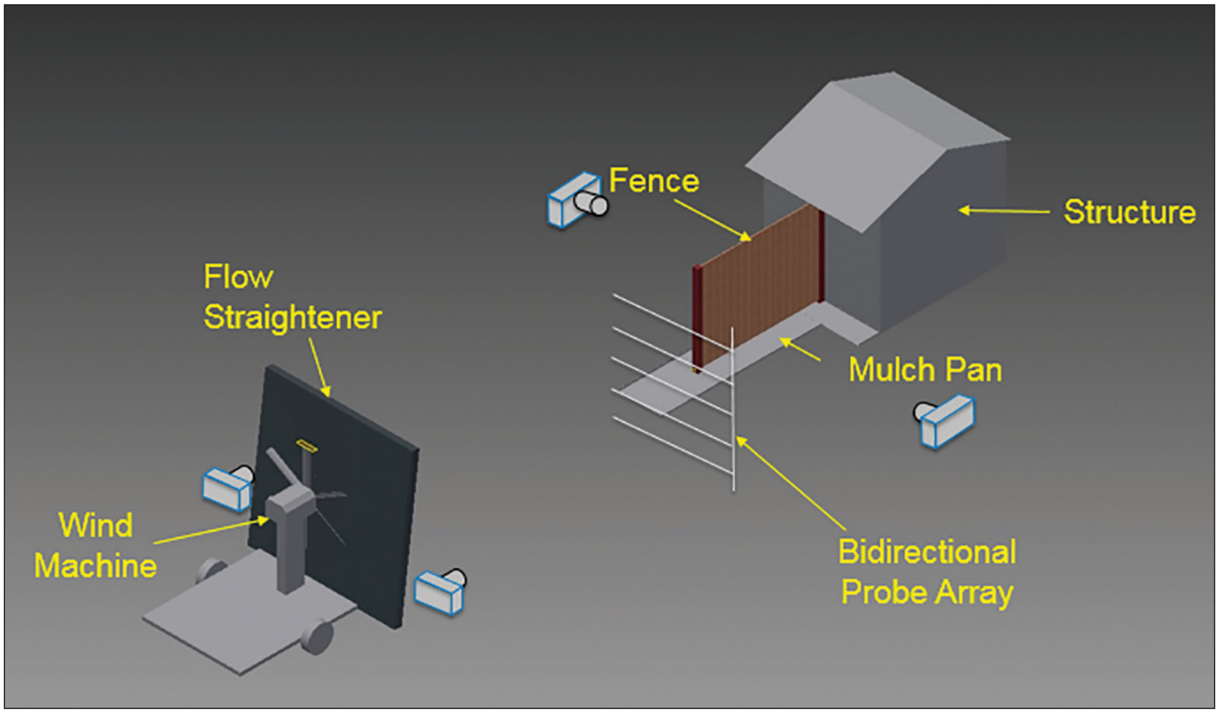

Figure 1—Experimental setup.

Butler, Kathryn; Johnsson, Erik L.; Tang, Wei. "Structure Vulnerability to Firebrands from Fences and Mulch." Paper presented at The Fire Continuum Conference, Missoula, MT, US. May 21, 2018 - May 24, 2018.

an anemometer mounted on a shed away from the experimental setup, and the ambient temperature was measured with a thermocouple near the test setup. Four video cameras monitored the experiment from right and left sides and from each side of the fan.

The ambient wind speed was required to be less than one-third the nominal wind speed in order to carry out the experiment. Under these conditions, the impact of the ambient winds on the wind field generated by the fan was minimal.

Procedure

A propane burner was used to ignite the fence or mulch bed at the base of the fence farthest from the structure. After 90 seconds, when the fire was judged to be self-sustaining, the fan was turned on, a timing clock was started, and the winds were brought to the speed required by the experiment. The experiment ended when a fire in the mulch bed at the base of the structure reached the wall and after fire had also reached the end of the fence or fence mulch bed. Flames at the wall from spot fires were extinguished if the fire had not yet spread over the entire length of the fence with mulch bed. At the end of the test, the clock was reset and all fires were extinguished with a water hose.

Uncertainties

The measurements of wind speed, distances, and times discussed in this paper each have uncertainties associated with them. Uncertainties generally consist of several components, which are grouped into two categories according to the method used to estimate their value. Type A uncertainties are evaluated by statistical methods, and type B uncertainties are evaluated by other means, often based on scientific judgment using all available relevant information (Taylor and Kuyatt 1994). Type B uncertainties are evaluated by estimating lower and upper limits a_- and a_+, such that the probability that the value lies in the interval a_- to a_+ is essentially 100 percent. If the value is equally probable to lie anywhere within the interval, the best estimate is $(a_+ + a_-)/2$, with standard deviation $u_j = a/\sqrt{3}$, where $a = (a_+ - a_-)/2$. Once all components have been estimated by either type A or type B analysis, they are combined using the square root of the sum of the squares (RSS) method to yield the combined standard uncertainty (estimated standard deviation), u_c. Finally, expanded uncertainties are given by $\pm\, ku_c$, where $k = 2$ is the coverage factor for a confidence level of 95 percent.

Table 1 shows the components of uncertainty for the measurements given in this paper. The extensive data collection on wind speed enables the evaluation of type A uncertainties; most other uncertainties on this list are type B, either estimated through scientific judgment or obtained from the literature.

Wind speed uncertainties involve the bidirectional probe design and the measurement statistics from the wind field. A paper by McCaffrey and Heskestad (1976) states that velocities are estimated within ±10 percent provided the approach flow direction is within approximately 50° of the probe axis. Since the variability of the fan was greatest at the lowest setting, which was close to the idle speed, statistical analysis was carried out for each wind speed level separately. Repeatability was calculated as the standard deviation of the average wind speed for each experiment (the average from five probes in the central wind field) from the average wind speed overall. The random component reflects the fluctuations in measured wind speed due to turbulence, and was calculated by the root-mean-square of the standard deviations of wind speed over all experiments at each wind speed level.

The time to spotting required identification of two events in videos taken by the camera positioned to the right or left side of the experiment. The first event was the time at which the fan was turned on. The engagement of the fan engine could be determined very accurately, although it should be noted that the wind speed was adjusted for up to 20 seconds afterwards before reaching a steady state value. The second event was the ignition within the target mulch bed of the first spot fire that eventually reached the wall of the structure. After identification in one of the videos, this spot fire was tracked backwards in time to the point at which the first sign of smoke could be detected in the mulch, which could be defined within an estimated ± 5 seconds. These sources of uncertainty are likely dwarfed, however, by the repeatability of time to spotting for multiple tests under the same conditions and the random nature of firebrand generation and ignition processes, neither of which is available for this study.

Table 1—Uncertainty in experimental data.

Variability	±0.01 m	±0.01 m	±0.02 m

* Type A uncertainty (evaluated by statistical means). All other uncertainties are type B (evaluated by other than statistical means).

The separation distance between the fence or mulch bed and the wall of the structure was established by using a tape measure to adjust the location of the fence with mulch bed to the desired position. Sources of uncertainty include the placement of the tape measure and the ability to adjust the position of the fence with mulch bed accurately.

The mulch bed thickness varied over its surface due to the nature of the mulch as overlapping particles whose individual thicknesses are an appreciable fraction of the thickness of the mulch layer. The mulch bed thickness depended on the evenness of the spreading over the mulch bed and the uniformity of the compaction.

The target mulch bed at the base of the shed was not confined by a lip on the outside edge facing the fence, allowing firebrands to land on the target mulch without needing to clear a height. The width of the target mulch bed thus varied over its length.

Variations of dimensional values were estimated using scientific judgment.

Experimental Combinations

During 2016 and 2017, 111 experiments were carried out in the configuration just described. Figure 2 shows the distribution of experiments that have been performed on a variety of combinations of fences and mulch, at four separation distances from 0 m to 1.8 m, and at three wind speeds of 6 m second^{-1}, 10 m second^{-1}, and 14 m second^{-1}. The fences include privacy fences constructed of western redcedar (*Thuja plicata*) and vinyl and lattice fences constructed of redwood (*Sequoia* spp.) and pine. The mulches include shredded hardwood mulch at two thicknesses, pine bark mulch, and pine straw mulch.

RESULTS

Burning Characteristics for a Privacy Fence with Mulch Bed

Figure 3 shows an image from a typical experiment with a western redcedar fence sitting in a bed of shredded hardwood mulch. In this experiment, the wind speed was 10 m second^{-1} and the separation distance between the end of the fence and the small structure was 1.8 m. This image shows the conditions at about 4.5 minutes after the fan was turned on following ignition of the fence and mulch. At this point firebrands had ignited spot fires in the mulch bed at the base of the structure at several locations. A few spot fires can be seen at the front edge of the mulch bed, in addition to one close to the wall. The fence itself was burning along its entire length, although discoloration and other signs of deterioration show that the fire has remained low on the fence, not even reaching half of its height.

Other phenomena apparent from the video itself include pieces of mulch that moved out of the bed under the structure and rolled on the pavement toward the fence or the sides of the experiment. The smoke and flames from the combination of fence and mulch bed generally extended toward the structure, while smoke and flames from the mulch bed at the base of the structure extended toward the fence. These observations are consistent with a horseshoe vortex that occurs at the base of a structure at right angles to a flow stream (Martinuzzi and Tropea 1993). Figure 4 shows this feature in a model of the experimental

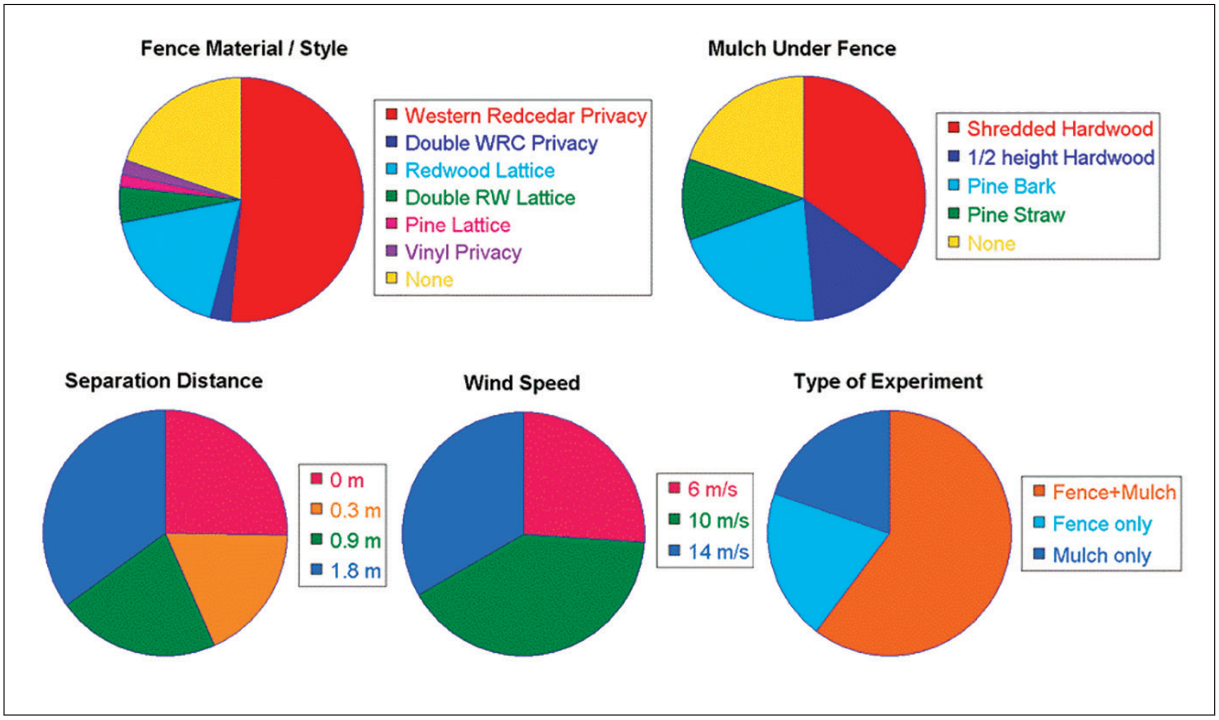

Figure 2—Distribution of experiments by fence type, mulch type, separation distance from wall, wind speed, and experiment type (fence with mulch beneath, fence only, or mulch only). WRC = western redcedar.

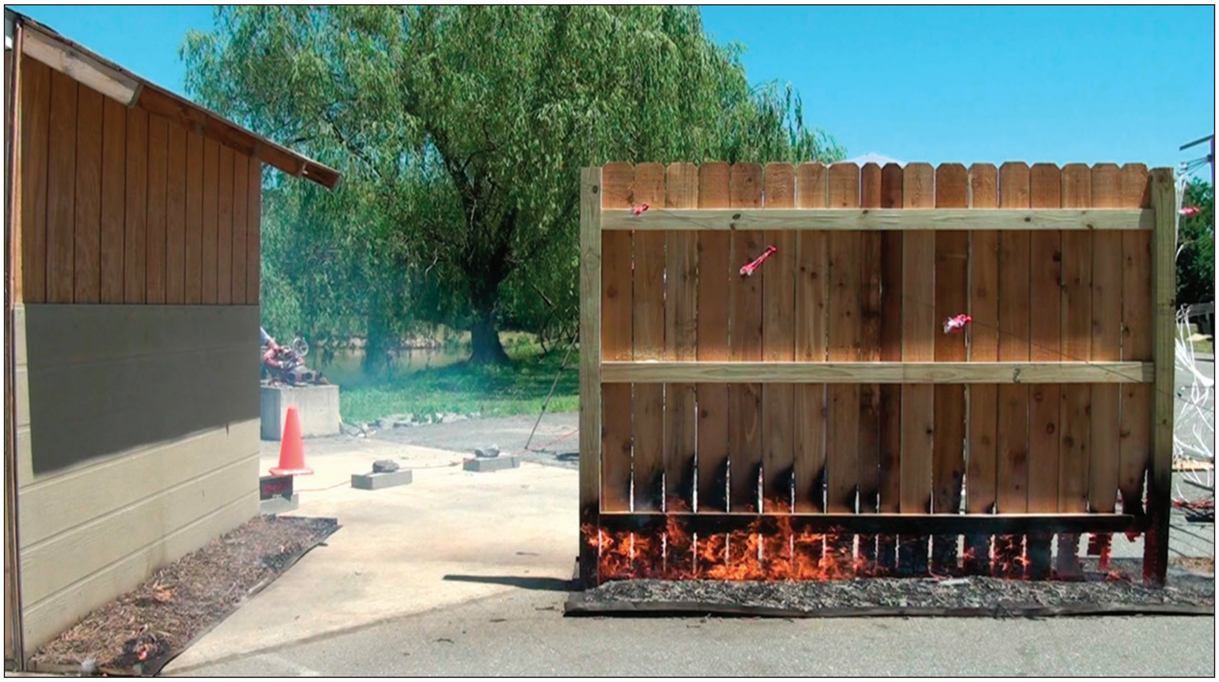

Figure 3—Image from video of western redcedar fence combined with shredded hardwood mulch.

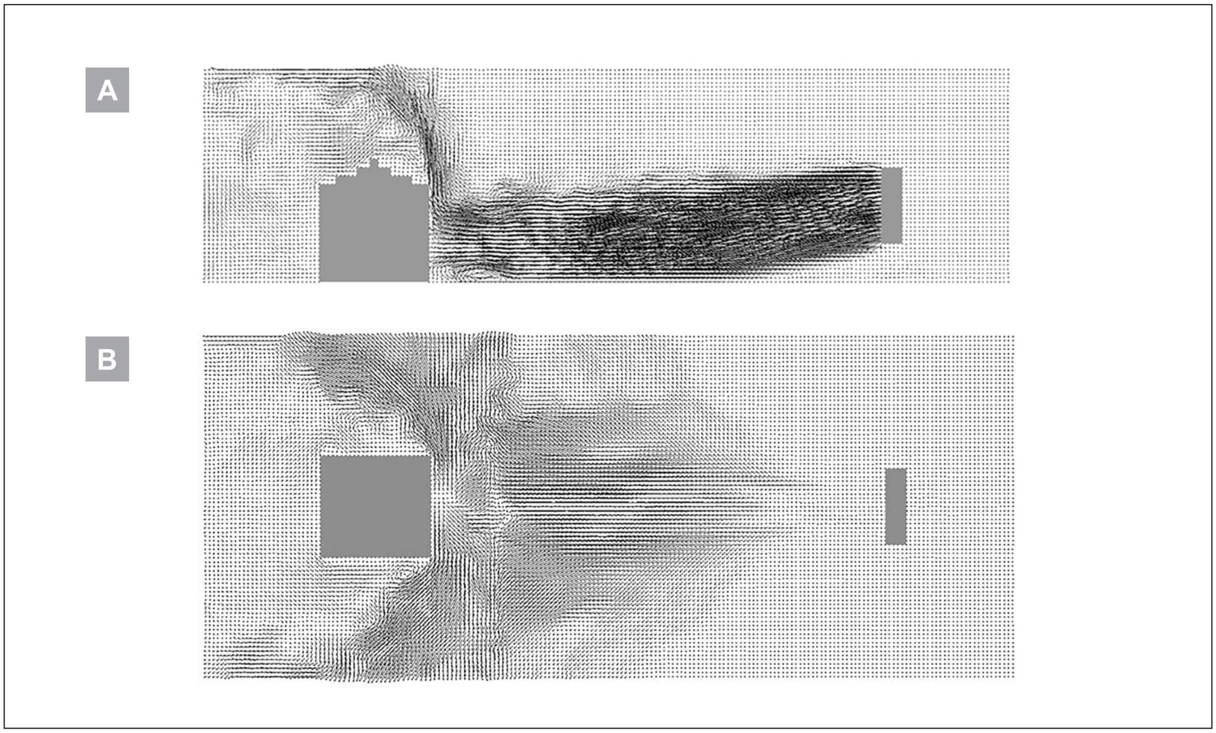

Figure 4—Instantaneous flow field from Fire Dynamic Simulator model, showing (A) side view and (B) top view in a plane close to the ground. Note the recirculation zone near the base of the structure wall.

setup using the NIST Fire Dynamic Simulator (FDS) (McGrattan et al. 2013). The vortex causes particles and smoke in the mulch bed at the base of the structure to be generally transported away from the wall and to the sides. Firebrands that are lofted, however, may be carried along the top of the vortex or drop out of the flow directed over the top of the structure, to be deposited at the base of the structure where they can ignite combustible materials close to the wall.

Spotting Time

This set of experiments represents a survey of the effects of fences and mulch on the spread of fire to a structure, directly or through firebrands and in a variety of conditions. Few experiments have been replicated, and many phenomena involved in firebrand spotting, such as generation of firebrands and ignition processes, are stochastic in nature. The analysis of this data was therefore based on uncovering trends and on discovering different modes of behavior, rather than on quantitative results.

One of the simple measures that has been determined from the video records is the length of time between turning on the fan and ignition within the target mulch bed at the base of the structure of the first spot fire that eventually reached the wall. Ignition was detected by the first sign of smoke.

Effects of Wind Speed and Separation Distance

In figure 5, the time to spot is plotted as a function of the nominal wind speed of the fan. The experiments represented in this plot are the 22 experiments performed on mulch alone and 67 experiments on fence and mulch combinations that are included in the pie charts of figure 2.

Figure 5 demonstrates several trends. First, the time to spot generally decreases as a function of wind speed. Second, the spotting times for fences in combination with mulch beds tend to be shorter than for mulch alone. Third, the spotting times are on the order of minutes. For 6 m second-1 winds, spotting occurs in 30 minutes or less, while for 14 m second^{-1} winds, spotting occurs in less than 7 minutes in every case. If a home is undefended during a WUI fire, these firebrands pose a serious threat to the home.

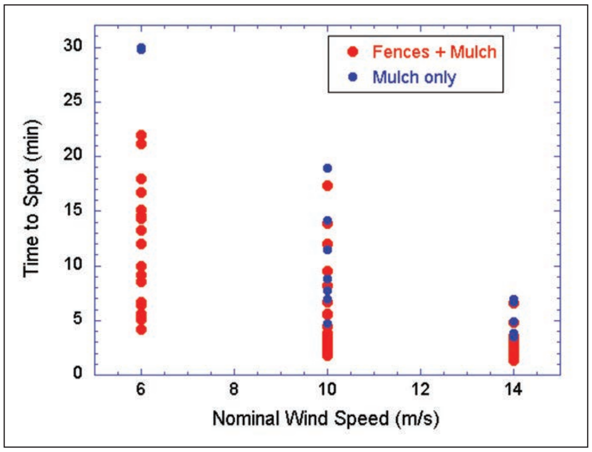

Figure 5—Spotting time as a function of nominal wind speed for experiments on mulch beds only (blue) and combinations of fence and mulch bed (red).

Firebrand spotting consists of three mechanisms: firebrand generation, firebrand transport, and ignition of the surrounding fuels (Koo et al. 2010). High speed winds break off and loft firebrands more readily. They also transport firebrands faster and farther. The ability of firebrands to ignite a spot fire in the mulch bed depends on many factors, including the characteristics of the firebrand and mulch bed, the contact between firebrand and mulch, and the local environment at the location of the firebrand. Higher speed winds deliver more oxygen to the ignition site and support smoldering (Filkov et al. 2016). However, if a critical wind speed is exceeded, the firebrand may be quenched by the cooling effect (Song et al. 2017).

Figure 6 shows that there is not a strong relationship between the time to spot and the separation distance between the end of the fence or mulch bed and the wall of the structure. This suggests that the spotting time is controlled by either firebrand generation or ignition, and that transport is not an important factor in this set of experiments, where the distance between fence and structure was relatively short.

In these experiments, spot fires appeared to be ignited by single firebrands. Not every firebrand landing in the target mulch bed found conditions favorable for ignition. Typically, a handful of spot fires (seldom more than 10) were ignited in the time period before 1 of those fires reached the wall.

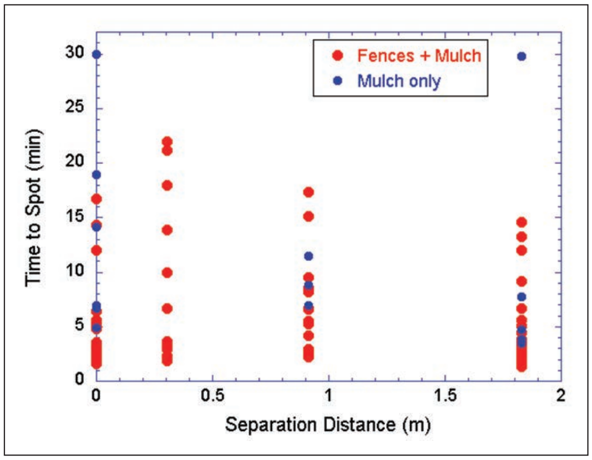

Figure 6—Spotting time as a function of separation distance for experiments on mulch beds only (blue) and combinations of fence and mulch bed (red).

Fences Without Mulch

In the absence of mulch beneath the fence, firebrand spotting was generally considerably slower, if it occurred at all; spotting occurred in only 8 of the 22 experiments with fences alone. The times to spot for these experiments are shown in figure 7.

Without mulch, the ignited fences tended to smolder rather than flame. This was a slow process that in the majority of cases did not result in spot fires. An exception is shown in figure 8, in which a smoldering piece of the fence has broken off at high wind speeds and ignited a spot fire near the wall.

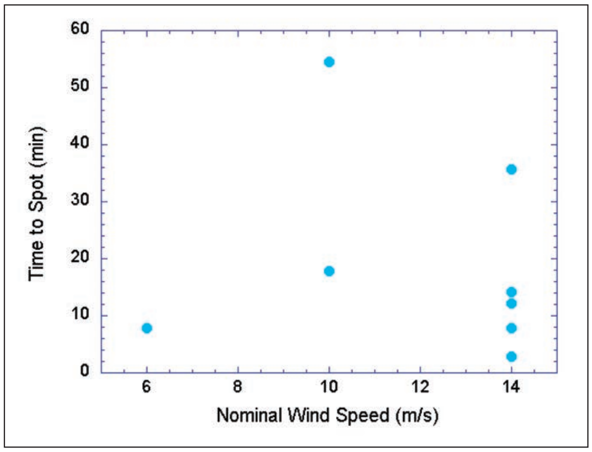

Figure 7—Spotting time as a function of nominal wind speed for experiments on fences only in which spotting occurs.

Exceptional Cases

This set of experiments demonstrated some special cases for which the fire behavior differed significantly from similar experiments.

Double Lattice Fences

A single redwood lattice fence combined with a shredded hardwood mulch bed burned with flames staying close to the ground, as shown in figure 9. This image was taken 12 minutes into the experiment. The behavior is similar to that seen with the privacy fence in figure 3.

Compare this to figure 10, in which redwood lattice fence panels have been attached to both sides of the end posts, with a spacing of 0.09 m between them. This image was taken 3 minutes into the experiment, at which point the double lattice fence is fully engulfed. The space between the fences is partially shielded from the wind field, which promotes flame attachment and spread. The changes in convective heat transfer introduced by the second fence, plus the radiative exchange between the fences, act to intensify the fire.

The time to spotting was 15 minutes in the case of the single lattice fence and 7 minutes for the double lattice fence, after the peak fire behavior in each case.

The fire behavior of the double lattice fence is sufficiently enhanced that the mulch bed beneath the fences is not necessary. Figure 11 shows a double lattice fence without mulch beneath, at 4 minutes into the experiment. Spotting in the target mulch bed occurred at 7 minutes, after the fence had collapsed into a burning pile on the ground.

Parallel Privacy Fences

The addition of a second western redcedar privacy fence parallel to the first changed the fire behavior in a similar way to the double lattice fence. Figure 12 shows a single privacy fence with hardwood mulch beneath after 20 minutes. In figure 13, a second privacy fence was arranged at a spacing of 0.20 m from the first. This could occur, for example, if two neighbors decided to build privacy fences on the property line of their respective parcels. This configuration greatly enhanced the fire behavior. Figure 13 shows the conditions 5 minutes into the experiment.

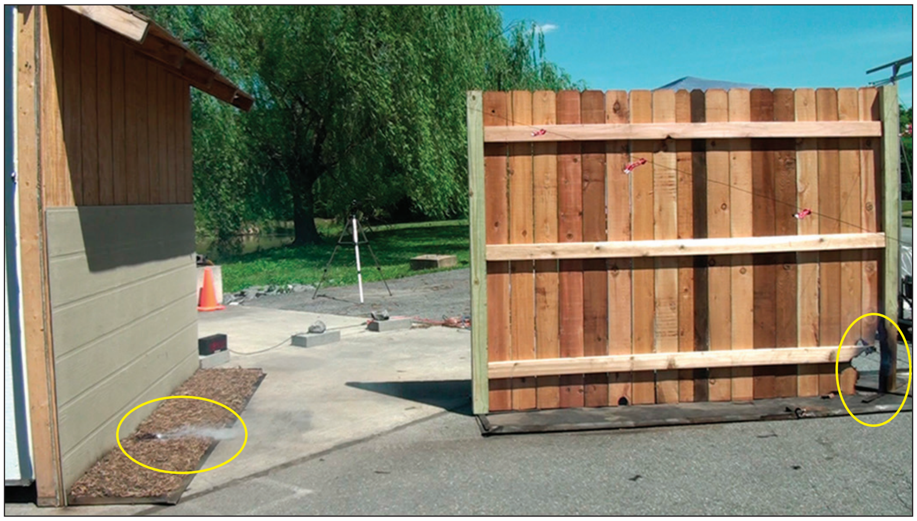

Figure 8—Firebrand spotting for western redcedar privacy fence with high wind speed (14 m second^{-1}) and at 1.8 m separation distance from wall.

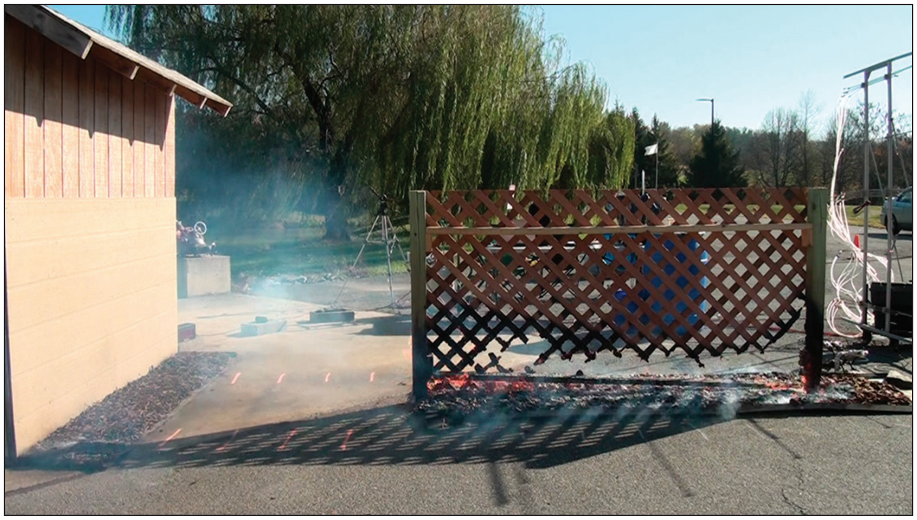

Figure 9—Single redwood lattice fence in hardwood mulch at low wind speed (6 m second^{-1}).

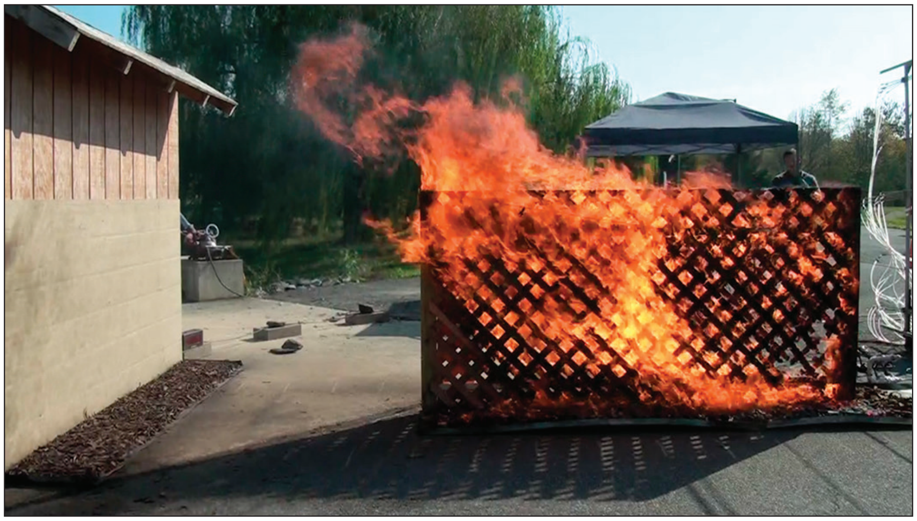

Figure 10—Double redwood lattice fence in hardwood mulch at low wind speed (6 m second^{-1}).

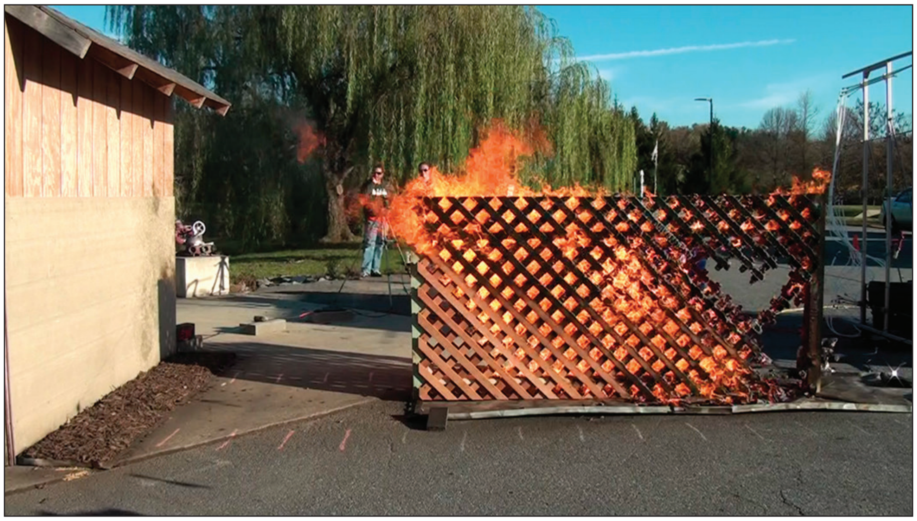

Figure 11—Double redwood lattice fence without mulch at low wind speed (6 m second^{-1}).

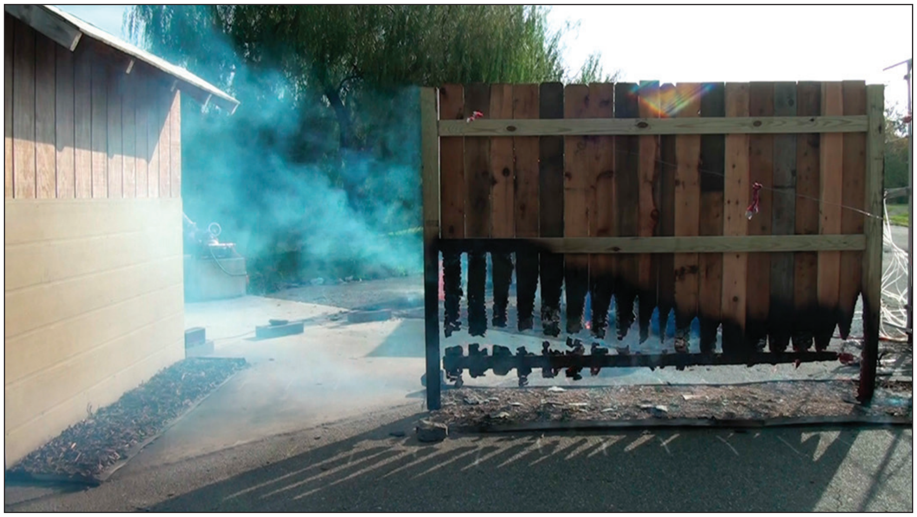

Figure 12—Single western redcedar privacy fence in hardwood mulch at low wind speed (6 m second^{-1}).

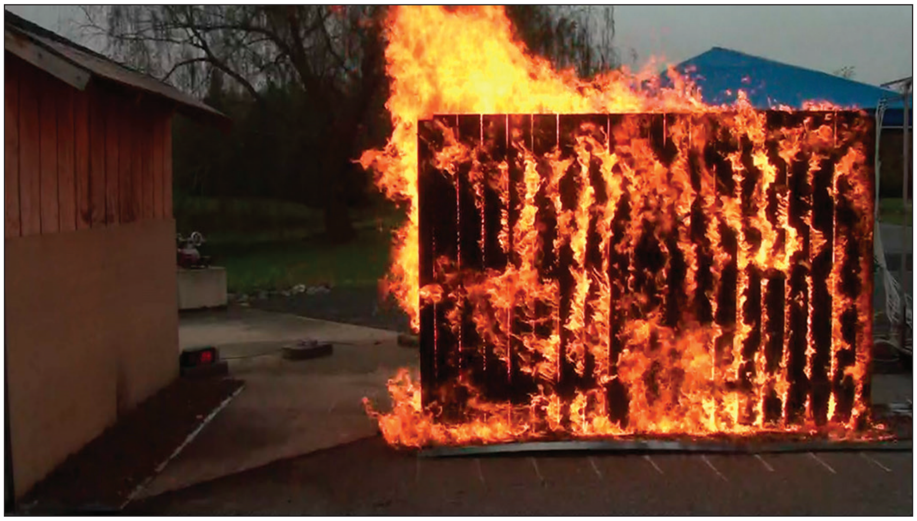

Figure 13—Parallel western redcedar privacy fences separated by 0.20 m in hardwood mulch at low wind speed (6 m second^{-1}).

Butler, Kathryn; Johnsson, Erik L.; Tang, Wei. "Structure Vulnerability to Firebrands from Fences and Mulch." Paper presented at The Fire Continuum Conference, Missoula, MT, US. May 21, 2018 - May 24, 2018.

The time to spotting was 13 minutes for the single privacy fence and 5 minutes for the parallel privacy fences.

Unlike the double lattice fences, a mulch bed beneath the parallel privacy fences was necessary for enhancing the fire behavior. Figure 14 shows that without the mulch bed the parallel fences smoldered slowly, similar to the behavior seen in figure 8 for a single privacy fence without a mulch bed beneath.

Pine Straw Mulch

A final example of unusual fire behavior was encountered with a bed of pine straw mulch. This mulch burned intensely and rapidly. However, the firebrands produced by pine straw mulch were too fine to ignite the target mulch bed. Figure 15 shows a pine straw mulch bed in direct contact with the target hardwood mulch bed at the base of the structure. Although the flames have reached the target mulch bed, no ignition took place.

If the pine straw mulch bed was combined with a western redcedar privacy fence, however, the pine straw quickly ignited the whole bottom of the fence, and spot fires were ignited in the target mulch bed by firebrands from the fence.

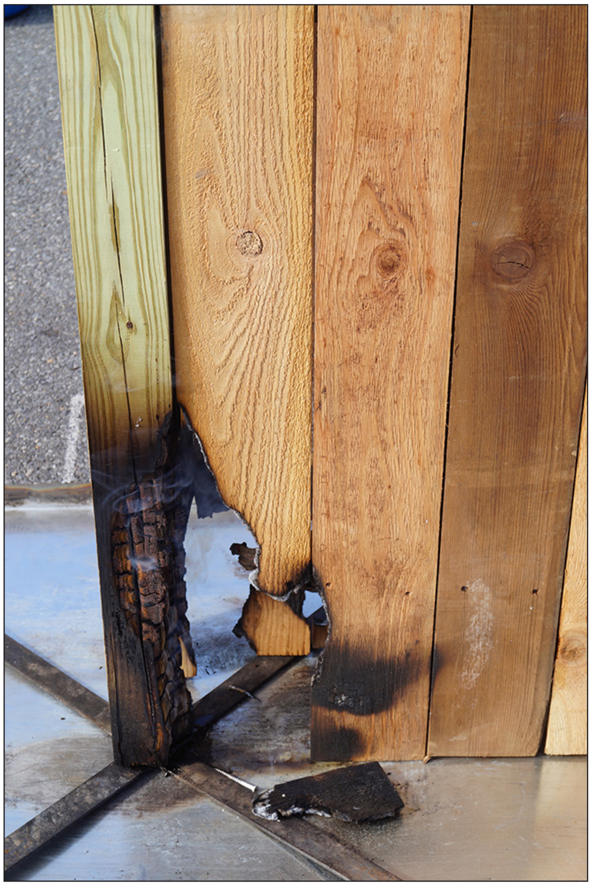

Figure 14—Parallel western redcedar privacy fences without mulch at low wind speed (6 m second^{-1}).

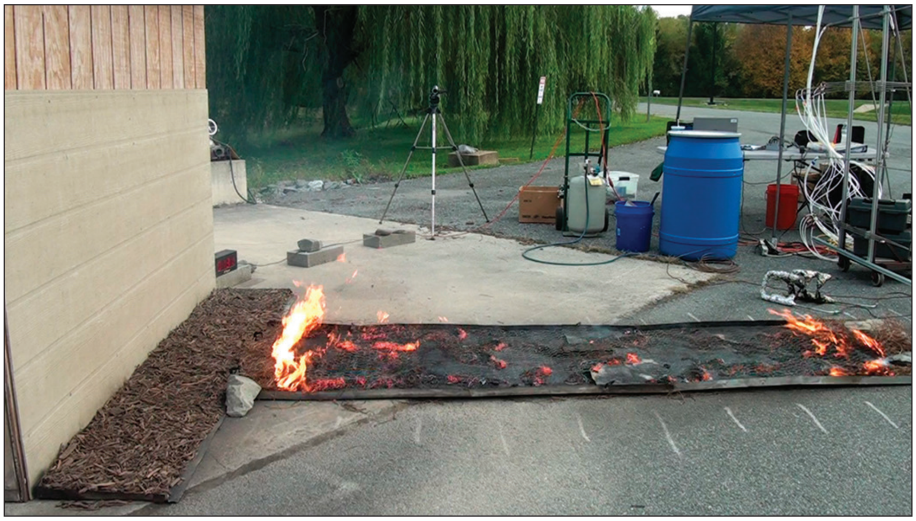
Figure 15—Pine straw mulch bed in contact with target hardwood mulch bed.



Removing the Structure

An additional three experiments were performed in which the small structure was removed from the area downwind of the firebrand source, the target mulch bed was moved to a distance 23 m from the source, and the burning source was subjected to a wind field of 14 m second^{-1}. The space between the source and target was asphalt and concrete, representing a worst case (i.e., favorable) scenario for transport of the firebrands over the ground. Roads and driveways make this a realistic condition for a WUI neighborhood. Figure 16 shows the experiment in which a double lattice fence has been ignited. A bed of shredded hardwood mulch and a woodpile were used in the other two long-range experiments. In each case, spot fires ignited in the target mulch bed 23 m from the firebrand source within 5 minutes after the wind machine was set to deliver high wind speeds. It should be noted that most of the spot fires occurred in the middle of the target mulch, indicating that the firebrands were lofted at some point rather than simply moving over the surface of the ground.

CONCLUSIONS

This limited series of field experiments on ignited mulch beds, fences, and combinations of fence and mulch bed in a wind field in front of a structure demonstrates that firebrand spotting may occur within 2 to 20 minutes of ignition. Spotting often occurred after peak flaming and was affected by wind fields near the structure.

For this set of wind velocities and approach angle, fence configurations, and materials, the time to spotting tended to decrease with increasing wind speed, but it did not show a strong relationship with separation distance. This is consistent with the wind having important effects on firebrand generation and on the local ignition environment.

For this series, the combination of a fence and a mulch bed appeared to decrease the time to spotting over either the mulch bed or the fence alone.

In the absence of a structure, firebrand spotting can occur within a few minutes even at long range.

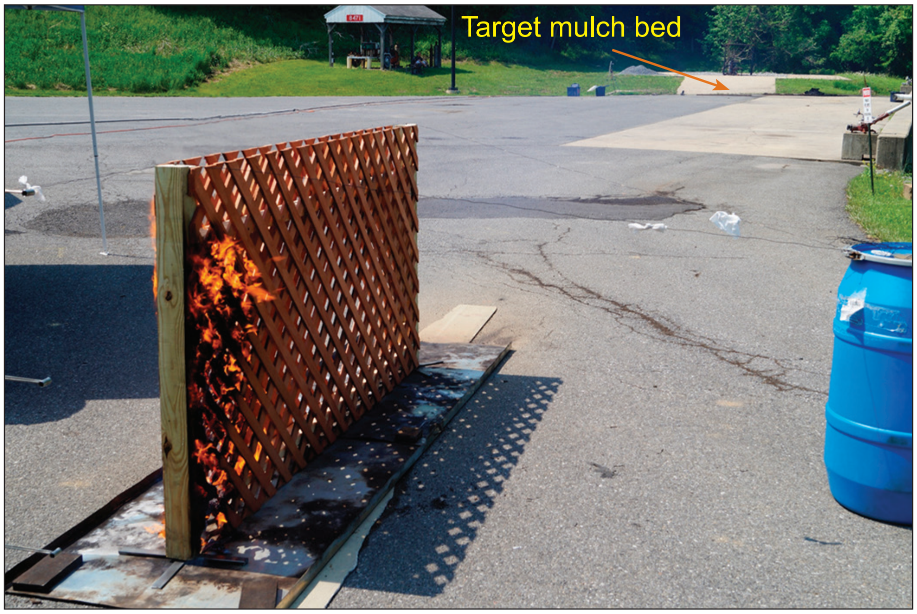


Figure 16—Double lattice fence experiment without a structure and with a mulch bed situated 23 m from the far end of the fence.

Future experiments will include effects of mitigation, including coatings and fence height above the ground, and aging on the generation and spotting of firebrands from fences.

ACKNOWLEDGMENTS

The Frederick County Fire and Rescue Training Facility in Frederick, Maryland made this work possible by allowing us to perform the experiments on its property. Discussions with Alex Maranghides have guided this work. Our thanks also go to Marco Fernandez, whose help with instrumentation, logistics, and operations has been essential to running the experiments, to Mariusz Zarzecki for his help with both experiments and analysis, and to Eric Auth, Rachel McIntyre, and Michael Pryor for their contributions as summer students.

ABSTRACT

Additive manufacturing enables the production of customized and complex parts. These two aspects are very attractive for aerospace and medical sectors. However, in these critical sectors, governed by strict safety requirements, the quality of the parts is of paramount importance and the technology has advanced at a much faster pace than regulations and quality controls. The reliability of the parts must be guaranteed, and hence quality control is needed. Considering the complexity of additively manufactured part shapes, the inspection methods need to be non-destructive, three-dimensional, and volumetric. X-ray computed tomography is presently the most appropriate method, but the relative high cost and testing duration make routine inspection difficult. Thus, alternative non-destructive volumetric methods are required. In this paper, four alternative methods, utilizing acoustic waves (resonant acoustic method, process compensated resonance

Introduction

One of the main advantages of additive manufacturing (AM) is to allow the fabrication of very complex-shaped parts, including with inner cavities, that cannot be manufactured with conventional methods from a single block of material. Another main advantage of AM is the possibility to build customized parts for roughly the same price as some high-volume parts. These advantages are very much appreciated in the aerospace and medical sectors. But AM has been shown to produce specific types of defects in as-built parts, such as cross-layer defects, layer-specific defects, and unconsolidated/trapped powder defects. In these critical aerospace and medical sectors, the quality requirements of the parts are particularly severe, and the parts must be certified before they can be used in their intended application. This is a challenge for quality control of parts with such complex geometry and inner cavities, especially those with the high surface roughness levels typically of AM surfaces. The inspection methods must be non-destructive, volumetric to screen inner cavities, appropriate for high roughness and complex shapes, but also inexpensive and fast for routine inspections. Among existing volumetric non-destructive testing (NDT) methods, X-ray tomography is presently the most appropriate method to inspect the inner features and defects of complex AM parts. However, X-ray tomography is expensive and the scanning process takes a long time. In addition, the resulting scan files are very large; thus, they are not easily viewable. So, even if X-ray tomography is recommended for first article inspection (FAI), it is not suitable for routine inspection of high-volume production of customized parts, for example. Alternative methods to X-ray tomography must be explored [1, 2].

First, all the NDT volumetric methods that are currently used for the characterization of conventionally manufactured parts require a new understanding for how they interact with AM parts. Then, further development of existing NDT methods, or novel ones, are greatly needed to handle the level of complexity that AM presents.

The resonant acoustic and ultrasound NDT linear volumetric methods are potentially valuable techniques that need to be explored for AM parts.

This paper presents the capabilities of some of the existing acoustic and ultrasonic volumetric NDT methods to inspect AM parts with specific defects. The artifacts[1] proposed by ISO TC261/ASTM F42 Joint Group 59 (JG59) "NDT for AM parts" are used in this study. The paper also presents results obtained with X-ray computed tomography (XCT) using synchrotron radiation as a comparison.

The paper is structured as follows: the first section is dedicated to the presentation of the JG59 and their standards development regarding NDT inspections using a specially designed artifact; the second section describes the fabrication of this artifact in different materials; and the last section presents the principles, inspection results on the artifacts, and benefits/drawbacks of the following five volumetric NDT methods:

- whole-body inspection methods using acoustic waves – (1) resonant acoustic

[1] The English spelling of “artefact” will be used instead of the American spelling of “artifact” in the ISO/ASTM standard.

method (RAM) and (2) process compensated resonance testing (PCRT),

- selective inspection methods using ultrasonic waves – (3) conventional ultrasonic testing (CUT) and (4) phased array ultrasonic testing (PAUT) methods, and
- X-ray for comparison – (5) X-ray computed tomography (XCT) using synchrotron radiation (SRXCT).

STANDARDIZATION GROUP ISO TC261-ASTM F42 ON AM – JOINT GROUP JG59 ON NDT FOR AM PARTS

Since AM is causing a revolution in manufacturing capabilities, many industries are interested to take advantage of these methods. However, each time a new technology grows in capability and use, standardization issues arise that must be overcome for the technology to continue its advancement. Several standards developing organizations (SDOs) are addressing this subject. The International Organization for Standardization (ISO) and ASTM International have implemented a formal agreement to co-develop a series of AM standards through several joint groups (JG). JG 59 of ISO Technical Committee (TC) 261 and ASTM F42 is dedicated to NDT for AM parts.

Goal of the JG59

Several standards dedicated to NDT of manufactured parts already exist, and the JG59 does not aim to duplicate these standards. AM is very different from other manufacturing processes like casting, forging, machining, etc. With AM, parts are built layer by layer from raw feedstock such as metal powder, so one might say that the part is manufactured simultaneously with the material. This also means that the microstructure of the built material and the potential for embedded defects are specific to the AM technology. As mentioned previously, AM enables manufacturers to build very complex geometries, though with rough surfaces. Therefore, existing NDT methods must be evaluated for AM applicability. These methods might need to be adapted to accommodate AM characteristics. Furthermore, new NDT methods may also be needed. Thus, a primary goal of the JG59 "NDT for AM parts" is to write a best practice guide presenting potential NDT methods suitable for post-process inspection of AM metallic parts, referring to existing NDT standards when appropriate. This best practice guide will contain a list of typical AM defects that can be found in two of the main types of metal additive manufacturing process categories used in industry: power bed fusion (PBF) and directed energy deposition (DED). It will give recommendations for NDT methods suitable for the special features of AM. A first version of this guide should be complete by the end of 2018.

To develop this guide, joint group members have designed and fabricated several artifacts with typical AM defects in different materials. These artifacts were then characterized with different NDT methods by the JG59 members (Table 1) to evaluate the behaviors and potential for each NDT method for use with AM parts.

Star artifact with typical AM defects

This artifact was designed by JG59 to be optimized for laboratory 450 kV X-ray computed tomography (XCT). The size of the artifact depends on the density of the material. It is in the shape

Obaton, Anne Francoise; Butsch, Bryan; McDonough, Stephen; Laroche, Nans; Gaillard, Yves; Tarr, Jared; Bouvet, Patrick; Cruz, Rodolfo; Donmez, Alkan. "Evaluation of Nondestructive Volumetric Testing Methods for Additively Manufactured Parts." Paper presented at ASTM Symposium on Structural Integrity of Additive Manufactured Parts, Washington, DC, US. November 06, 2018 - November 08, 2018.

of a star (Fig. 1), hence its name: star artifact. The artifact contains the following defects unique to AM parts:

1. Cross-layer defects that are represented by vertical cylinders of different diameters but the same length. These cylinders are connected to each other and open to outside at the bottom of the star, so that powder is released at the largest diameter cylinder;
2. Layer-specific defects that are represented by horizontal cylinders of different diameters but the same length, with an open end to release powder;
3. Unconsolidated/trapped powder defects that are represented by spheres of different diameters and internal cylinders in various orientations.

Voids and porosities are common defects found also in conventional manufacturing and are mostly covered by existing NDT standards.

These defects are located into critical areas such as deep sections and hard-to-reach areas, in five different regions. Two versions of the star design, designated as S1 and S2, were used in the evaluation of NDT methods (Fig. 1). In these two versions the defects are of the same size, same height along the part, and the same orientation; the only difference is their locations. The S2 design has the defects in thinner sections of the star branches, while the S1 design has the defects in the thicker sections. All defects are in the range of 100 µm-800 µm in diameter.

At NIST, we evaluated statistical NDT methods that required a large number of samples. Considering this fact, we decided to build half-size stars also. However, the sizes of the defects remained the same.

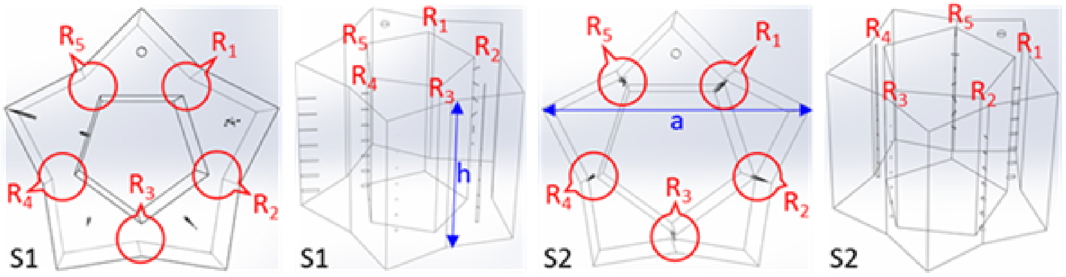

FIG. 1 Schematics of the AM star artifacts (design S1 and S2) proposed by JG59 (where R is a Region in the artifact, h and a define the height and width of the artifact, respectively, and numerical values are given in Table 2).

STAR ARTIFACT FABRICATION

The star artifacts were manufactured by different members of the JG59, depending on their capabilities in terms of AM equipment and materials. NIST built star artifacts in cobalt chromium (Co-Cr) (Figs. 2 a and b) and in stainless steel (SS) (Figs. 2 c and d) using AM machines belonging to the laser PBF process category. Zodiac Aerospace built aluminum star artifacts using also a laser PBF process. The characteristics of the manufactured star artifacts are shown in Table 2 and a picture representing the finished star artifacts is shown in Fig. 3. Since some of the NDT methods investigated require statistical analysis, significantly more artifacts (specifically, SS artifacts) were built for those methods to establish the baseline for artifacts with no defects. Furthermore, in order to evaluate the capability of such techniques to sort parts based on the numbers of defects they contain, stars with different numbers of defects were manufactured in two very similar builds (i.e., the same location on the AM build platform, with two or three marginally different parts added on the platform between the first and second build):

- ➢ 8 similar parts with defects in the 5 Regions, such as defined by the JG59;

Obaton, Anne Francoise; Butsch, Bryan; McDonough, Stephen; Laroche, Nans; Gaillard, Yves; Tarr, Jared; Bouvet, Patrick; Cruz, Rodolfo; Donmez, Alkan. VOLUMETRIC NDT METHODS EVALUATED

Non-destructive inspection methods can be separated into two main groups: (1) surface methods enabling only a surface inspection of the test object (e.g., by visual, dye penetrant,

Obaton, Anne Francoise; Butsch, Bryan; McDonough, Stephen; Laroche, Nans; Gaillard, Yves; Tarr, Jared; Bouvet, Patrick; Cruz, Rodolfo; Donmez, Alkan. "Evaluation of Nondestructive Volumetric Testing Methods for Additively Manufactured Parts." Paper presented at ASTM Symposium on Structural Integrity of Additive Manufactured Parts, Washington, DC, US. November 06, 2018 - November 08, 2018.

magnetic particles, etc.) and (2) volumetric methods enabling volumetric inspection of the test object (e.g., by eddy current, ultrasound, radiography, thermography, acoustic emission, X-ray tomography, etc.) [3]. Volumetric methods can also be divided into two main groups: whole-body inspection methods and selective inspection methods. The whole-body inspection methods do not provide information about defect locations, whereas selective inspection methods do provide such information. We have investigated volumetric methods from both groups in order to evaluate their respective potential for inspecting AM parts.

Whole-body inspection methods

Resonant ultrasound spectroscopy (RUS) methods

Principle of resonant ultrasound spectroscopy (RUS) methods

There are several variants of resonant ultrasound spectroscopy (RUS) methods, as described in ASTM E2001 [4], but their basic principles are similar. These whole-body inspection approaches compare the frequency spectrum of the mechanical resonances of a set of reference parts, known as “good parts”, with the frequency spectrum of the mechanical resonances of the test parts. These are pass/fail assessments. Two similar objects will have similar resonant frequency spectra. A shift of the frequency peaks of a part, compared to the statistical variation from the similar good parts, will be the signature of a structural change of the part (e.g., changes in part geometry and/or material properties associated with the mass, stiffness, and damping).

A characterization using RUS methods includes several steps. The first step consists of a mechanical impulse of the test object to make it vibrate as free as possible. Under this excitation, the object vibrates at its natural resonant frequencies. At the second step, the response of the test object is monitored by a sensor, and the frequency spectrum is recorded. At the third step, this spectrum is compared to the spectrum of the good parts, which are obtained following the same first two steps. For this comparison, first the well-defined resonant peaks for each good part are identified. A subset of such resonant peaks that are consistent for all reference parts peaks and have distinct separation with bad parts are selected for further consideration. The ranges (boundaries) in variations in each resonant peak frequency of the good parts are evaluated, these are called “criteria”. Outliers of these variations must be excluded from these ranges. The measured resonant peak frequencies of the test parts are compared against the corresponding ranges in frequencies of the good parts. All test parts with frequency peaks outside of these boundaries are rejected as faulty parts.

Resonant acoustic methods (RAM) and process compensated resonance testing (PCRT), described in ASTM E2534 [5], are two types of RUS methods.

Principle of resonant acoustic method (RAM)

In the resonant acoustic method (RAM), the excitation is done by an impact hammer (first step) and the resulting acoustic frequency data is obtained with a microphone. There are no contact probes that need to interact with the test part. This allows the parts to resonate in as free a state as possible. The output of the microphone is converted into a frequency spectrum using a high-speed analog to digital converter (24 bits) performing a fast Fourier transform to determine resonant peaks (second step). Finally, a statistical analysis conducted with software reveals if the test parts fall within the defined criteria or not (third step). If at least one of the measured resonant peak frequencies of the test part lays outside of the established frequency ranges of the good part, the test part is considered bad.

Resonant acoustic method (RAM) inspection of the SS half-size star artifacts

Fig. 4 shows the setup used for the resonant acoustic method (RAM) measurements [6] of eighty-eight SS half-size stars (Fig. 5), resulting from the two successive builds (Table 2). Among them, twenty from each build were manufactured as reference parts with no defects and were considered as reference parts to define the baseline for the criteria. The stars were systematically weighed before the test as the inspection software enables weight compensation. Then, the star artifacts were impacted with an automatic hammer on the sides of their bottom faces, as these positions were experimentally found to provide the least amount of damping. Each part was impacted three consecutive times at three different branches of the star at the base. This procedure allowed us to check for repeatability and reproducibility. For consistent impacts on every part, the same positions on the same branches of the stars were always struck. The frequency window considered for analysis ranged from 500 Hz to 50 kHz, and a resolution of 3.5 Hz was chosen which gives an acquisition time of 0.23 s.

We considered the first and second builds separately. The data on the twenty reference parts were first gathered, and then the rest of the twenty-four stars with defects were tested. The tests were repeated on two consecutive days. The acceptance criteria to define the baseline for comparison of the resonant peaks, from this first set of data, were set up over six frequency bands, as shown in. Fig. 6. This figure shows the complete spectrum for a single part test in blue. The vertical green lines show the bands of the resonant peaks chosen for evaluation. These criteria are used by the software to sort the bad parts from the good. The data for a part must pass all the criteria in order to pass resonance testing.

There is a constant shift, for all peaks, in the frequency spectrum between build 1 and build 2 (Table 3). However, the same criteria (same width) could be chosen between build 1 and build

2. It is common (especially in a powder metal build process) to see small shifts in resonant spectra from build to build due to variations in the raw material, manufacturing conditions, environmental conditions, etc. It should be noted that the general shape of the frequency spectrum does not change from build to build, just a constant shift in frequency is observed, based on changes to the mass or stiffness of the parts. It should also be noted that the spectrum shift is a global shift for the entire build and does not affect the ability to sort the good parts from the defective parts.

The overall outcome of the resonant acoustic test for the eighty-eight SS half-sized star artifacts is displayed in Table 4.

We were able to define criteria that allowed us to sort the good parts from the ones with internal defects. The reference parts showed a significant difference in resonance. However, in the range of frequencies analyzed, the parts could not be sorted based on the number of defects they contain.

The main benefits and drawbacks of the resonant acoustic method (RAM) are summarized below.

Benefits of the method	➢ easy to use ➢ fast ➢ simpler and faster than PCRT ➢ no restriction in size ➢ no restriction in shape ➢ no roughness restriction ➢ no part set-up required ➢ suitable for medium to high volume ➢ able to identify defective parts ➢ suitable for production end of line testing, or routine quality inspection
Drawbacks of the method	➢ not possible to identify the type or location of defects in the part

Process compensated resonance testing (PCRT)

Principle of process compensated resonance testing (PCRT)

Process compensated resonance testing (PCRT) [5] uses piezoelectric transducers in contact with the part, but otherwise is very similar to RAM. Excitation of the part uses a piezoelectric transducer to generate a low-energy swept-sine wave, generally with ultrasonic frequencies (5 kHz-500 kHz). Then the frequency response is recorded with other piezoelectric transducers. Each test requires configuring a specific fixture and optimizing data collection settings for each new part geometry.

The PCRT system used to characterize the star artifacts is fully automated with one transmitter and two receiver transducers. For data analysis, the system uses a Z-score [7] to identify outliers of resonance peak variations within a population of parts. In addition, when a simple resonance analysis is insufficient due to interlacing of the spectra for good and bad parts, the system uses a pattern recognition tool such as the Mahalanobis-Taguchi system (MTS) [8] for sorting of the parts.

Process compensated resonance testing (PCRT) inspection of the SS half-size star artifacts

Fig. 7 shows the setup used for the PCRT inspection of seventy-four of the eighty-eight SS half-size stars resulting from the two successive builds (Table2). Twenty and eighteen parts were considered as reference parts from builds 1 and 2, respectively. For each part, data were collected between 25 kHz and 225 kHz in less than three minutes, and then processed using Z-score and MTS analysis.

The repeatability of resonance measurements was evaluated using one reference part, over thirty repetitions. The variations, expressed as the standard deviations, in each measured peak frequency over thirty repetitions were calculated. The frequency peaks with large variations were eliminated from the set of peaks to be used for the defect detection criteria. The standard deviations for the remaining twenty-six resonant peaks were between 0.05 % and 0.013 % of the mean peak frequencies.

PCRT partial spectra for four good and four bad parts are compared in Fig. 8, which shows that the shift in frequency between good and bad parts is not the same for every resonant peak. To deal with this, a proprietary pattern recognition algorithm (VIPR [9] for Vibrational Pattern Recognition) is used to differentiate the parts with defects from the parts with no defects. To confirm repeatability, these tests were run three times. Each test run gave the same results. The overall results are presented in Fig. 9 and in Table 5. As with RAM, we were able to sort the good parts from the ones with internal defects. However, the parts could not be sorted by the number of defects they contain.

The main benefits and drawbacks of process compensated resonance testing (PCRT) are summarized below.

Benefits of the method	➢ fast but not as fast as RAM ➢ no restriction in size ➢ no restriction in shape ➢ no roughness restriction ➢ suitable for medium to high volume ➢ able to identify defective parts ➢ suitable for production end of line testing, or routine quality inspection
Drawbacks of the method	➢ part set-up required ➢ not possible to identify the type or location of defects in the part

Selective inspection methods

Selective inspection methods use scanning techniques to inspect only selected regions of a part, possibly from multiple directions.

Paper presented at ASTM Symposium on Structural Integrity of Additive Manufactured Parts, Washington, DC, US. November 06, 2018 - November 08, 2018.

Conventional ultrasonic testing (CUT)

Principle of conventional ultrasonic testing (CUT)

Conventional ultrasonic testing (CUT), as described in ASTM E1001 [10], uses generally one or more piezoelectric transducers, which can act as transmitter, receiver, or both, to produce ultrasound into the test part. The emitting frequencies are theoretically ranging from 20 kHz upwards to 1 GHz, depending on the density of the material and on the size of the smallest defect to be detected. The ultrasound wavelength ($\lambda=v/f$, where v is the velocity of sound in the material of the tested part and f is the sound frequency) must be roughly the size of the smallest defect. Decreasing the wavelength allows detection of smaller defects but reduces the penetration depth because attenuation increases significantly. When the CUT is performed in contact mode, a thin film of couplant need to be spread on the surface of the transducer to increase the transmission of the ultrasonic waves into the part. This eliminates variations due to microscopic air pockets, which greatly impede ultrasound. Acoustic impedance of the couplant should be similar to that of the test part. But, CUT can be also performed in non-contact mode. In that case, the transducer and part are immersed in a tank of liquid (generally water) which also serves as the couplant. This allows the ultrasound beam to be scanned over various regions of a part with minimal variations in coupling.

When sound waves transmitted into the part, reflection/transmission/refraction occurs at each boundary separating a defect from the surrounding material, and at the boundaries defining the part itself. The resultant echoes are detected by a transducer and processed to determine the presence of the defects and their approximate locations. The detailed scanning procedure and signal processing must compensate for confounding phenomena such as mode conversion, scattering, and shadowing. These phenomena can prevent observation of some defects.

Obaton, Anne Francoise; Butsch, Bryan; McDonough, Stephen; Laroche, Nans; Gaillard, Yves; Tarr, Jared; Bouvet, Patrick; Cruz, Rodolfo; Donmez, Alkan. "Evaluation of Nondestructive Volumetric Testing Methods for Additively Manufactured Parts." Paper presented at ASTM Symposium on Structural Integrity of Additive Manufactured Parts, Washington, DC, US. November 06, 2018 - November 08, 2018.

There are three possible ways of presenting the information (Fig. 10):

1. A-scan (X-axis: *time*, Y-axis: *reflected wave amplitude*): shows peaks on a graph (oscilloscope). The graph represents the amplitude of the reflected sound wave as a function of time. Position on the X-axis reflects the depth of each reflecting feature or flaw. Position on the Y-axis reflects the amplitude of the echo from each reflecting feature or flaw.
2. B-scan (X-axis: *linear position of the transducer*, Y-axis: *depth of the reflector,* grey levels or colors: *reflected wave amplitude*): shows an image with different grey levels or colors corresponding the amplitude of the reflection from each reflecting feature or flaw. Position on the X-axis shows the position of the transducer along its scan path. Position on the Y-axis reflects the depth of each reflecting feature or flaw.
3. C-scan (X-axis: *linear position of the transducer on the X axis*, Y-axis: *linear position of the transducer on the Y-axis,* grey levels or colors: *reflected wave amplitude, time of flight or depth*): shows an image viewed from the top (planar view) of a region of interest within the volume of the test specimen. The images display different grey levels or colors corresponding to the amplitude, time of flight, or depth of the signal for different positions of the transducer scanning the surface of the part. A C-scan image is formed in a plane normal to a B-scan image.

The CUT system used to inspect the star artifacts is associated with a software system (ODIS from OKOS), including amplitude, time domain and frequency domain, and imaging in real-time or post collection review. The software enables simultaneous A-B-C-scan collection. The color code on the images indicates the amplitude of the signal (i.e., change in attenuation) such as displayed in Fig. 11, where blue corresponds to low amplitude and white to high amplitude.

Conventional ultrasonic testing (CUT) inspection of the aluminum S1 star artifact

The aluminum S2 design was tested, but defects could not be detected. Therefore, only the scanning of the aluminum S1 design will be described. The computer-aided design (CAD) of the S1 aluminum star artifact is shown in Fig. 12. This part was tested in the configuration shown in Fig. 13. One transducer, acting as a transmitter/receiver, was used with the artifact immersed in water. The part was first scanned from the top, and then from each side of its branches (Fig. 13). The schematics of the scanning strategies are shown in Fig. 14. The characteristics of the transducer used for both scans are displayed in Table 6. The respective water path distances between the transducer and the test artifact during the scan were 132 mm for the top surface scan, and 83 mm for the side surface scans. The gain was adjusted to 39 dB to increase the sensitivity. Then, in order to outline the important features inside the artifact, two time-domain windows (data 1 and data 2) were defined on the A-scan, such as the one shown in Fig. 15. These windows correspond to two different Regions (depths) of interest in the artifact. Their widths (with corresponding ranges of depths) were determined based on the speed of sound in the material. The speed of sound given in the literature for wrought aluminum was chosen (as 6375 m/s). However, this value might be different in layer-by-layer manufactured aluminum. Consequently, the uncertainty on the corresponding depths of interest is not negligible. Data 1, the red rectangle on Fig. 15, excludes the top and rear surfaces of the part, whereas data 2, the green rectangle on Fig. 15, selects the Region around the rear surfaces. The C-scan images shown in Fig. 16 through Fig. 20 are based on these two time-domain windows focusing on two different Regions of depth.

Since all the defects in the artifact are in the same position along its height, the first defect does not allow the rest of the defects to be inspected by CUT from the top surface of the star. In contrast, the C-scan images recorded from the side surfaces of the star artifact and presented in Fig. 16 through Fig. 20 reveal more information:

- The cylinders with different orientations (d_{12}, between Regions 1 and 2) cannot be observed in near field from sides labeled 1A and 2B on Fig. 16, probably because the gain was constant with distance. However, the larger ones can be seen in far field from the side labeled 3B (Fig. 17), but not from the side labeled 5A (Fig. 20).
- The vertical cylinders with different diameters (d_{23}, between Regions 2 and 3) cannot be seen from the side labeled 1A (Fig. 16) because the cylinders with different orientations (d_{12}) hide them. The larger cylinders can be seen from all sides, in near and far fields.
- The spheres of different diameters (d_{34}, between Region 3 and 4) cannot be seen from any sides because the sphere shape is complex to detect with ultrasound waves. Indeed, this geometry scatters the waves in every direction. Thus, the reflected wave reaching the transducer is very low in energy. In this experiment, the energy of the reflected wave might be too low to be detected.
- The horizontal cylinders of different diameters located on an outside edge of the star (d_{45out}, between Regions 4 and 5) are not seen from most sides. This is probably due to the fact that they are positioned right at the borders of the time windows. So, since the widths of these windows are not accurate, they might be outside. However, they can all be seen and discretized in far field from the side labeled 3A (Fig. 18). They appear right in the middle of the image rather than on an edge probably because of diffraction at the R4 edge of the star.

- The horizontal cylinders of different diameters located on an inside edge of the star (d_{45in}, between Regions 4 and 5) are not seen from most sides probably because they are very small (2 mm long) and located on an edge. However, the larger ones can be seen from the side labeled A4 (Fig. 19) in near field.
- There was a mistake in the CAD data used to manufacture the aluminum S1 star artifacts. One of the cylinders with a different orientation is isolated from the others (d_5 in Region 5, Fig. 12). We might see it from the side labeled 1B (Fig. 20) in near field. The reason why it is not seen from the other sides is probably due to its orientation.

Except for the spheres, all other types of larger defects were detected from at least one side, though they were not discretized in size. However, the interpretation of the images is not straight forward and needs experience. In addition, the defects and their localization were known in advance. In the case of blind inspection, the analysis would have been even more difficult. Furthermore, dimensional measurements were not possible. However, despite the surface roughness of the AM parts, we were able to scan the star artifacts from as-built surfaces, even from side surfaces which are generally rougher than the top surfaces in AM. So, the roughness of the surface did not preclude CUT. Moreover, it should be noted that the size and thickness of the aluminum star does not allow inspection with laboratory 225 kV X-ray computed tomography (XCT). Laboratory 450 kV XCT is required. This underlines an advantage of UT methods for large parts – 450 kV XCT systems are relatively rare.

The main benefits and drawbacks of the conventional ultrasonic testing (CUT) method are summarized below.

Benefits of the method	➢ few roughness restrictions ➢ real-time imaging

	➢ less restriction in size than X-ray computed tomography ➢ able to identify the type and location of defects in the part
Drawbacks of the method	➢ part set-up required ➢ need experience ➢ shape restriction ➢ not suitable for high volume and routine quality control ➢ no real discretization in size ➢ no dimensional measurements

Phased array ultrasonic testing (PAUT)

Principle of phased array ultrasonic testing (PAUT)

The principle of phased array ultrasonic testing (PAUT) is very similar to that of CUT. However, instead of consisting of a single piezoelectric transducer, the PAUT probe is composed of an array of piezoelectric transducers. Each transducer of this array can be pulsed independently with respect to the others to generate several waves that will interfere. The waves that are in phase will be added together (constructive interference), whereas the ones that are out of phase will cancel each other (destructive interference). This results in a unique wavefront constituting a synthesized focused beam that can be oriented (controllable angle), shaped (controllable focal distance and focal spot size) and swept electronically. Dynamic control of the beam enables examining the complex shapes across a range of different perspectives without moving the probe. The spatial resolution of the images is linked to the number of elements in the array. The larger the number of elements, the better the resolution.

It is possible to improve the performance of the above-mentioned standard PAUT system by implementing a data acquisition method called full matrix capture (FMC) with a post-processing reconstruction algorithm known as total focusing method (TFM) [11, 12, 13]. In the generic FMC acquisition method, a single transducer of the array is pulsed and the time domain signals (A-scans) are captured by all transducers in the array and stored for later processing. This is done for all transducers of the array. The number of data sets acquired is the square of the number of transducers. Thus, a 128-transducer probe will produce 16384 raw A-scans. The offline data processing uses the complete set of time-domain data from all combinations of transmitting and receiving transducers. The reconstructed image from the A-scans is equivalent to making coherent summations over all transducers in order to focus at each point in the target Region. Thus, FMC combined with TFM enables offline reconstruction of a more detailed image (with better spatial resolution, perspective, and defect definition) than a standard PAUT imaging method where all array elements create a unique wavefront to form a beam with a fixed focus.

The instrument [14] that was used to perform the PAUT of the star artifacts implements both FMC and TFM. However, it permits also the acquisition of standard PAUT data. The software associated with the hardware enables simultaneous A-B-C-scan displays, but also a D-scan which is similar to the C-scan but in a perpendicular direction. If the C-scan displays an image in the plane (XY), then the D-scan will display the image in the orthogonal plane (ZY). During the translation of the PAUT probe, the beam inside the probe is swept in the perpendicular direction to scan the entire surface. The color code on the images is the same as the one described above for the CUT images (Fig. 11).

Phased array ultrasonic testing (PAUT) – total focusing method (TFM) of the aluminum S1 and S2 star artifacts

The S1 and S2 designs of the aluminum star artifacts, with corresponding CAD shown in Figs. 12 and 21, could be both tested using PAUT-TFM. Only one linear probe acting as a transmitter/receiver was used to induce the longitudinal waves. The probe is 32 mm long and composed of 128 transducers separated from each other by 0.25 mm (center to center). The star artifact, immersed in a tank of water for the coupling (Fig. 22), was scanned only from one side of its branches (Fig. 22), from the top to the bottom of the star (Y axis – i.e., sideways as shown in Fig. 22). The transducers were operated at a center frequency of 10 MHz (bandwidth of 6 MHz), which corresponds to a wavelength of 0.62 mm in aluminum. The water path distance between the probe and the scanned surface of the artifact during the scan was 12.5 mm. Finally, the analog gain was adjusted to 40 dB to acquire the data. The digital gain can be subsequently adjusted on the reconstructed image (300 pixels x 400 pixels) offline.

The A, B, C, and D-scan presented in Fig. 23 through Fig. 26 for the S1 design, and in Fig. 27 through Fig. 31 for the S2 design, show interesting results:

- Three of the cylinders with different orientations can be seen from side 1A (Fig. 23). The orientations of the other cylinders prevent detection.
- Five vertical cylinders with different diameters can be detected from side 2A (Fig. 24) using the three optimized digital gains chosen to display the images. The cylinders with smaller diameters, down to 100 µm, can be detected with increased

gain (Fig. 24 bottom images) at the expense of the reduced quality of the image (lower signal to noise ratio).

- Three of the spheres of different diameters can be seen from side 3A (Fig. 25).
- Three of the horizontal cylinders of different diameters (10 mm long) located on an outside edge of the star can be seen from side 4A (Fig. 26). Their position on the edge hides the others.
- Some horizontal cylinders of different diameters located on an inside edge of the star are seen from side 4A (Fig. 26). They are located on an edge and are short (2 mm long), so they are difficult to differentiate from the reflection of the edge.
- It does not seem that we can see the single cylinder manufactured by mistake.

The defects are more visible on PAUT-TFM images from the S2 design than from the S1 design.

- Six cylinders with different orientations (instead of three in the S1 design) can be seen in Region 5 from side 4A (Fig. 31). This means that we can visualize defects down to 200 µm in diameter in various orientations.
- All vertical cylinders can be seen in Region 4 from the side labeled 3A (Fig. 30) like in the S1 design, though with increased gain. This means that we can visualize defects down to 100 µm in diameter.
- All spheres (instead of three in the S1 design) can be seen in Region 4 from the side labeled 3A (Fig. 29). This means that we can visualize defects down to 100 µm in diameter.
- The horizontal cylinders are easier to see when located inside the star artifact (Fig. 28), than when located outside the star artifact (Fig. 27). Four of the them are seen

in Fig. 28.

Thus, due to its high spatial resolution when used with FMC/TFM, the PAUT method reveals individual defects and even allows rough dimensional measurements. The interpretation of the images is easier than in CUT but is still not straight forward. However, like in CUT, the surface roughness did not prevent the part from being tested, and the size of the part was not an obstacle. Apart from the better resolution than in CUT, another real advantage of the PAUT-TFM methods is to be able to perform static inspection by steering the beam instead of scanning the probe. This is of particular interest for complex shapes that cannot be scanned.

The main benefits and drawbacks of the phased array ultrasonic testing (PAUT) – total focusing method (TFM) method are summarized below.

Benefits of the method	➢ possibility of inspection without scanning by steering the beam ➢ less restriction in shape than CUT ➢ less restriction in size than X-ray computed tomography ➢ fast scanning (real-time), faster than CUT ➢ few roughness restrictions ➢ able to identify the type and location of defects in the part ➢ discretization in size ➢ rough dimensional measurements
Drawbacks of the method	➢ part set-up required ➢ need experience ➢ requires more experience and training than CUT ➢ more expensive than CUT

X-ray computed tomography with synchrotron radiation (SRXCT)

Principle of X-ray computed tomography (XCT)

Tomography is a volumetric imaging method. It consists of probing a test part with electromagnetic or sound waves at different angular positions of the part, recording the interactions of these waves with the test part for each angle independently, and post-processing these data with a reconstruction algorithm to give a volumetric image. A tomographic device includes a wave source, a sensor that detects the effects of interaction between the waves and the test part (e.g., attenuation, reflection, diffusion, diffraction), and a translation stage with a rotating platform on which the test part is positioned. The most commonly used waves are X-rays, as the short wavelength allows the spatial resolution of the image to be better. The best-known method of X-Ray tomography is designated by the acronym XCT for "X-Ray computed tomography" [15, 16, 17]. In a laboratory XCT system, the X-Ray source consists of a high-voltage power supply (usually the voltage (*U*) ranges between 10 kV and 450 kV) and an X-Ray tube made of two electrodes: a filamentary cathode, usually of tungsten, and an anode, which is the target. By applying an electric current (I) to the cathode, electrons are extracted; then by applying a high potential difference (U) between the anode and the cathode, the electrons are accelerated to collide with the target, focused on a spot on the target, to emit X-Rays.

ASTM E1695-95 [18] describes two factors that affect the quality of a XCT image: geometrical unsharpness, which limits the spatial resolution, and random noise, which limits the contrast sensitivity. Spatial resolution influences the ability to detect small geometrical features in the object, while contrast sensitivity influences the ability to detect inhomogeneities in the object. The geometrical unsharpness is linked to the size of the focused spot. This size depends on the required power for the measurement ($P=UI$), which depends on the thickness and density of the test part. The thicker and higher density of the part, the higher the power required, which creates a larger focus spot. An increase in the size of the focus spot induces more geometrical unsharpness. Thus, a larger focus spot results in a decrease in the spatial resolution. The random noise is linked to the brilliance of the source, which is proportional to the number of photons produced per second. The higher the brilliance, the lower the random noise. Thus, a higher brilliance results in a higher contrast sensitivity.

The produced X-Ray beam is polychromatic (multi-wavelength) which is not ideal since artifacts (an artificial characteristic on the image) can appear on the image due to beam hardening (i.e., loss of the low energies in the source spectrum due to their absorption by the test part).

And finally, the beam is commonly conical. This shape causes the magnification (*mag*) of the part on the detector to depend on its position between the source and the detector. The closer the part to the source, the larger its magnification on the detector, which is commonly a flat panel composed of a matrix of pixels. This magnification and the size of a pixel of the detector ($pixel_{size}$)

Obaton, Anne Francoise; Butsch, Bryan; McDonough, Stephen; Laroche, Nans; Gaillard, Yves; Tarr, Jared; Bouvet, Patrick; Cruz, Rodolfo; Donmez, Alkan. "Evaluation of Nondestructive Volumetric Testing Methods for Additively Manufactured Parts." Paper presented at ASTM Symposium on Structural Integrity of Additive Manufactured Parts, Washington, DC, US. November 06, 2018 - November 08, 2018.

will defined the spatial resolution of the image. Indeed, the spatial resolution is related to the size of the voxel (equivalent in three-dimensional (3D) of a pixel on the image) defined by:

$$voxel_{size} = pixel_{size}/mag \qquad (1)$$

The detector records the attenuated intensity of a ray, which is proportional to the thickness and density of material crossed. This enables acquiring two-dimensional (2D) images (i.e., greyscale images that show the radiation attenuation through the material) called projections. These projections, acquired over 360˚ around the test part, enable the reconstruction of the image in 3D.

Even though laboratory XCT is the more widespread X-Ray tomographic system, tomography is also performed with a synchrotron radiation X-ray source (SRXCT).

Principle of X-ray computed tomography with synchrotron radiation (SRXCT)

Synchrotron radiation is generated by electrons confined in a large loop and accelerated in a magnetic field. Due to the bending of their trajectory, the electrons accelerate or decelerate losing energy and thus produce electromagnetic radiation with a wide polychromatic spectrum from far infra-red to hard X-Rays. The use of a monochromator enables selecting a monochromatic X-Ray beam used to perform CT. The detector is generally a scintillator combined with a camera. Otherwise the SRXCT principle of image acquisition and reconstruction is the same as for laboratory XCT.

Compared to laboratory XCT, in addition to being monochromatic instead of polychromatic, the synchrotron beam is collimated instead of conical, and its brilliance is much higher than laboratory XCT. These are the three main differences between sources from laboratory XCT and synchrotron radiation. These differences are of paramount importance as they enable better spatial resolution, better contrast sensitivity, and fewer artifacts. Indeed, the benefit of a **monochromatic beam** is that it prevents artifacts on the image. The first benefit of a **parallel beam** is that the part does not need to be scanned over 360˚, but simply over 180˚.The information acquired is identical from one side to the other. The second benefit is that there is no focused spot which would create geometric unsharpness and thus decrease spatial resolution. The last benefit is that there is no magnification which means that the spatial resolution is defined only by the pixel size of the detector. The benefit of **high brilliance** is that it decreases random noise and thus increases contrast sensitivity.

X-ray computed tomography with synchrotron radiation (SRXCT) of the CoCr S2 star artifact

An XCT beamline (ID19) [19], from the European Synchrotron Radiation Facility (ESRF) located in Grenoble, France, was used to characterize the S2 design of the CoCr star artifact, with corresponding CAD shown in Fig. 32. The acquisition parameters are given in table 7 and the different images, processed with the ImageJ software, are displayed in Fig. 33 through Fig. 37.

The spatial resolution of the images is indisputably better than the ones from the UT methods. All defects are clearly located and imaged. Inspection of the 3D images also indicated an organic defect (hot tear or crack) at the base of the star (Fig. 38). The resolution of the images enables dimensional comparison with the CAD model (Fig. 39).

The main benefits and drawbacks of X-ray computed tomography (XCT) are summarized below.

Benefits of the method	➢ no restriction in shape ➢ no roughness restrictions ➢ able to identify the type and location of defects in the part ➢ discretization in size ➢ dimensional measurements
Drawbacks of the method	➢ part set-up required ➢ need experience ➢ not suitable for high volume and routine quality control ➢ more expensive than any other NDT methods

CONCLUSION

We have investigated four volumetric NDT methods as potential alternatives to XCT for faster and cheaper characterization for routine control and inspection of additively manufactured metal parts: two whole-body inspection methods using acoustic waves (RAM and PCRT) and two selective inspection methods using ultrasound waves (CUT and PAUT-TFM). The two whole-body inspection methods gave similar results. The parts with defects could be separated from the parts without defects, but the parts with defects could not be sorted based on the number of defects they contained. The results of the two selective inspection methods were significantly different. The CUT method allowed detection of most of the defects with low spatial resolution, though defects 5 mm apart could not be discriminated. Furthermore, the defects were not detected from every direction; successful results depended on the side inspected . The PAUT-TFM resulted in higher resolution images than CUT, allowing detection and separation of nearly all defects for a given side inspection. As a comparison we performed SRXCT which gives better spatial resolution, better contrast sensitivity, and fewer artifacts than laboratory XCT.

The whole-body inspection methods allowed only the identification of defective parts, whereas the selective inspection methods allowed identification of the type of the defect. In applications like routine inspections, it is sufficient to determine that a part is non-conforming in order to reject it. Then if localization and size of defects are needed to evaluate the defect criticality and impact on part performance, a secondary evaluation could use a selective inspection method.

Further volumetric NDT methods, such as non-linear acoustic methods, should be investigated in order to boost the application of additive manufacturing in critical sectors and to guarantee the reliability of parts for critical applications.

ACKNOWLEDGMENTS

We would like to particularly thank Wilson Vesga, Ben Dutton (convenor of the JG59), and David Ross-Pinnock from MTC for their investment in the group and the valuable information provided to help us. We are also grateful to Zodiac-Aerospace for building the star artifacts in aluminum, to Sofiane Terzi and Barbara Fayard from Novitom for the SRXCT inspection, and to Julieanne Heffernan from Vibrant for the PCRT inspection.

A Study of Timing Constraints and SAS Overload of SAS-CBSD Protocol in the CBRS Band

***Abstract*—In the Citizens Broadband Radio Service (CBRS) band, the Federal Communications Commission (FCC) has set stringent timing constraints for the lower tier users to vacate the channel on which an incumbent shipborne radar appears. The standards body formulating various specifications for the CBRS operation has taken these timing constraints into consideration in the Spectrum Access System (SAS) – CBRS Device (CBSD) protocol. A transmitting CBSD continually heartbeats with its SAS. When required, the SAS sends commands to vacate a channel through these heartbeat messages. In this paper, we study the impact of the heartbeat interval on the CBRS system in terms of meeting the FCC timing constraints. We also study how the heartbeat interval can overload a SAS and how it can be used to determine the number of CBSDs a SAS can serve without causing unnecessary suspension of CBSD transmissions. We show the tradeoff between using a short heartbeat interval to meet the timing constraint early and the number of CBSDs that can be served by a SAS without causing unnecessary suspension of CBSD transmissions.**

I. Introduction

The Federal Communications Commission (FCC) recently published rules for commercial operators to use the 3.5 GHz band, also termed as Citizens Broadband Radio Service (CBRS) band, on a priority based sharing [1]. A Spectrum Access System (SAS) manages the use of spectrum in the CBRS band. A CBRS device (CBSD) has to get authorization from its managing SAS to use the spectrum and must vacate the spectrum when instructed by its SAS to do so. The communication protocol between a SAS and a CBSD has been standardized by the Spectrum Sharing Committee (SSC) of the Wireless Innovation Forum (WInnForum), commonly referred to as the *SAS-CBSD* protocol [2]. The CBRS band operationally is a three tiered system. The incumbents operate in tier-1 with the highest priority. The commercial operators may operate in tier-2 with medium priority or in tier-3 with lowest priority. One of the incumbents in the CBRS band is the shipborne Navy radars. When an incumbent Navy radar appears within the harmful interference range of deployed CBSDs, a SAS has to carefully identify the CBSDs which should be instructed to vacate the channel (in which the radar is operating) such that the interference to the radar receiver falls below a given threshold. The presence of Navy radars is detected by a set of sensors, known as Environment Sensing Capability (ESC) sensors, usually deployed along the coast of the US. The FCC rules have stringent timing requirements for the SAS and the CBSDs to protect incumbent radars from harmful interference. Once a SAS is notified of the presence of a Navy radar by an ESC, the SAS must ensure that the CBSDs, which may cause harmful interference to the radar, have vacated the channel within 300 s [1]. Once a CBSD has been instructed by the SAS to vacate the channel, the CBSD must do so within 60 s [1].

The SAS-CBSD protocol specification has been carefully designed to ensure that the timing requirements set forth by the FCC rules can be met [2]. A CBSD requests authorization to transmit on a channel (frequency range) by sending a grant request to the SAS. Each active grant in the SAS-CBSD protocol has a heartbeat mechanism through which the CBSD knows that the SAS is alive and vice-versa. A CBSD has to send a Heartbeat Request message to its managing SAS periodically for each of its active grants. How frequently a CBSD should send a Heartbeat Request message is decided by the SAS by setting the *heartbeatInterval* parameter. An actively transmitting Grant has a timer called *transmitExpireTime* timer. If and when this timer expires, the CBSD will have 60 s to turn off its transmission. Hence, to meet the end to end timing requirement of 300 s, the value of transmitExpireTime timer should not be more than 240 s for actively transmitting grants. The transmitExpireTime timer thus guards against violation of timing constraints in case communication between SAS and CBSD fails. A SAS can also change various protocol parameter values through the heartbeat messages to control the system timings. For example, the transmitExpireTime timer value and heartbeatInterval value can be changed through the hearbeat messages. All the request messages originate from the CBSDs and the SAS reponds to them with the corresponding response messages. Thus, when a SAS gets the notification from an ESC that an incumbent has appeared on a channel, the SAS has to wait for the next Heartbeat Request message to instruct the CBSD to vacate the channel via the corresponding Heartbeat Response message. There is a tradeoff between heartbeatInterval and processing load on the SAS. When the heartbeatInterval is small, the SAS can instruct the CBSD to vacate a channel sooner, but the processing load on the SAS is higher since the heartbeat rate is higher. On the other hand, when the heartbeatInterval is large, the processing load on the SAS is lower, but the SAS has to wait longer, on the average, to intsruct a CBSD to vacate a channel. The latter configuration can push the time a SAS takes to ensure that a CBSD vacates the channel close to the time limit of 300 s.

A SAS also needs to have adequate provisioning of processing resources so that it can handle CBSD request messages in

*The author was at National Institute of Standards and Technology when this work was done.

Sahoo, Anirudha; El Ouni, Naceur; Shenoy, Vineet. "A Study of Timing Constraints and SAS Overload in the CBRS Band using SAS-CBSD Protocol." Paper presented at 2019 IEEE Global Communications Conference (GLOBECOM), Wikola, HI, US. December 09, 2019 - December 13, 2019.

a timely manner. Since Heartbeat Request messages are the most frequent messages a SAS receives, their load dominates in determining the processing resource requirement of a SAS. If a Heartbeat Request message is dropped or sufficiently delayed due to lack of processing resources at a SAS, then the transmitExpireTime timer at the CBSD would expire. This would force the CBSD to suspend its transmission. This obviously is an unnecessary timeout caused by poor provisioning of processing resources in the SAS which leads to inefficient use of the spectrum.

Various efforts towards spectrum sharing in the US are summarized in [3]. The article also presents an example SAS architecture that facilitates tiered services in the CBRS band. The FCC rules on the CBRS operation were published in [1]. Based on the FCC rules, the Spectrum Sharing Committee (SSC) of Wireless Innovation Forum (WInnForum) has developed requirements for commercial operation in the CBRS band [4]. The WInnForum SSC has also developed the specification for the SAS-CBSD protocol [2]. Besides these, there has not been any work on the SAS-CBSD protocol that is publicly available.

To the best of our knowledge, there is no study on the SAS-CBSD protocol that is available in the public domain. Hence, the motivation behind this paper is two fold. First, we want to study the impact of heartbeatInterval on the performance of the CBRS system in terms of meeting the end to end timing constraint. Second, we want to study how message overload on a SAS impacts the performance of the CBRS system in terms of unnecessary timeouts of the transmitExpireTime timer which leads to suspension of CBSD transmission. To achieve these goals we have developed a basic simulator of the SAS-CBSD protocol. The protocol is implemented using the Omnet++ discrete event simulator package [5]. Our experiments were run for a CBRS system having very high number of CBSDs (up to 50 000) in the system. So, we believe the scale of simulation is similar to what we may see in practice. Our results show that a moderate mean hearbeatInterval of 150 s provides a good balance between handling the processing load and meeting the timing constraint. For a given SAS message service rate, our study also provides approximately how many CBSDs the SAS can serve without causing unnecessary timeouts (which would cause CBSDs to stop their transmissions). We present an approximate method of calculating the number of CBSDs a SAS can manage for a given request service rate, without causing unnecessary transmitExpireTime timeouts. This model can be used, for example, by SAS providers to decide when a new SAS process should be spawned to serve increasing number of CBSDs.

II. Simulation of SAS-CBSD Protocol

A. *Brief Description of the SAS-CBSD Protocol*

The SAS-CBSD protocol has two state machines: *Registration State Machine* and *Grant State Machine*. A CBSD starts out in the Unregistered state. When it registers with its SAS, it goes through the Registration State Machine as shown in Figure 1. If the registration is successful it transitions into Registered state. Once the CBSD is in Registered state, it is allowed to ask for spectrum grants. Spectrum grant is the process by which a CBSD asks the SAS for authorization to transmit in a particular frequency range at a particular transmission power and follows the Grant state machine shown

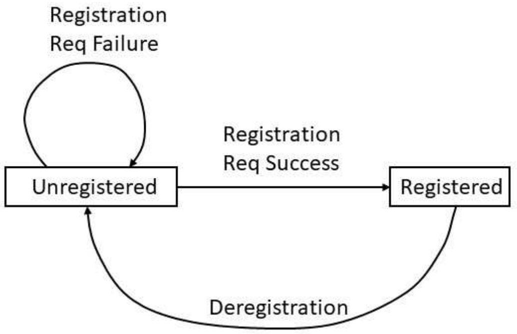

Fig. 1. Registration State Machine of CBRS (adapted from [2])

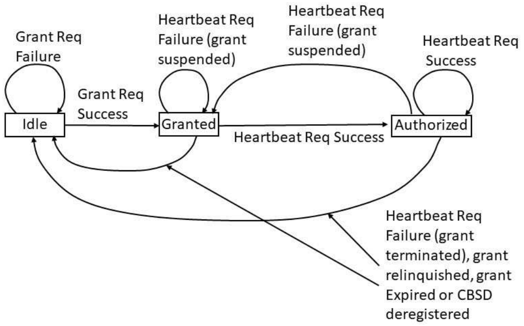

Fig. 2. Grant State Machine of CBRS (adapted from [2])

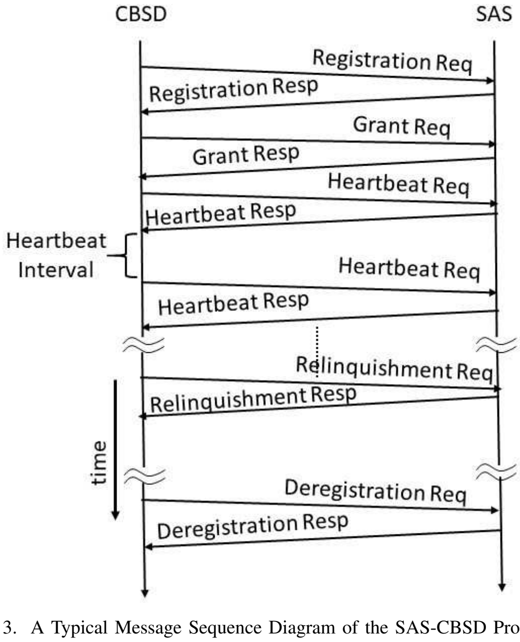

Fig. 3. A Typical Message Sequence Diagram of the SAS-CBSD Protocol

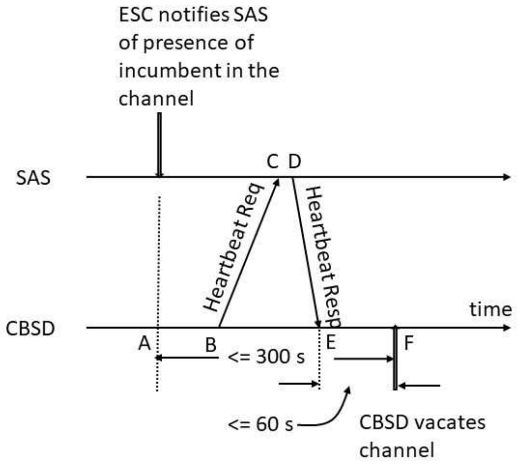

Fig. 4. Timing Constraint of CBRS

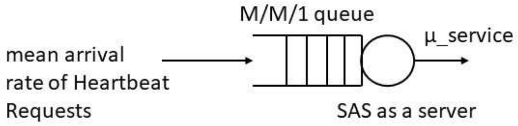

Fig. 5. SAS Message Processing Model

in Figure 2. A CBSD sends a Grant Request to its SAS while in the Idle state. The SAS checks if the grant does not cause harmful interference to other users (as per the Part 96 rules [1]), and if not, the CBSD is granted persmission and it goes into Granted state. If the Grant Request fails, the CBSD stays in the Idle state. A CBSD is not allowed to transmit while in the Granted state. It starts a heartbeat process while in the Granted state by sending a Heartbeat Request message. If the Heartbeat Request is successful, then the CBSD receives a successful Heartbeat Response from the SAS and moves to Authorized state, at which time it is allowed to transmit. A CBSD has to continue sending Heartbeat Requests periodically while in the Authorized state and can continue to transmit as long as it receives successful Heartbeat Responses. The SAS can ask the CBSD to stop transmission by indicating failure in the Heartbeat Response, in which case the CBSD moves to the Granted state from the Authorized state. A SAS may want to do this, for example, if an incumbent appears on the channel used by the CBSD and may experience harmful interference. A CBSD keeps heartbeating in the Granted state to wait for a successful Heartbeat Response from the SAS to move to the Authorized state and resume its transmission. When the CBSD does not want to transmit on that channel any more, it sends a Relinquishment Request to the SAS. The SAS deallocates the resources from the CBSD and sends a Relinquishment Response message to the CBSD. When a CBSD does not wish to participate in the CBRS band any more, it deregisters from its SAS and goes into the Unregistered state as shown in Figure 1. Figure 3 shows a typical successful message sequence diagram of the SAS-CBSD protocol.

Since spectrum is shared in the CBRS band on a priority basis, a SAS may ask a CBSD to vacate its occupied channel to prevent harmful interference to a higher priority incumbent through the Heartbeat Response message. Hence, periodic heartbeat is essential to protect higher priority incumbents. How frequently heartbeats should be sent is decided by the heartbeatInterval parameter which is set in the Heartbeat Response message by the SAS. Since it is possible that Heartbeat Request or Heartbeat Response messages may be lost, there is a transmitExpireTime timer that runs at the CBSD. The value of this timer is decided by the SAS and is carried in a Heartbeat Response message. If Heartbeat Request or Response is lost, then the transmitExpireTime timer will eventually expire at which point the CBSD has to turn off its transmission. There are stringent timing requirements set forth by the FCC for the lower priority user to vacate the channel when a higher priority incumbent radar appears in the same channel. As per the Part 96 Rules [1], a SAS should make sure that when an incumbent appears on a channel, the CBSDs that may cause harmful interference to the incumbent should stop transmitting within $300\,\mathrm{s}$ from the time the SAS is notified about the presence of the incumbent. The FCC rules also specifies that a CBSD has up to $60\,\mathrm{s}$ to turn off its transmission from the time its managing SAS directs it to do so. Thus, the maximum value of transmitExpireTime timer when a CBSD is in the Authorized state is $240\,\mathrm{s}$. Hence, the heartbeatInterval should be less than $240\,\mathrm{s}$ when a CBSD is transmitting in the Authorized state to prevent the CBSD from unnecessarily shutting down its transmitter due to expiry of transmitExpireTime timer. These timing constraints are depicted in Figure 4. A SAS gets notification from the ESC that an incumbent has appeared on the channel at time A. The SAS has to wait for the next Heartbeat Request message from the CBSD to inform it to stop its transmission. The CBSD sends a Heartbeat Request at time B. The SAS sends a Heartbeat Response which carries a command from the SAS to the CBSD to stop transmission. Once the CBSD receives this command at time E it should stop transmission within $60\,\mathrm{s}$. As mentioned earlier, the time the SAS is notified of the presence of an incumbent to the time the CBSD vacates the channel, should not be more than $300\,\mathrm{s}$, i.e., duration between A and F should be less than or equal to $300\,\mathrm{s}$. From the figure it is clear that the heartbeatInterval parameter plays an important role in deciding how soon or late the CBSD will be able to vacate the channel. Note that the worst case happens when SAS gets ESC notification right after it sent out a Heartbeat Response message. In this case, the SAS would get to notify the CBSD to vacate its channel when it gets the next Heartbeat Request that would arrive after heartbeatInterval. Hence, large heartbeatInterval would lead to a SAS taking longer to ensure that a CBSD vacate the channel. In this study, we evaluate performance of CBRS system in terms of time taken to vacate a channel after a SAS is notified of presence of an incumbent radar in the channel.

As mentioned earlier, after receiving the first successful Heartbeat Response, a CBSD goes into the Authorized state and has to continue to heartbeat periodically while it is transmitting in the Authorized state. When there are thousands of authorized grants managed by a SAS, these periodic heartbeats exert significant processing load on the SAS. If processing power of a SAS is not adequately provisioned, then the SAS may not be able to provide Heartbeat Responses in a timely manner. This could lead to transmitExpireTime timer to expire, resulting in unnecessary suspension of CBSDs which do not get Heartbeat Responses in time. Using the SAS-CBSD simulator we evaluate the limits of a SAS in terms of number of CBSDs it can serve successfully.

B. SAS-CBSD Protocol Simulator

1) Message Processing Model: We use the M/M/1 queueing model to represent the message processing service of a SAS provided to various messages sent from its CBSDs (Figure 5). While this model keeps the analysis simple, it gives a fairly good insight into the timing contstraints and SAS overload aspects of the protocol. Among all the messages, the Heartbeat Request message is the most frequent message arriving at the SAS, whereas other messages are relatively infrequent. Hence, the arrival to the M/M/1 queue is approximated by considering only the Heartbeat Request messages. The service rate of the queue is the rate at which the SAS can process a message ($\mu\_service$) and the mean arrival rate (λ_msg_arr) is approximated by the taking the ratio of number of existing grants in the system to the mean heartbeatInterval time. In the simulation, when a message arrives, we check the utilization ($\frac{\lambda\_msg\_arr}{\mu\_service}$) of the queue at that instant, and if it is greater than or equal to 1, then we drop the message. This indicates that the SAS is not provisioned with adequate processing resources and hence the message is dropped.

The above M/M/1 queueing model can be used to calculate the maximum number of CBSDs that a SAS can manage such that there is no unnecessary shut down of CBSDs. Let λ_msg_arr be the mean arrival rate of messages to the SAS, $\mu\_service$ be the mean service rate of the SAS, N_CBSD be the number of CBSDs, G be the maximum number of grants a CBSD is allowed to have and HBI_mean be the mean heartbeatInterval. We consider only Hearbeat Request messages to compute the processing load on a SAS, since other messages arrive relatively infrequently. Hence, the mean message arrival rate at the SAS is given by

$$\lambda\_msg\_arr = \frac{N\_CBSD \times G}{HBI\_mean} \tag{1}$$

To prevent loss of messages at the SAS because the SAS cannot handle the rate at which messages are arriving, the M/M/1 queue should be stable, i.e., utilization of the queue should be less than 1. Hence,

$$\frac{\lambda\_msg\_arr}{\mu\_service} < 1 \tag{2}$$

Using (1) in (2) we get

$$N\_CBSD < \frac{HBI\_mean \cdot \mu\_service}{G} \tag{3}$$

Thus, (3) provides a method to calculate the maximum number of CBSDs a SAS can serve so that it can process messages in a timely manner.

2) Modeling Detection of Incumbent Radar: We have a simple mechanism for modeling detection of incumbent shipborne radar. The incumbent radar appears according to an exponential distribution with mean arrival rate $\lambda\_incumbent$ (see Table I for these parameters and their values) and the channel on which it appears is randomly chosen. When a shipborne radar is detected, we randomly choose $Grants\_affected\_by\_incumbent$ percentage of total grants which are operating in the same channel as the incumbent and put those grants in suspension, i.e., they go into Granted state. We understand that this is far from the real operation of a SAS. In a real operation, a SAS has to compute path loss from each CBSD in the neighborhood of the shipborne radar to the radar receiver and compute the aggregate interference at the radar receiver. If the aggregate interference is more than the specified Interference to Noise (I/N) threshold of -6 dB [4, Requirement R2-IPM-01] then the SAS has to identify which CBSDs should be turned off to bring the aggregate interference down below the threshold. The exact requirement for this operation is specified in [4, Requirement R2-SGN-24]. Even though our shipborne radar protection model does not resemble the real operation, it is adequate to provide essential insight into the time sensitive aspects of vacating a channel by a CBSD.

3) Implementation Details: We have implemented the SAS-CBSD protocol using OMNET++ discrete event simulation software [5]. The core parts of the implementation are the two state machines of the protocol for which we have used the Finite State Machine (FSM) support provided in the Omnet++ simulator [6] and the models presented in the previous sections. The Grant State Machine of a CBSD cannot start unless the Registration State Machine of the CBSD is in the Registered state. Hence the Grant State Machine is implemented as a nested state machine which is supported by Omnet++ [6, Section 4.10.1]. Grant Requests are sent from each CBSD according to a Poisson process, i.e., the interarrival of two consecutive Grant Requests is exponentially distributed. The lifetime of a grant is also exponentially distributed. Each CBSD is allowed to have up to 7 grants. Total number of channels in the system is set to 10. When a CBSD sends a Grant Request, it randomly chooses one of the 10 channels for the grant. The parameters used in our experiments and their values are listed in Table I.

III. Simulations and Results

In this section we describe our experiments and present the results. We primarily ran two types of experiments. The first type is designed to show the effect of overloading the SAS in terms of message handling. In this experiment the focus was only on the message handling of the SAS and hence simulation of presence of incumbent radar was not enabled. The second type of experiment was carried out to study how quickly CBSDs vacate the channel when an incumbent radar appears on the channel to satisfy the timing constraint set forth by the FCC. Table I lists the important parameters and their values used in our experiments.

A. Unnecessary Timeout

In this set of experiments, the mean message service rate of the SAS is fixed (as per M/M/1 queue service rate) while the

Sahoo, Anirudha; El Ouni, Naceur; Shenoy, Vineet. "A Study of Timing Constraints and SAS Overload in the CBRS Band using SAS-CBSD Protocol." Paper presented at 2019 IEEE Global Communications Conference (GLOBECOM), Wikola, HI, US. December 09, 2019 - December 13, 2019.

Parameter	Description	Distribution	value
λ_{grant}	mean interarrival rate of Grant Requests	exponential	$300\,\mathrm{s}^{-1}$
$grant_{life}$	mean lifetime of Grant	exponential	$900\,\mathrm{s}$
λ_{incumb}	mean interarrival rate of incumbent	exponential	$(1/180)\,\mathrm{s}^{-1}$
$incumb_{life}$	mean lifetime of presence of incumbent	exponential	$300\,\mathrm{s}$
$heartbeatInterval$	parameters of heartbeat interval	uniform	[70, 110] s [120. 180] s [200, 240] s
$\mu_{service}$	mean SAS service rate	exponential	40, 60 s^{-1}
T_{sim}	simulation time	–	$86\,400\,\mathrm{s}$ (1 day)
$HB\_success\_rate$	percentage of hearbeat success	–	$100\,\%$
$Grant\_success\_rate$	percentage of grant success	–	$95\,\%$
$Grant\_suspend\_rate$	percentage of grant put into suspension when incumbent appears	–	$100\,\%$
$Grants\_affected\_by\_incumbent$	percentage of existing grant affected when incumbent appears	–	$90\,\%$
G	maximum num of grants per CBSD	–	7
$MAX\_CHANNELS$	maximum number of channels	–	10

TABLE I
PARAMETERS USED IN OUR SIMULATION

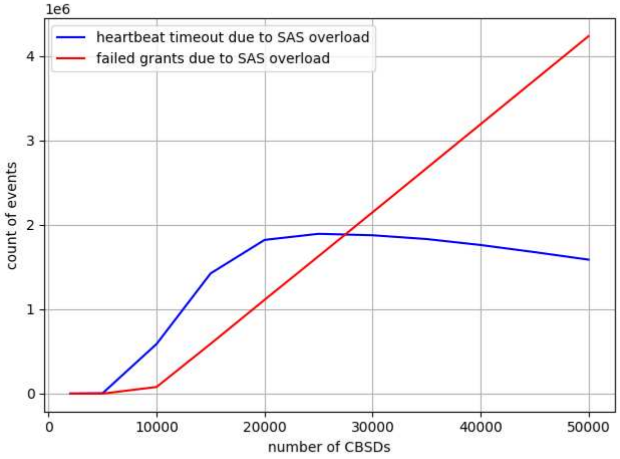

Fig. 6. Unnecessary Timeout vs Num of CBSDs (service rate=40 rps)

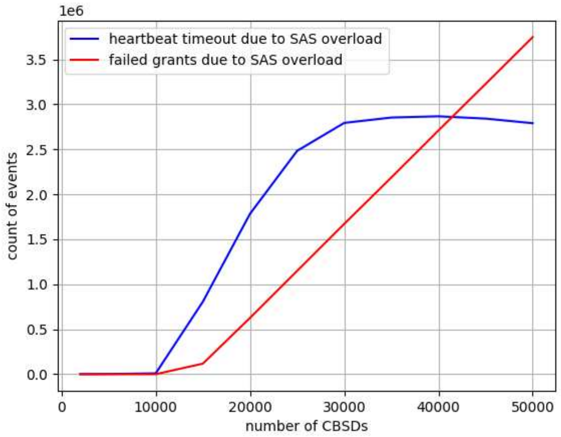

Fig. 7. Unnecessary Timeout vs Num of CBSDs (service rate=60 rps)

number of CBSDs is progressively increased. As the number of CBSDs increases, the number of grants also increases, which in turn increases the number of heartbeat messages to be handled by the SAS. Thus, the message handling load on the SAS increases. At some point the SAS fails to keep up with the rate at which the Heartbeat Request messages arrive. This leads to some Heartbeat Request as well as Grant Request messages being dropped. When a Heartbeat Request message is dropped, the CBSD does not get the corresponding Heartbeat Response message. Hence, the transmitExpireTime timer in the corresponding Grant *unnecessarily* times out. This would force the CBSD to stop its transmission. Clearly this situation arises due to poor provisioning of processing power of the SAS and is not desirable by the commercial operators.

Figure 6 presents the unnecessary heartbeat timeout and failed grants (due to SAS overload) vs number of CBSDs when the mean SAS service rate is 40 requests per second (rps) and the heartbeatIntervals of grants are uniformly distributed between $200\,\mathrm{s}$ and $240\,\mathrm{s}$. For a given number of CBSDs the simulation is run for $86\,400\,\mathrm{s}$ (1 day). The heartbeat timeout remains low until about 5000 CBSDs after which it rises rapidly. But beyond $20\,000$ CBSDs, it tapers off. The failed grant count starts to take off rapidly around $10\,000$ CBSDs and continues to increase. Since grants fail, there are less number of grants in the system. Hence, when the high number of Grant Requests fail, the number of heartbeat failures does not increase and more or less remains flat.

Figure 7 depicts the same performance metrics but with mean SAS service rate of $60\,$rps. The SAS can handle more CBSDs compared to the $40\,$rps case before heartbeats start to time out. For this case the heartbeat fail count takes off at around $10\,000$ CBSDs which is higher than the corresponding point when service rate is 40 rps. However, once the heartbeat fail count rises, it rises more rapidly compared to $40\,$rps case.

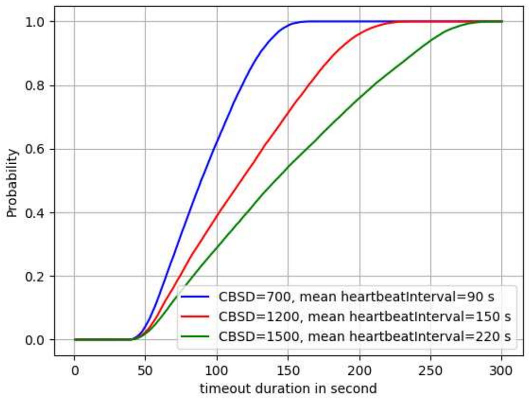

Fig. 8. CDF of Duration of CBSDs Vacating a Channel (service rate=60 rps)

The failed grant count remains zero until about 10 000 CBSDs after which it takes off. The grant fail count happens to be lower than that for the 40 rps case for a given number of CBSDs. Hence, there are more active grants in the system than 40 rps case which implies that there are more heartbeat requests. This leads to a higher heartbeat fail count compared to the 40 rps system.

B. Time to Vacate a Channel

In this experiment, we enabled presence of incumbent radar as per the parameters specified in Table I. When an incumbent radar appears, the SAS randomly chooses 90 % of grants which are in the same channel as the radar and instructs those CBSDs to suspend the grants via Heartbeat Response message. We assume that the SAS sets transmitExpiryTime timer to zero when it commands the CBSD to suspend the grant in the Heartbeat Response message. Hence, the CBSD has up to 60 s to vacate the channel. Figure 8 shows the Cumulative Distribution Function (CDF) of the CBSDs vacating the channel for different mean heartbeatInterval. In this experiment we assume that the SAS is adequately provisioned with processing power such that there is no Heartbeat Request or Grant Request message loss. To achieve this, for a given mean heartbeatInterval, we calculate the number of CBSDs (using (3)) such that the SAS does not drop any message due to overloading of message arrival. For example, when the heartbeatInterval is uniformly distributed between (200, 240) s, the mean hearbeatInterval is 220 s. If a SAS has a service rate of 60 rps, then using (3), the SAS can handle up to 1885 CBSDs. So, we fix the number of CBSDs at 1500. From Figure 8, it can be noticed that when the mean heartbeatInterval increases, more and more grants vacate the channel closer to the 300 s limit. In fact, for a mean heartbeatInterval of 220 s some grants vacate channel very close to 300 s. Since there is randomness involved in the process, it is not advisable to have CBSDs vacating the channel so close to the deadline although it allows more CBSDs to be served for a given SAS service rate. Hence, a heartbeatInterval of 220 s may not be a good choice. On the contrary, if heartbeatInterval is set to a low value of 90 s, then CBSDs can vacate the channel much ahead of the deadline. However, shorter heartbeatInterval exerts heavy load on the SAS which means a smaller number of CBSDs (only 700 CBSDs when mean heartbeatInterval is 90 s) can be served by the SAS for a given service rate. Setting heartbeatInterval to around 150 s seems to be a good choice to achieve a reasonable balance between the number of CBSDs a SAS can manage and the time taken for CBSDs to vacate a channel. Note that the SAS service rate does not have much effect on the CDF of time taken by CBSDs to vacate a channel when SAS is operating close to its full capacity (i.e., close to M/M/1 server utilization of 1). This is true in our study, since the number of CBSDs a SAS manages is set close to the maximum possible value as per (3).

IV. Conclusion and Future Work

We have developed a basic SAS-CBSD protocol simulator to study the impact of heartbeatInterval on the CBRS system in terms of meeting the end to end timing constraint set forth by the FCC rules. We also use the simulator to study how message overload on a SAS leads to unnecessary timeout of transmitExpireTime timer which leads to suspension of CBSD transmission thereby reducing spectrum utilization. Through our experimental results we have shown the tradeoff between time taken to meet the end to end timing constraint and the number CBSDs that can be served by a SAS without causing unnecessary supension of CBSD transmission. With a lower heartbeatInterval the end to end timing constraint of vacating a channel can be met earlier, however, the number of CBSDs a SAS can serve will be lower. Based on our results, setting heartbeatInterval to around 150 s may strike a good balance between the tradeoffs.

Implementing a more practical model to represent the method of vacating a channel when an incumbent shipborne radar appears on the channel can be an useful future work. This would require implementing a propagation model and the so called *move-list* algorithm (which identifies the CBSDs that should vacate the channel when a incumbent shipborne radar appears on the channel) defined in the standards [4].

ABSTRACT

A workshop on Challenges in Representing Manufacturing Processes for Systematic Sustainability Assessments, jointly sponsored by the U.S. National Science Foundation, the U.S. National Institute of Standards and Technology, ASTM International, the American Society of Mechanical Engineers, and the Society of Manufacturing Engineers, was held in College Station, Texas on June 21, 2018. The goals of the workshop were to identify research needs supporting manufacturing process characterization, define limitations in associated education practices, and emphasize on challenges to be pursued by the advanced manufacturing research community. An important aspect surrounded the introduction and development of reusable abstractions of manufacturing processes (RAMP), which are standard representations of unit manufacturing processes to support the development of metrics, methods, and tools for the analysis of manufacturing processes and systems. This paper reports on the workshop activities and findings, which span the improvement of engineering education, the understanding of process physics and the influence of novel materials and manufacturing processes on energy and environmental impacts, and approaches for optimization and decision-making in the design of manufacturing systems. A nominal group technique was used to identify metrics, methods, and tools critical to advanced manufacturing industry as well as highlight the associated research challenges and barriers. Workshop outcomes provide a number of research directions that can be pursued to address the identified challenges and barriers.

Keywords: Unit Process Modeling, Advanced Manufacturing, Nanomanufacturing, Sustainable Manufacturing, Engineering Education

1. INTRODUCTION

The advanced manufacturing research community has been recently exploring wide-ranging issues attendant with additive manufacturing, bio-manufacturing, nanomanufacturing, and smart manufacturing, among other technical domains. However, the integration of findings across these domains, especially in support of sustainable manufacturing analysis, has become increasingly challenging due to the complexity of information and the domain expertise necessary for its interpretation [1]. Further, the reusability of results is inhibited by the lack of standard methods for interpretation, e.g., reproducing results from life cycle assessment (LCA) remains a challenge [2].

The pursuit of sustainable manufacturing requires balancing competing objectives, including cost, time, and environmental and social considerations. The complexity of modeling these objectives increases during the assessment of process-related manufacturing impacts. Assessing system-level sustainability performance is further complicated by the uncertain emergent properties of systems [3], but it is ultimately vital to comparing alternative designs of products and production systems for sustainable manufacturing. Standard approaches for acquiring and exchanging manufacturing process information will lead to more consistent process characterization and may contribute to a consolidated repository of process models for reuse across advanced manufacturing domains [4]. Improved process

[1] Contact author: shankara@oregonstate.edu

modeling (e.g., using data-driven and physics-based approaches), along with the ability to compose a variety of process models, will ensure more effective communication of computational analytics and may facilitate sharing of sustainability performance data [5].

Engaging industrial and academic researchers in presenting and discussing related work is critical for sharing best practices, exposing gaps in technical and educational research and practice, and developing new research agendas. To facilitate this, two workshops have been organized that focused on research to support modeling of manufacturing processes across production scales (e.g., discrete, batch, and continuous) using a variety of manufacturing methods (conventional manufacturing, nanoscale manufacturing, additive manufacturing, and others) applied in various fields (e.g., mechanical, electrical, chemical, nuclear, biochemical, and biological).

This paper presents motivations for the 2018 workshop, based on the prior 2017 workshop (Section 2). It summarizes the workshop activities (Sections 3-6) and presents an outlook for future directions the manufacturing research community might explore (Sections 7). A full workshop report is forthcoming.

2. PRIOR WORKSHOP OUTCOMES

A workshop on Formalizing Manufacturing Processes for Structured Sustainability Assessments, supported by the U.S. National Science Foundation (NSF), was held in conjunction with the 2017 ASME Manufacturing Science and Engineering Conference (MSEC) of the American Society of Mechanical Engineers (ASME) and the 45th North American Manufacturing Research Conference (NAMRC) of the Society of Manufacturing Engineers (SME) on June 7, 2017. The workshop was announced by the National Institute of Standards and Technology (NIST) in partnership with ASTM International, NSF, and ASME. The objectives of the workshop were to:

1. Model different unit manufacturing processes (UMPs);
2. Apply the new ASTM E3012-16 standard for various UMPs; and
3. Provide models suitable for system analysis based on the reusable standard format.

The workshop attracted several dozen participants from industry, academia, and government labs. Results from this workshop [1] highlighted the need for an open repository of process models. The workshop identified many emerging efforts including both standards and research, and outlined a vision for coalescing these efforts towards an open process model repository. In addition, lessons from the 2017 workshop led to proposed revisions of ASTM E3012-16 [6]. Experience through the workshop revealed a need for more rigorous definition of the concepts presented in the standard to support consistent application and implementation. In response to this need, E60.13, the ASTM subcommittee on Sustainable Manufacturing, is revising E3012 with a more robust information model. The forthcoming information model will facilitate more consistent characterizations of physical artifacts in production systems, leading to better reusability of models and reproducibility of environmental analyses.

Based on 2017 workshop results and findings from ongoing research, a 2018 workshop was planned to

1. Provide a venue for participants from industry, government labs, and academia to exhibit manufacturing process developments of their own interest;
2. Identify educational and research challenges and requirements relevant to manufacturing process model development and validation;
3. Expose the research community to developments in the recent standards for modeling manufacturing processes being proposed to the ASTM E60 subcommittee;
4. Identify candidate models to populate an extensible repository of reusable manufacturing process models;
5. Gather inputs on best practices for sharing, reusing, extending, and composing models of conventional and advanced manufacturing processes for characterizing manufacturing systems;
6. Develop a roadmap that defines key research gaps and strategies for addressing system-level modeling; and
7. Enable sharing of model development experiences for evaluating sustainability performance.

3. 2018 WORKSHOP OUTCOMES

The 2018 workshop, titled *Challenges in Representing Manufacturing Processes for Systematic Sustainability Assessments*, supported by NSF's Nanomanufacturing program, was held in conjunction with the 2018 ASME MSEC and the 46th SME NAMRC conferences on June 21, 2018 at Texas A&M University, College Station, TX, and sponsored by ASME, ASTM International, NIST, NSF, and also SME.

The workshop, comprised of two half-day sessions and an evening poster session, engaged the research community in discussions of emerging topics in advanced manufacturing, nanomanufacturing, sustainable manufacturing, and engineering education. The workshop hosted 46 student participants from the NIST RAMP Challenge competition [7], which included six teams of 23 student finalists. Also, there were two dozen participants from industry, academia, and government labs. As part of the workshop, undergraduate and graduate students were able to present their research in manufacturing process development, process modeling, and sustainability performance assessment.

Expected outcomes of the workshop were to identify needs for UMP characterization to support system-level sustainability assessment, to define limitations in associated engineering education and research practices, and to prioritize the challenges to be pursued by the advanced manufacturing research community to best meet industry needs in adopting and applying analytical methods for improving process and system performance. The workshop outcomes summarized in Section 7 were gathered through brainstorming discussions aimed at identifying the barriers and opportunities in several topics of relevance to advanced manufacturing research.

4. 2018 WORKSHOP OVERVIEW

The theme for the 2018 workshop was *Tracking Resources and Flows through the System*. The morning session began with presentations from a NIST-hosted challenge competition on modeling UMPs. After the student presentations, workshop organizers presented use cases of applications exploring unit process modeling and system composition, including those from industry, research, and educational settings, in the form of lightening talks (Section 5). A moderated discussion after the talks fielded audience comments and questions about the cases discussed and points made.

In the afternoon session, facilitated breakout conversations with the attendees were used to gather inputs on methods, issues, and challenges in sharing, reusing, extending, and composing process models for characterizing manufacturing systems, as well as strategies to overcome these challenges, including engineering curriculum development needs. Organizers applied a modified nominal group technique [8], which typically follows this flow: 1) Introduction; 2) Individual idea generation; 3) Idea sharing; 4) Group discussion; and 5) Voting and ranking of ideas. This approach effectively involved all participants, who arrived with varying levels of experience and perspectives on the topics.

Workshop participation was open to MSEC/NAMRC conference attendees with broad interests in teaching engineering students and conducting basic and applied research in manufacturing. Academic researchers with foci in advanced manufacturing, nanomanufacturing, and engineering education were particularly encouraged to attend. NIST RAMP Challenge participants were also encouraged to attend, since they had practical application knowledge based on their work completed for the competition. Section 5 summarizes the workshop lightening talks, which addressed the workshop theme.

5. SYNOPSIS OF THE LIGHTENING TALKS

The lightening talks were presented by workshop organizers and affiliated subject matter experts. Topics focused on various applications of advanced manufacturing technologies in industry and research. The talks centered around the goal of engaging the research community in discussions of emerging topics in advanced manufacturing, nanomanufacturing, sustainable manufacturing, and engineering education.

5.1 Nanomanufacturing

Khershed Cooper, a program director in the NSF Advanced Manufacturing program, defined nanomanufacturing as the fabrication of nano-scale building-blocks (nanomaterials, nanostructures), their assembly into higher-order structures, and the integration of these into larger scale systems with manipulation and control of matter at the nano-scale. Research challenges were noted in processes, metrics, precision, speed of production, unit processes, and integration and packaging. Nanomanufacturing processes should be controllable, reproducible, repeatable, and reliable. Production should be scalable, affordable, safe, have high yields and efficiency. Nano-products should be of high quality, durable, and exhibit desired performance and functionality. With these factors in mind, appropriate metrics to be evaluated can be determined, e.g., precision placement, feature size, and density.

Machine learning has an integral role in nanomanufacturing processes. For example, raw materials serve as an input for an advanced manufacturing system, which outputs meta-materials that exhibit both performance and quality characterized via *in situ* metrology. These characterizations are inputs to a machine learning node. Customer specifications are also an input to the machine learning node. Outputs of the machine learning node are tuned process parameters that feed back into the advanced manufacturing system for process optimization.

Next, Ajay Malshe, a professor of mechanical engineering at the University of Arkansas, outlined three main drivers for standardization in nanomanufacturing: efficiency, yield, and a diverse operating environment. It is important to maintain a business perspective on standardization by keeping factors such as return on investment (ROI) and productive yield in mind. Efficiency is important to business and should be thoroughly considered in developing standard nanomanufacturing methods.

Future nanomanufacturing research efforts are anticipated in three waves: 1) Nanoparticle-based production; 2) Nano-scale template-based production; and 3) True self-assembly for production. Two eminent objectives are 1) Repeatability, reliability, and reproducibility (3Rs), and 2) Product, productivity, and producibility (3Ps). In particular, nano-products should be scalable and minimize waste.

Current nanomanufacturing limitations can be seen through the lens of industry. One limitation is increasing stress levels in the research lab because of a dramatically changing *invention-to-product* life cycle. Further sources of limitations are the complex solutions required. There is a need to account for the frequency of products changing hands. Additionally, there is a missing link between research and industrial application, which could be mitigated by researchers addressing the industry needs. The overall vision for manufacturing science and engineering research is to support the development of the 3Rs and 3Ps for sustainable nano-manufactured products with ROI.

5.2 Systems integration: Additive manufacturing

Kevin Lyons, a senior research engineer in the NIST Systems Integration Division, presented on additive manufacturing and its components: part design using CAD tools, followed by CAD adjustments for additive manufacturing, part build, part post-processing, verification, and validation. Three main focus area in additive manufacturing include industry drivers, research challenges, and scientific and engineering approaches.

Limited connectivity exists between additive manufacturing lifecycle activities and supply chain activities. There is also a disconnect between additive manufacturing software tools, as well as limited process understanding and knowledge of design decision support [9]. The management and representation of additive manufacturing models and knowledge are isolated in industry, and data is generated individually and is costly through additive manufacturing lifecycle activities without coordination. Additionally, because of the heterogeneous nature of these models, it is difficult to combine these models.

The collection and curation of data remains a main research challenge for additive manufacturing. Further, the diversity of the additive manufacturing operating environment gives rise to some important questions, e.g., *How do researchers integrate across the various models while considering the inherent complexities, underlying assumptions, and constraints?* and *How will the models be coordinated?* Design for Additive Manufacturing (DfAM) [10] is an approach to characterize performance and life cycle considerations using design methods or tools for process optimization. Drivers of DfAM include providing manufacturers approaches to capture design rules for different additive manufacturing processes by using formal representations. Additionally, DfAM provides the architecture to derive design rules in a computer-interpretable way, allowing the effective exchange of additive manufacturing information.

5.3 Sustainable engineering education

Fazleena Badurdeen, a professor of mechanical engineering at the University of Kentucky, presented challenges in educating engineers about sustainable manufacturing. There is a need to demonstrate reduced negative environmental impact through sustainable manufacturing, offer improved energy and resource efficiency, provide operational safety, and improve personal health, all at the product, process, and systems levels. Throughout the lifecycle of the product, the 6Rs (reduce, recycle, reuse, recover, redesign, and remanufacture) are implemented at all points, such as redesign during product manufacturing [11].

Realizing sustainable manufacturing innovations requires developing an educated and skilled workforce. This idea falls in line with the United Nation's Sustainable Development Goal 4 (*Ensure inclusive and equitable quality education and promote lifelong learning opportunities for all*) [12]. A lifecycle approach can be applied to recruit, reeducate, and retrain at all levels for building a workforce pipeline [13]. Additionally, a need for a multi-disciplinary approach, which incorporates convergent research and education, to address sustainable manufacturing challenges has to be emphasized. Various programs and funding opportunities can facilitate efforts to bolster sustainable manufacturing education. For example, the NSF Education and Human Resources (EHR) directorate sponsors programs such as the Research on Learning in Formal and Informal Settings. Programs such as these can promote activities that strengthen Science, Technology, Engineering, and Mathematics (STEM) education and prepare future STEM leaders for a rapidly developing work environment.

5.4 Unit Process Life Cycle Inventory (UPLCI)

Barbara Linke, an associate professor of mechanical engineering at the University of California Davis, presented on the Unit Process Lifecycle Inventory (UPLCI) method [14], which is entering its ninth year of development. UPLCI uses industrial information for a single manufacturing process (a machine) to estimate material inputs, energy use, material loss, and dependencies of process parameters with respect to product design. UPLCI is a multi-institutional effort by Katholieke Universiteit Leuven, Northeastern University, Oregon State University, Purdue University, University of California Davis, University of Michigan, University of Virginia, University of Wisconsin, and Wichita State University.

Creating a UPLCI follows a clear, easy-to-follow template, and has breadth to allow different materials and designs. UPLCI require about a month for development, suitable for graduate class project or part of thesis. Moreover, the Springer journal *Production Engineering,* sponsored by the German Academic Society for Production Engineering, now publishes UPLCI studies. The unit process is decomposed into physics-driven equations that describe the energy and material consumption. UPLCIs can be integrated together to evaluate a manufacturing line leading to a completed part or product. The UPLCI approach plans to develop life cycle inventories for around 100 varied manufacturing processes, of which 31 have been completed, with categories including heat treatment, surface finishing, joining, auxiliary, material conversion, and material reducing.

Another unit process inventory approach was created under the Cooperative Effort on Process Emissions in Manufacturing (CO2PE!) framework [15]. Challenges in UPLCI methods include data quality and availability, how to reduce complexity while remaining generic, managing empirical models, materials dependency, energy-dependence on machine set-up, and an unclear vision of whether auxiliary processes are to be included or not. As supporters of UPLCI continue to solve these problems, the demand for inventorying models will continue to increase.

The UPLCI method provides an appropriate means to identify sources of data, collect appropriate models to characterize manufacturing processes, and evaluate performance for general scenarios. However, the storage of UPLCI requires a formal representation to improve robustness. Relating UPLCI studies with ASTM E3012 is a promising approach forward [16].

5.5 Manufacturing process modeling standards

KC Morris, Information Modeling and Testing Group Leader from NIST's Engineering Laboratory and Arvind Shankar Raman, a graduate research assistant in mechanical engineering at Oregon State University, presented a standards-based methodology for extending manufacturing process models for sustainability assessment. They discussed the current lack of assessment tools, which presents analysis challenges. An operational deficiency of analysis applications to support system-, process-, and machine-level manufacturing decisions limits system analysis capabilities. Data collection and reporting has been one of the biggest challenges for manufacturers in pursuing sustainability assessment.

Efforts to characterize manufacturing processes, including UPLCI and CO2PE!, have focused on developing information models that are distinct and specific to processes of concern, sometimes making them limited in their extensibility to related processes. Often these models must be developed from scratch. A question to address becomes, *How do researchers develop methodologies that allow companies to collect, analyze, and disseminate data-driven conclusions about sustainability factors linked to unique manufacturing processes?*

To realize reusability and extensibility, developing models at the appropriate abstraction is critical. Appending an existing model with information about auxiliary systems, such as exhaust gas pressure control systems, monitoring equipment, and electric boosting systems, would constitute a high order variant of the manufacturing process considered [17]. Similarly, if properly developed, models should remain valid after removing information regarding a particular physical setup to be applied to alternative scenarios. For example, in the case of manual drilling, a robust abstraction would facilitate the characterization of multiple instances of drilling regardless of its functional manifestation, e.g., electric hand drilling or using a drill press.

Existing work can be expanded by characterizing data exchange information or linking variables, to facilitate composability. Additionally, an information exchange framework can be created that enables model composability for manufacturing system characterization. Information validation would be critical to its success. The end state of this work would be realizing the framework in commercial software applications.

5.6 Factory Optima: A web-based software

Alex Brodsky, a professor of computer science at George Mason University, presented on a web-based system for composition and analysis of manufacturing service networks based on a reusable model repository [18]. The architectural design allows for rapid software solution development for descriptive, diagnostic, predictive, and prescriptive analytics of dynamic production processes. This architecture emerged in response to the limitations of decision-making tools and models that enable smart manufacturing.

One such limitation is due to the fact that most analysis and optimizations tools are currently developed from scratch, which leads to high cost, long-duration development, and restricted extensibility. Additionally, numerous computational tools are designed to model individual activities, which require the use of specialized, low-level mathematical abstractions. This proposition for an architecture that addresses these limitations is unique in that the middleware layer was based on reusable, modular, and extensible knowledge bases. However, the architecture lacks systematic design of the unit manufacturing process models, which are based on linear functions as opposed to being physics-based, typically involving non-linear functions.

Factory Optima is a high-level system architecture based around a reusable model repository and the unity decision guidance management system (DGMS). The software framework and system enables composition, optimization, and trade-off analysis of manufacturing and contract service networks. This work is unique in its ability to perform tasks on arbitrary service networks without manually crafting optimization models. Industrial case studies are needed to further develop the architecture. In addition, stochastic optimization-based deterministic approximations, and model calibration and training will aid in improving the commercial utility of the tool.

6. BREAKOUT SESSION AND REFLECTION ACTIVITY

Parallel breakout discussions were facilitated by six subject matter experts (the workshop presenters and I.S. Jawahir, a professor of mechanical engineering at University of Kentucky). Discussions were guided by Karl Haapala, an associate professor of manufacturing engineering at Oregon State University, and focused on advanced discrete manufacturing processes, nanomanufacturing at scale, additive manufacturing, process-level sustainability assessment, system-level sustainability assessment, and engineering education in advanced manufacturing. Scribes captured the ideas generated during three timed sessions. These are summarized in Section 6.1.

Each group discussed challenges and opportunities related to metrics and indicators, models and algorithms, and tools and methods. The groups were prompted to progress through the discussion in three four-minute intervals. Participants distributed themselves among the six topic areas and were given 14 minutes per facilitated discussion round to brainstorm ideas related to the topic. The final two minutes of each round were allotted to reviewing the ideas that were shared and collected. The structure of this breakout session allowed for a continuous flow of perspectives and ideas that were guided toward identifying challenges and approaches to overcoming them for each topic.

The final stage of the afternoon workshop session involved an individual reflection activity, which posed two questions: *What do you see as the most pressing need for advanced manufacturing research or advanced manufacturing education?* and *What do you see as the key next step to be taken to address a pressing research or educational challenge in advanced manufacturing?* Participants recorded their individual responses to these questions on notecards, as described in Section 6.2.

6.1 Breakout session results

The breakout session consisted of small-group brainstorming along three subtopic lines: metrics and indicators, models and algorithms, and tools and methods. The results are reported along the same lines. Discussions revolved around challenges, barriers and solutions to overcome them.

Topic 1: Advancing discrete manufacturing processes

Metrics and Indicators: Challenges include product customization, standardization, and bolstering the flexibility of processes. One key barrier is to connect process level controls and system level metrics. Modeling interdisciplinary/dynamic processes can be extremely difficult.

Models and Algorithms: The complexities in model composition and optimization pose barriers to developing flexible models and algorithms. Participants identified a need to support related product categories with similar models across multiple enterprises. Additionally, transient analysis is required for developing robust models of complex systems, especially non-steady state manufacturing elements. Scheduling intricacies pose a challenge for modeling flexible discrete systems.

Tools and Methods: Participants noted that robots, which are widely used in discrete product manufacturing, can be extensively integrated to achieve process improvements. It was also established that machine learning classifications of problems is increasingly an important in advancing the understanding and optimizing the performance of discrete manufacturing processes.

Topic 2: Nanomanufacturing at scale

Metrics and Indicators: Participants identified some of the key metrics and indicators that need to be considered for nanomanufacturing as follows: fluid type, electron beam power, scan rate, beam diameter, material removal rate, structural resolution, feature size, tolerances, nanoparticles (e.g., silver), medium, roll-to-roll, roll speed, printing speed, ink spread, sintering conductivity, circuit device design, and reactor design.

Models and Algorithms: To model the metrics and indicators identified in the above, participants noted existing models and algorithms. Some of the current modeling categories include fluidic modeling, roll-to-roll modeling, circuit modeling, molecular dynamics, and density functional theory (DFT). Participants indicated that currently models or algorithms for other metrics and indicators of interest do not exists.

Tools and Methods: Participants indicated that some of the common tools for modeling and analyzing nanomanufacturing include MATLAB, scanning electron microscopes (SEM), transmission electron microscopes (TEM), computational fluid dynamics (CFD), finite element method (FEM), finite volume method (FVM). The UMP Builder based on ASTM E3012 [19] was also noted as an enabler of analysis. Key advancements in tools have been achieved using machine learning (for prediction), image processing, and fuzzy logic, with advancements in computing technology and an increase in usage of artificial intelligence techniques.

Topic 3: Additive manufacturing at scale

Metrics and Indicators: The participants identified some of the basic metrics for additive manufacturing: temperature, layer thickness, material uniformity, material density, extrusion rates, feed rates, internal geometries, product dimension constraints, melt pool geometries, and build time. More quality-oriented indicators identified were surface profile, accuracy, surface finish, repeatability, preventative maintenance, a need for post-processing operations, and control of multi-axis equipment.

Models and Algorithms: Some of the challenges identified were limitations to support structure optimization, design features, and fidelity of current models. A need exists for topology optimization and an expression of key performance indicators (KPIs) as a function of control parameters. Participants posited cloud-based process design is needed, by combining parameterized product design with process design.

Tools and Methods: The participants desired tools and methods which are able to provide information on selection of process, build orientation, material. Also the tools should be able to support metrology, in-process monitoring tools, quality, verification, validations, sustainable decision support tools, cross-validation tools, selection of models, cost models, and product design optimization methods.

Topic 4: Process level sustainability assessment

Metrics and Indicators: The participants indicated that metrics and indicators for sustainability at the process level include cost, environmental impact, energy, resources, waste minimization, safety, public policy, personal health, productivity and quality, all essentially addressing the three pillars of sustainability. At the process level, these metrics can be difficult to identify and quantify. Safety and public policy, for example, consider societal impacts, legislative and administrative issues, and ethics, which are difficult indicators to effectively assess.

Models and Algorithms: One of the key challenges identified by the participants is the limited models or algorithms that facilitate assessment of process-level sustainability metrics. Physics- and empirical-based methods were discussed, as well as predictive and optimization methods. In addition, participants identified process planning, sensors, and data-driven models as means to assess and improve process-level sustainability.

Tools and Methods: One important topic that emerged as a necessary element of effective sustainability assessment was education. A strong need for bolstering education was identified to address the growing demands and urgency of awareness and accurate sustainability assessment at the process level. Beyond education, the group identified training, skills, societal influence and behaviors as key tools and methods of importance regarding sustainability at the process level.

Topic 5: System level sustainability assessment

Metrics and Indicators: At the system level, lead time and resource availability appear to be metrics and indicators of worthy consideration, as well as material stability, resource availability, and reliability. Additionally, it is important to consider the interaction of multiple manufacturing processes involved at a system level, as one process usually is fed into the next, and the connection between those processes needs to be seamless to ensure more accurate assessment.

Models and Algorithms: For the systems level, it is important that models for risk assessment and for evaluating system dynamics are developed. Models describing manufacturing processes were found to have an important role in system-level sustainability assessment. Also, game theory can be applied iteratively to identify critical issues. Discussions also raised the point that network models should be developed, in addition to unit manufacturing process models.

Tools and Methods: Current challenges for modeling sustainability at the system level include how to collect and sort data. Methods for defining interactions of processes within the system would be helpful. Obtaining a system-level view is essential for the task of sustainability assessment. Participants identified the potential for application of machine learning in predictive modeling of systems level sustainability. Discussions also raised the idea of diagnostic problem identification through degradation classification.

Topic 6: Manufacturing engineering education

Metrics and Indicators: An indicator for education in advanced manufacturing is an identifiable increase in confidence

Shankar Raman, Arvind; Harper, Dustin; Haapala, Karl; Linke, Barbara; Bernstein, William Z.; Morris, KC. "Challenges In Representing Manufacturing Processes for Systematic Sustainability Assessments - Workshop On June 21, 2018." Paper presented at ASME 2019 International Manufacturing Science and Engineering Conference (MSEC2019), Erie, PA, US. June 10, 2019 - June 14, 2019.

in manufacturing classes. Participants also suggested that introducing students to advanced manufacturing at a young age (such as through the use of cartoons) would help increase their interests. A current indicator of weak advanced manufacturing education is the lack of sustainability studies in undergraduate studies. Overall, metrics for engineering education in advanced manufacturing are hard to define.

Models and Algorithms: Some of the models and algorithms associated with engineering education in advanced manufacturing include the applicability of sustainability in real life, easy to apply solutions and methods, and circular design. Additional models taught are design for x (DFx), end of life (EOL), and design for manufacturing (DFM) models (e.g., cost, feasibility, and material use). A robust advanced manufacturing curriculum should include systems engineering models.

Tools and Methods: The tools and methods for bolstering engineering education for advanced manufacturing largely include learning in groups and sharing knowledge. This includes overall manufacturing techniques that can be taught using in-house demonstrations. Basic technical skills to be taught include physics-based classes, which participants suggested being taught in conjunction with case studies and interactive in nature (i.e., labs associated with the material). To provoke students' thinking about sustainability earlier, the group recommended tracking sustainability in real life, and relating sustainability impacts to cost in industry. Hands-on exposure to learning the impacts of manufacturing and relating it to sustainability can be achieved using field trips to manufacturing facilities, for example.

6.2 Results from individual reflection

The answers to the first question (*What do you see as the most pressing need for advanced manufacturing research or advanced manufacturing education?*) were quite diverse, but can be grouped largely into the following categories:

1. Link between research and industry (24%)
2. Development of process models (20%)
3. Improvements in manufacturing education (20%)
4. Advancements in technology and methods of scalability (16%)
5. Encouragement of an interest in manufacturing (12%)
6. Validation of models (8%)

Based on these results, nearly a quarter of the participants thought a stronger link between research and industry was the most pressing need. This indicates a lack of research applications in industry, or at least perception of a lack thereof. The second category, development of process models, scored high as well, likely in response to the workshop discussions tailored toward addressing a need for more models to fill current characterization gaps. Somewhat surprisingly, however, validation of said models did not score as high, even though it was consistently presented as one of the more pressing needs throughout the workshop. This may be a result of an overlap between categories, as some responses qualified for a position in the "link between industry and research" category, but may have also referred to validation.

For the second question (*What do you see as the key next step to be taken to address a pressing research or educational challenge in advanced manufacturing?*), the same six categories were applicable to the responses, in a slightly different order:

1. Improvements in manufacturing education (39%)
2. Link between research and industry (17%)
3. Development of process models (13%)
4. Encouragement of an interest in manufacturing (13%)
5. Advancements in technology and methods of scalability (9%)
6. Validation of models (9%).

As demonstrated here, when posed with questions about the future of manufacturing, a large fraction of the participants regarded education as pivotal to its progression. This and the "encouraging an interest" category are closely related; together they assume a majority of responses to the second question. Based on these results, there is consensus that strengthening the advanced manufacturing community in both numbers and ability is crucial to addressing all the research and industry needs posed during the workshop.

7. FUTURE OUTLOOK

The outcomes of the workshop are expected to benefit research programs, for example, by advancing basic and applied research in topic areas such as sustainability of nanomanufacturing processes and nano-products, digitization of continuous and batch processes, development of physics-based models of manufacturing processes, and efficient process and system models for cloud (cyber) manufacturing. Based on the foregoing, the following research directions emerged:

a) Machine learning methods can support fundamental understanding of a variety of discrete manufacturing processes, e.g., nanomanufacturing, and system-level sustainable manufacturing analysis and optimization.

b) Bridging the gap between process-level controls and system-level metrics can enable deeper insight for discrete and bulk product manufacturing. A mapping of product categories that have similar models and can be used across multiple enterprises is also needed.

c) Transient analysis of complex manufacturing systems can lead to robust manufacturing process models.

d) Metrics and indicators for nanomanufacturing are plentiful and span process parameters, material properties, and part characteristics. They should be unified/harmonized to enable technology comparisons.

e) Scalability in nanomanufacturing needs to lead to reduced defects and defectives, improved metrology, and measurement of moving parts and assemblies.

f) Scalability of additive manufacturing requires material, geometry, and support structure optimization methods.

g) Additive manufacturing key performance indicators must be connected as a function of process controls.

h) In additive manufacturing, integration of *in situ* and out-of-process metrology, sustainability decision tools, model selection tools, cost models, and product design optimization tools, are all areas of research need.

i) Societal influences of sustainable manufacturing, e.g., stakeholder behavior, must be better understood.

j) Engineering education approaches are needed to address the growing urgency for accurate sustainability assessment at the process and system levels.
k) Systemic sustainable manufacturing requires insight from risk assessment and system dynamics methods.
l) Robust methods to characterize interactions of processes, activities, and decisions across a system are needed to advance systemic sustainable manufacturing.
m) Diagnostic problem identification can be aided through degradation classification of physical assets.
n) Developing and sharing metrics for improving the effectiveness of learning in advanced manufacturing should be a focus of engineering education research.

ACKNOWLEDGEMENTS

This material is based upon work supported by the National Science Foundation (NSF) under Grant No. 1831141. The authors wish to thank the NSF for their generous support of this research. The authors also extend a warm thank you to the invited speakers, competitors, and supporters of the 2018 workshop.

DISCLAIMER

No endorsement of any commercial product by NIST is intended. Commercial materials are identified in this report to facilitate better understanding. Such identification does not imply endorsement by NIST nor does it imply the materials identified are necessarily the best available for the purpose.

Evaluating Critical Temperatures of Axially Loaded I-shaped Steel Members Using ANSI/AISC-360 Appendix 4 and Finite Element Model

Ana Sauca[1], Chao Zhang[2], Mina Seif[3], Lisa Choe[4]

Abstract

Stability is paramount to the load-carrying capacity of structural steel members subjected to fire. Actual buckling strengths of steel members in fire become lower than that at ambient temperature since modulus of elasticity and yield strength significantly diminish with increasing temperatures. Appendix 4 of the ANSI/AISC-360 specification provides an equation for calculating the flexural buckling stress of columns at temperatures greater than 200 °C. However, finite element analysis showed that columns can fail by buckling at temperatures below 200 °C if the applied axial load is greater than 80 % of its ambient compressive strength. This paper presents: (i) critical temperatures estimated using both the Appendix 4 equations and finite-element analysis and (ii) parametric study results showing effects of applied load level, member slenderness, and steel grades on the critical buckling temperature. Closed form equations are developed and presented along with limitations that were identified.

1. Introduction

The critical temperature method has been considered a useful tool to evaluate failure temperatures of loaded steel members exposed to a standard fire (e.g., ISO-834 (International Standard ISO 834-1:1999)). The Eurocode 3 (EC3) standard (EN 1993-1-2, 2005) specifies the critical temperature method for steel members supporting given axial or flexural loads. This method assumes that a loaded steel member is heated uniformly along its length and across the cross-section. For steel members without any instability phenomenon (e.g., tensile or flexural members) the critical temperature ($\theta_{a,cr}$) can be determined using Eq. (1) which is a function of the degree of utilization (μ_0) in Eq. (2), where ($E_{fi,d}$) is the design effect of actions for the fire design situation; ($R_{fi,d,0}$) is the corresponding design resistance of the steel member for the fire design situation at time (t) = 0.

Sauca, Ana; Zhang, Chao; Seif, Mina; Choe, Lisa. "Evaluating Critical Temperatures of Axially Loaded I-shaped Steel Members Using ANSI/AISC-360 Appendix 4 and Finite Element Model." Paper presented at Annual Stability Conference, St. Louis, MO, US. April 02, 2019 - April 05, 2019.

$$\theta_{a,cr} = 39.19ln\left[\frac{1}{0.9674{\mu_0}^{3.833}} - 1\right] + 482 \tag{1}$$

$$\mu_0 = \frac{E_{fi,d}}{R_{fi,d,0}} \tag{2}$$

For steel members prone to instabilities (e.g. columns), the critical temperature is presented in specific tabulated data (Vassart et al., 2014), depending upon the degree of utilization, the steel grade, and the non-dimensional slenderness. The non-dimensional slenderness can be determined using Eq. (3), where (*A*) is the gross cross-sectional area (for class 1, 2 and 3 cross sections) or the effective area of a cross section (for class 4 cross sections), (F_y) is the yield stress and (N_{cr}) is the elastic critical force for the relevant buckling mode based on the gross cross-sectional properties. In Eurocode 3 (EC3), for class 4 cross sections, the resistance and rotation capacity is limited by their local buckling resistance.

$$\bar{\lambda} = \sqrt{\frac{AF_y}{N_{cr}}} \tag{3}$$

Some national annexes of Eurocodes specify values for critical temperatures. For example, the British Standard (BS NA EN1993-1-2, 2005) provides critical temperatures for columns and beams. When evaluating the beams, the values of specified critical temperatures vary with fire protection, the support conditions of floor slabs, and the degree of utilization. When evaluating columns, the values of specified critical temperatures vary with the non-dimensional slenderness and the degree of utilization.

Appendix 4 of the American Institute of Steel Construction (AISC) specification for structural steel buildings, known as ANSI/AISC-360 (AISC, 2017), provides advanced and simple methods of analyses for fire conditions; however, it omits the critical temperature method. Hence, the objective of this study is to evaluate and compare the critical temperature of axially loaded I-shaped steel members using the simple method of analysis specified in ANSI/AISC-360 Appendix 4 and finite-element models. The parameters influencing critical temperatures were evaluated, such as the effects of applied load levels, member slenderness ratios, steel grades, and section compactness. Closed-form equations were developed and presented along with limitations that were identified.

2. Critical temperature of steel members using ANSI/AISC-360 Appendix 4

Buckling strengths of steel members subject to fire conditions decrease as the modulus of elasticity (*E*) and yield strength (F_y) diminish with increasing temperatures. Appendix 4 of ANSI/AISC-360 specifies Eq. (4) for calculating the flexural buckling stress (F_{cr}) at temperatures greater than 200 °C, where ($F_y(T)$) is the yield stress at elevated temperature; ($F_e(T)$) is the critical elastic buckling stress calculated from Eq. (5); (*E(T)*) is the elastic modulus at elevated temperatures; (L_c) is the effective length of member; and (*r*) is radius of gyration which is equal to $(I/A)^{0.5}$, where (*I*) is the area moment of inertia and (*A*) is the cross-sectional area.

$$F_{cr}(T) = \left[0.42^{\sqrt{\frac{F_y(T)}{F_e(T)}}}\right] F_y(T) \tag{4}$$

$$F_e(T) = \frac{\pi^2 E(T)}{\left(\frac{L_c}{r}\right)^2} \tag{5}$$

Chapter E of ANSI/AISC-360 uses Eq. (6) and Eq. (7) to calculate the flexural buckling stress (*F_{cr}*) at ambient conditions depending on the value of (L_c/r). In these equations, the yield stress (F_y), the Young's modulus (E), and the critical elastic stress (F_e) are all ambient temperatures values.

When $\frac{L_c}{r} \leq 4.71\sqrt{\frac{E}{F_y}}$ (or $\frac{F_y}{F_e} \leq 2.25$)

$$F_{cr} = \left(0.658^{\frac{F_y}{F_e}}\right) F_y \tag{6}$$

When $\frac{L_c}{r} > 4.71\sqrt{\frac{E}{F_y}}$ (or $\frac{F_y}{F_e} > 2.25$)

$$F_{cr} = 0.877 F_e \tag{7}$$

For columns with compact sections, the nominal compressive strength for flexural buckling at ambient conditions is computed using the flexural buckling stress at ambient conditions (F_{cr}) and the gross cross-sectional area (A) as presented in Eq. (8). For elevated temperatures, Eq. (4) from Appendix 4 of the ANSI/AISC-360 replaces Eq. (6) and (7) to calculate the nominal compressive strength for flexural buckling.

$$P_n = F_{cr} A \tag{8}$$

For columns with slender sections, the nominal compressive strengths at ambient conditions is computed using Eq. (9), where (A_e) is the effective areas of the cross section.

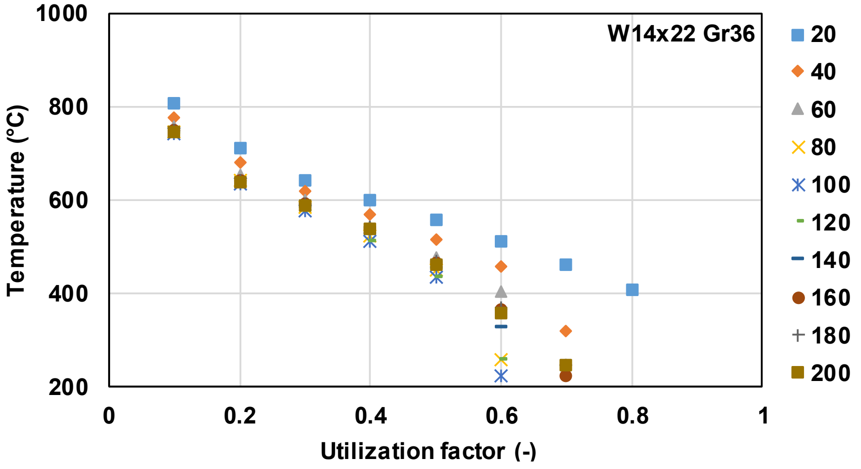
$$P_n = F_{cr} A_e \tag{9}$$

In this paper, the critical temperature can be calculated using the code equations presented above for the range of parameters presented in Table 1. The code-specified minimum yield stress (F_y) and modulus of elasticity of steel (E) are considered in this study. The uncertainty associated with the actual mechanical properties is not considered in this study. The utilization factor is defined as the ratio of $F_{cr}(T)$ in Eq. (4) to F_{cr} in Eq. (6) and Eq. (7) regardless of the section width-to-thickness ratios. The columns are considered simply supported.

Table 1. Considered data to evaluate the critical temperature

Section	Steel	Slenderness $\frac{L_c}{r}$	Utilization factor $\frac{F_{cr}(T)}{F_{cr}}$
W 14x22	Grade 36 (F_y=250 MPa)	20 – 200	0.1 – 1
	Grade 50 (F_y=345 MPa)	20 – 200	0.1 – 1
W 14x90	Grade 36 (F_y=250 MPa)	20 - 200	0.1 - 1
	Grade 50 (F_y=345 MPa)	20 - 200	0.1 - 1

Figure 1 presents the calculated critical temperatures of steel columns using ANSI/AISC-360 Appendix 4 as a function of the utilization ratio for various slenderness values. For columns with utilization factors smaller than 0.5, the effect of slenderness on the critical temperature is deemed small. At the same load level (i.e., utilization factor), the standard deviation of critical temperatures for all slenderness levels was less than 5 % of the averaged value. For utilization factors greater than 0.6, the critical temperature varies significantly with the column slenderness levels. Furthermore, for columns with slenderness values greater than 60 (except slenderness values of 160 and 200) and utilization factors greater than 0.6, the critical temperatures fall below 200 °C, which violates the temperature limit specified for use of Eq. (4) and Eq. (5). Hence, there is a need to limit the utilization factor and slenderness to compute critical temperatures using the AISC equations. The steel grade also has a minor impact on the critical temperatures for most of slenderness levels. Some variations in critical temperatures are observed for shorter columns (with slenderness values less than 40) at utilization factors higher than 0.6.



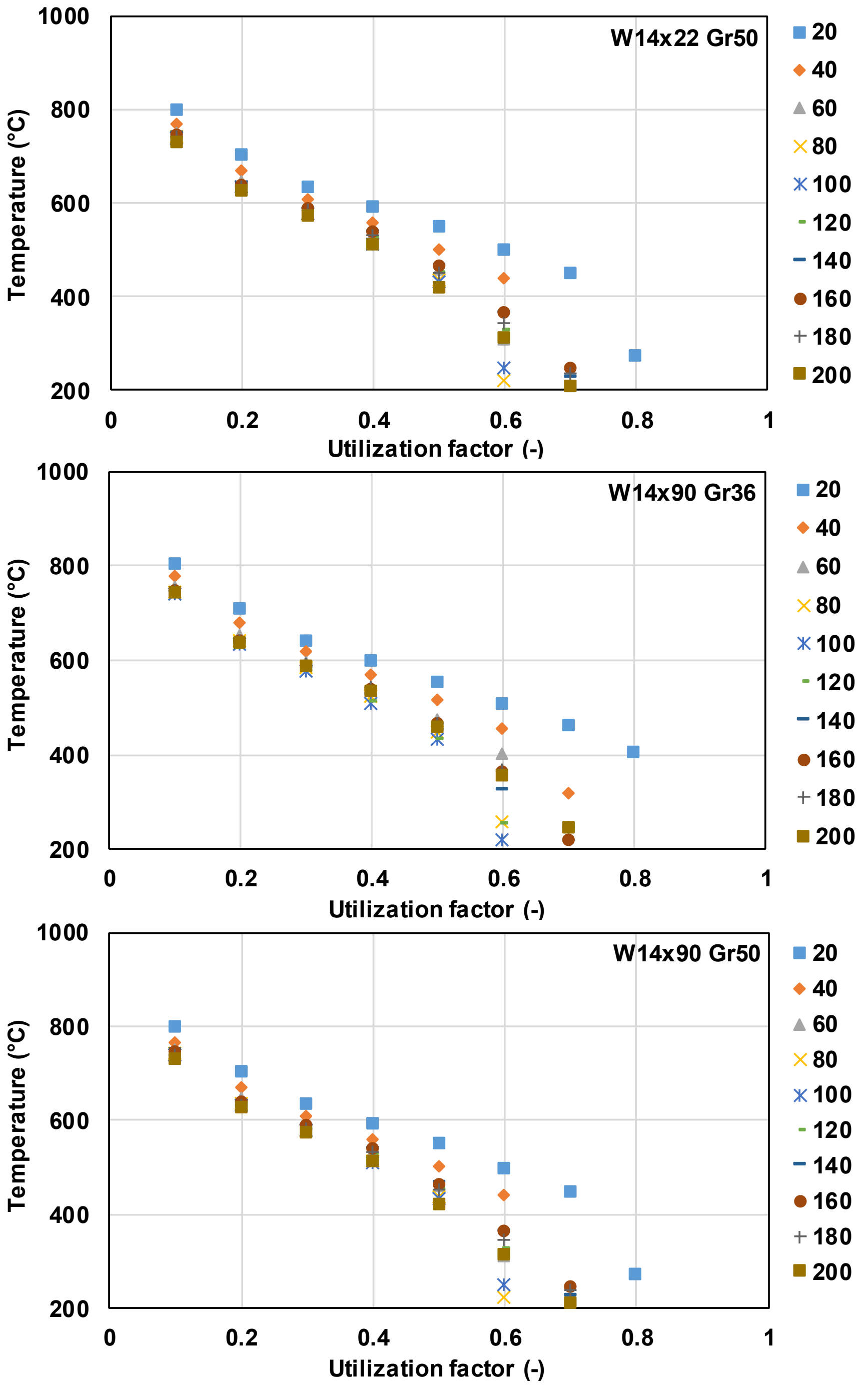


Figure 1. Critical temperature values computed using ANSI/AISC-360 Appendix 4 versus the utilization factor for various slenderness values

Sauca, Ana; Zhang, Chao; Seif, Mina; Choe, Lisa. "Evaluating Critical Temperatures of Axially Loaded I-shaped Steel Members Using ANSI/AISC-360 Appendix 4 and Finite Element Model." Paper presented at Annual Stability Conference, St. Louis, MO, US. April 02, 2019 - April 05, 2019.

3. Critical temperature of steel members using finite element analysis

The cases presented in Table 1 were further evaluated using the finite element analysis software package ANSYS (ANSYS, 2012). The steel column models were meshed with shell element SHELL181, which is a 4-node element with six degrees of freedom at each node. SHELL181 was used because it is suitable for linear, large rotation, and/or large strain nonlinear applications (Index of Software Ansys, 2018), and the change in shell thickness can be accounted for in the nonlinear analysis. The stub and slender columns were meshed using 50 elements for the length, 8 elements for the flange and 8 elements for the web based on the mesh density study presented in Table 2. Linear kinematic constraints were applied to the flanges and web at the column ends to enforce "rigid" planar behavior. At the column ends, the supports were simply supported. Axial force was applied on the center node of the end sections. Global and local initial geometric imperfections were implemented. The initial displacement at midspan was taken as the 1/1000 of the column length to simulate global geometrical imperfections. Local geometrical imperfections were implemented by scaling the deformation of the first (lowest) eigenmode from buckling analysis. The scaled value was the larger of a web out of flatness of (*d/150*) (Kim and Lee, 2002) or a tilt in the compression flanges of (b_f*/150*) (Zhang et al., 2015), where (*d*) and (b_f) are the height and width of the cross section, respectively. It is noted that for short columns, the local buckling modes are expected to dominate the stability behavior. No residual stresses were applied in the numerical models since the effect is regarded to be rather limited in structural fire analysis (Vila Real et al., 2007). A uniform temperature distribution was assumed through the column cross section and along its length. The EC3 material model was used in this study.

The finite element model of the columns is shown in the Figure 2. Some results of the uncertainty component associated with the size of mesh elements (Table 2) as well as the time step associated with the convergence criteria employed in numerical analysis (Table 3) are presented. In a mesh density study, When the column length, flange, and web consisted of the number of elements greater than 100, 16, and 16, respectively, the computed results were converged (0% difference). For computational efficiency, this study used 50 elements for the column span, 8 elements for each flange, and 8 elements for web. This yielded about 2 % difference for the slenderness ranging from 20 to 160. However, the difference in the time step did not significantly the convergence of predicted results. As shown in Table 3, both the increment of the analysis time and duration of the analysis time yields less than 1% difference.

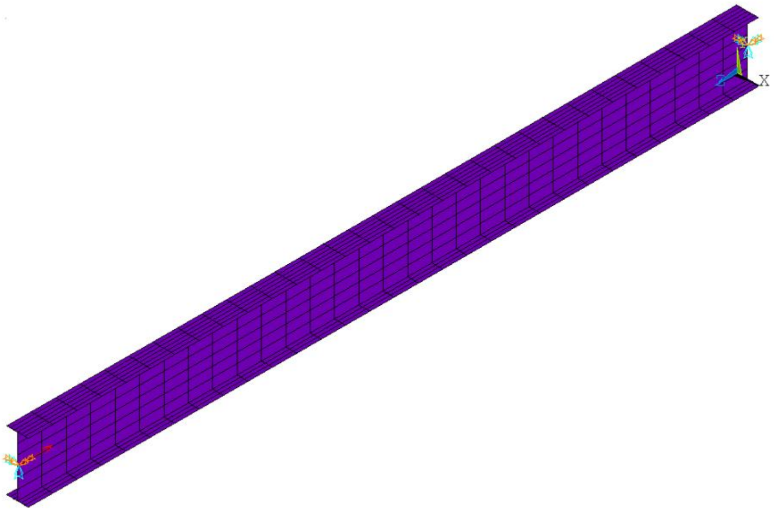

Figure 2. Shell finite element mesh and boundary conditions (ANSYS)

Figure 3 presents the evaluated critical temperatures of steel members using ANSYS versus the utilization ratio for various slenderness values. The critical temperature decreases almost linearly with increasing utilization factors for all slenderness levels. For W14x22 columns, the slenderness has a minor impact on the critical temperature at the same utilization factor. For W14x90 columns, a larger scatter was observed in critical temperatures at utilization factors greater than 0.4.

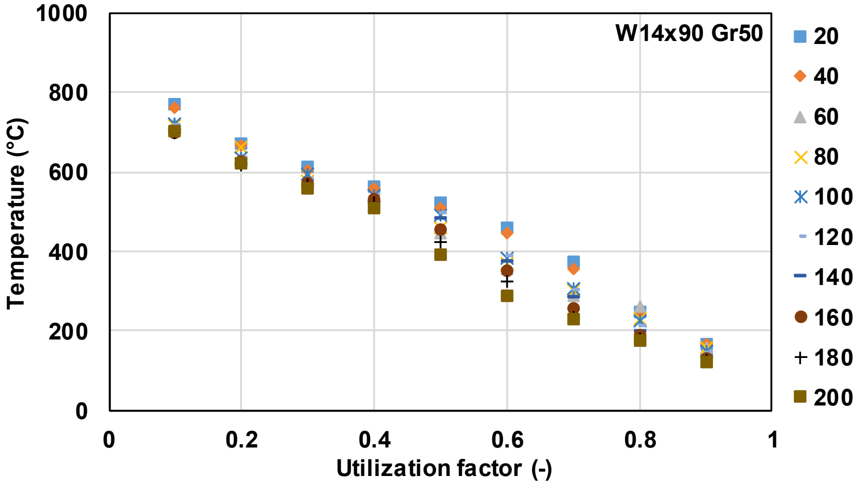

Figure 3. Critical temperature versus the utilization factor for various slenderness values using ANSYS

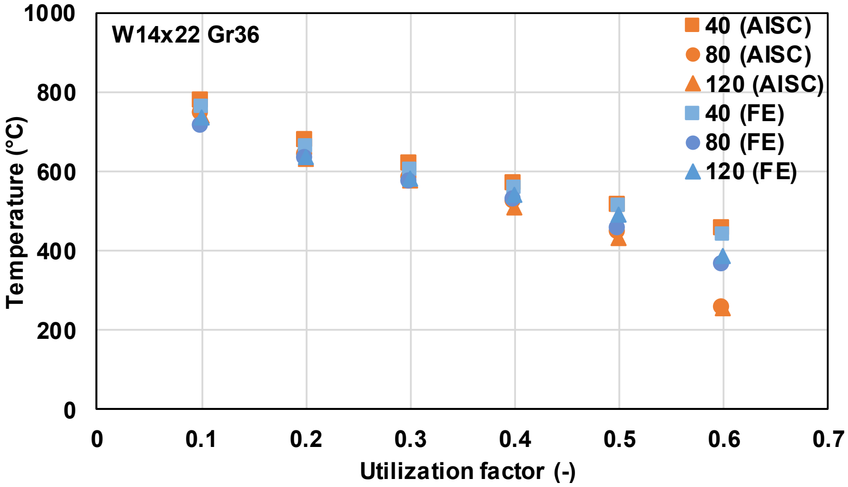
4. Critical temperatures of steel members using ANSI/AISC-360 Appendix 4 versus finite element analysis

Figure 4 shows a comparison of the computed critical temperatures using ANSI/AISC-360 Appendix 4 versus those computed using ANSYS at practical ranges of utilization factors (0.1 to 0.6) (Moynihan and Allwood, 2014) for slenderness values of 40, 80 and 120. The largest difference between the two methods is as large as 50% for the utilization factor of 0.6. In all the other cases, the temperatures estimated using these two methods are similar (with differences less than 10 %). The standard uncertainties of the finite element model based on the mesh density study and time step influence on the results are around 2.5%.



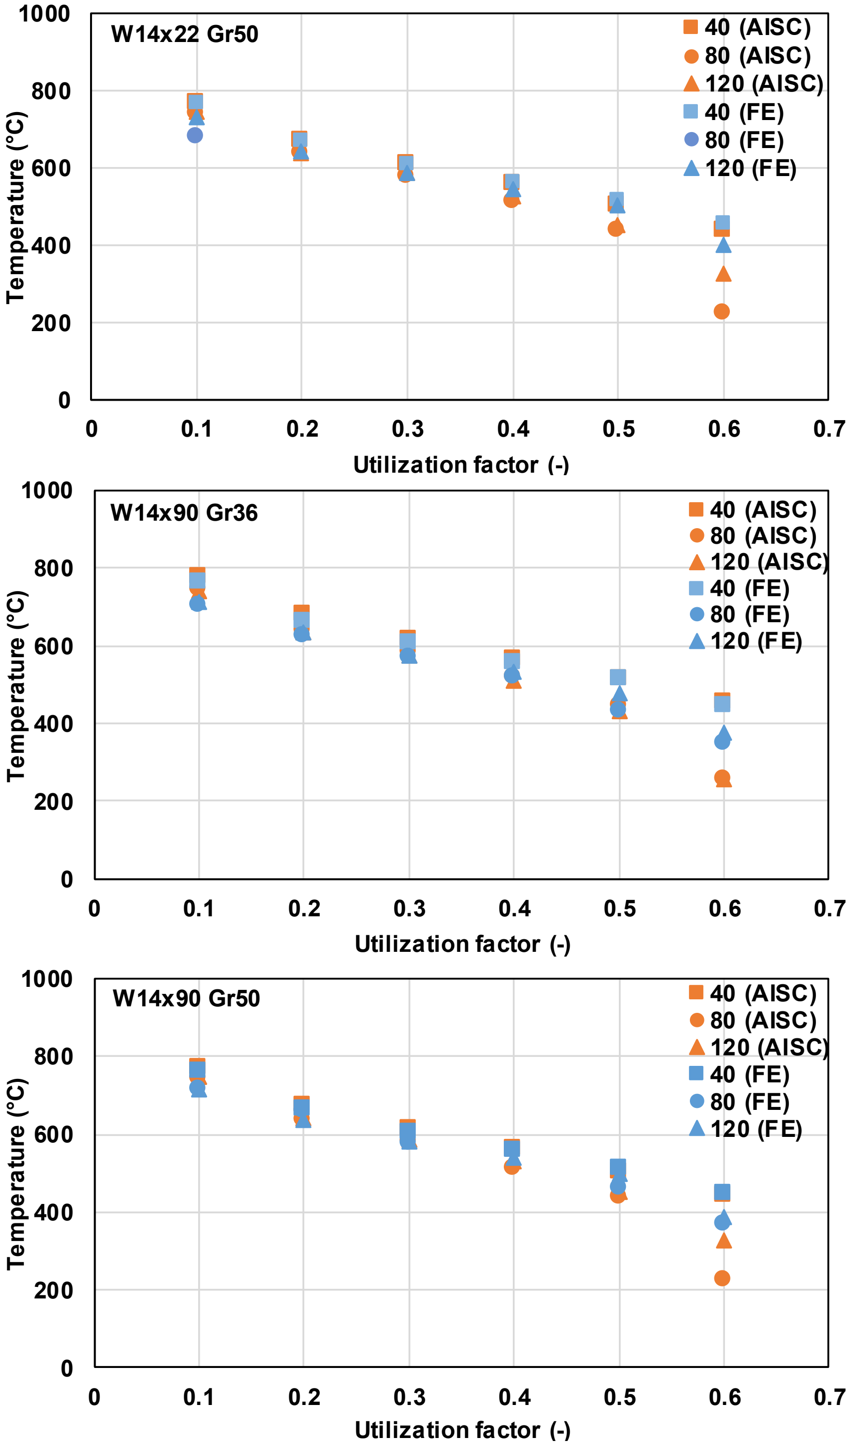


Figure 4: Comparison of critical temperatures versus the utilization factor for slenderness of 40, 80 and 120 based on AISC and ANSYS results

5. Closed formed equation for critical temperature

A closed formed equation for evaluating the critical temperature of steel columns was developed based on the results from the finite element analysis. The considered data were the ones with utilization factors less than 0.6 and temperatures above 400 °C. That is because in practice, (i) the utilization ratio of the columns is between 0.2 and 0.6 (Moynihan, M., C., and Allwood, 2014), and (ii) the degradation of the yield strength of the steel at elevated temperatures starts at 400 °C (Table A-4.2.1 of ANSI/AISC-360).

The critical temperature of steel columns is described in Eq. (10) and is a linear logarithmic function dependent upon the slenderness and the utilization ratio of the columns. The critical temperature equation was determined following the principles presented in the NIST/SEMATECH e-Handbook of Statistical Methods (http://www.itl.nist.gov/div898/handbook/). The standard error, the correlation coefficient (r) and the coefficient of determinations (r^2) are 21.20, 0.97 and 0.95 respectively.

The difference between the critical temperatures estimated using Eq. (10) and the finite element model is below 5% for utilization factors up to 0.4. The maximum difference of 14% occurred at a utilization factor of 0.5 and slenderness of 80.

$$T(°C) = 465.1 + 16.7ln\frac{r}{L_c} + 150.9ln\frac{F_{cr}}{F_{cr}(T)} \tag{10}$$

Figure 5 presents the 3D curve fitting of the data.

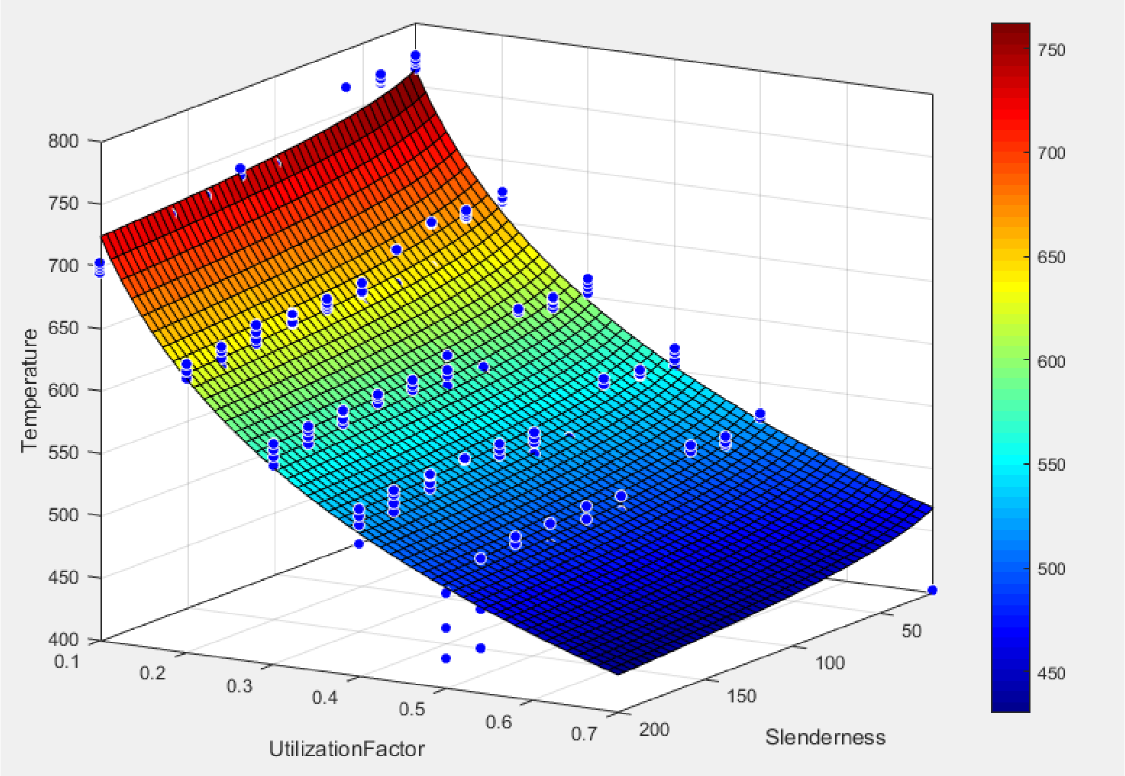

Figure 5: Curve fitting of the data

The proposed equation assumes that all columns cross-sections are uniformly heated, and the boundary conditions are simply supported. The proposed equation was compared with the British National Annex and the results showed differences under 10 %. Ongoing work expands this study, and includes a larger variety of cross-sections, material properties, and boundary conditions.

6. Summary and conclusions

Critical temperatures of steel columns were evaluated using both ANSI/AISC-360 Appendix 4 equations and ANSYS finite element analysis. Both methods yielded similar critical temperatures for utilization ratios less than 0.6. The parametric study shows that for utilization ratios less than 0.6, the impact of member slenderness and steel grades on the critical temperature is deemed small. For cases with a degree of utilization of 0.6 or higher, however, it is recommended to use finite element analysis. A closed form equation presented in this paper can also be used to estimate the critical temperatures of simply supported steel columns as a function of the member slenderness and the utilization ratio (below 0.6). Future work is needed to evaluate a larger range of section types, of material properties and boundary conditions.

Dynamic Compressive Tests of Alumina Dumbbells Using a Spherical Joint

Steven Mates[1], Richard Rhorer[2] and George Quinn[1]
[1]National Institute of Standards and Technology, 100 Bureau Drive, Gaithersburg, MD, USA
[2]Rhorer Precision Engineering, Gaithersburg, MD, USA

ABSTRACT

The dynamic compressive strength of ceramic armor materials is difficult to obtain experimentally due to the sensitivity of fracture strength to even small misalignments and end and surface effects. In this work we introduce a spherical joint into a compression Kolsky bar to investigate whether the joint can alleviate bending stresses due to minor misalignment in compression tests on alumina dumbbell specimens. Tests are conducted both with and without the spherical joint, and high-speed (75 000 frames/s) three-dimensional Digital Image Correlation (3D DIC) is used to measure both the strain field on the dumbbell specimen and motion, if any, in the spherical joint. Results indicate that the spherical joint is extremely sensitive to eccentric loading and in most cases increases rather than decreases the bending stresses in the test, leading to lower apparent fracture strengths.

KEY WORDS: Kolsky Bar, Dynamic Fracture Strength, Dumbbell Specimens, 3D DIC, High-Speed Video

INTRODUCTION

The design of ceramic armor systems requires precise knowledge of the dynamic mechanical behavior of the ceramic armor materials, including dynamic compressive fracture strength, which is typically measured using a Split Hopkinson Pressure Bar, or Kolsky Bar (1). The fracture strength of brittle materials is very difficult to measure accurately because of the extreme sensitivity of the test results to mechanical alignment, and to end and surface effects. Researchers at the U.S. Army Research, Development and Engineering Command (RDECOM) have developed a dumbbell-shaped specimen to avoid premature fracture from end splitting due to tensile stresses developed during elastic punching, lateral strain mismatches, and/or friction that can occur when simple cylindrical specimens are used. As part of this research effort, the US Army RDECOM organized a limited round robin test effort involving three laboratories. In this paper we report on the testing performed at National Institute of Standards and Technology (NIST) as part of the limited round robin.

Because dumbbell specimens often have much larger aspect ratios compared to usually short cylindrical or cubic specimens used for dynamic testing, they might be susceptible to premature failure from bending. Alignment of the Kolsky bar interface is therefore crucial if bending is to be minimized during dynamic compression testing of dumbbell specimens. Alignment quality is usually checked by doing Kolsky bar tests with no sample and with the bar ends pressed tightly together. Perfect alignment results in complete transmission of the elastic loading pulse and no reflected pulse. While this condition is achievable in practice, in the present study we investigated whether bending stresses caused by small misalignment of the interface could allow large axial loads to be transmitted while minimizing bending in a dynamic compression test of a ceramic dumbbell specimen.

The present study compares fracture strength experiments performed with and without a spherical joint. The joint consists of a precisely-machined spherical interface placed on the transmission side of the specimen in Kolsky bar test. High-speed, three-dimensional digital image correlation (3D DIC) is used to measure the motion of the specimen and the platens during testing. From these measurements, specimen rotation is measured by comparing displacement vectors of the cylindrical ends of the dumbbell specimens with the original specimen axis. If the specimen rotates during the test, bending stresses are likely. The rotation observed in the DIC data are correlated to the apparent fracture strengths. Finally, the effect of the spherical joint on both rotation and apparent fracture stress is determined by comparing the results against similar experiments without the spherical joint.

Rhorer, Richard; Quinn, George; Mates, Steven P. ”Dynamic Compression Tests of Alumina Dumbbells Using a Spherical Joint.” Paper presented at Society for Experimental Mechanics 2019 Annual Meeting, Reno, NV, US. June 03, 2019 - June 06, 2019.

EXPERIMENTAL

Specimens provided by the US Army RDECOM were manufactured according to the specifications shown in Fig. 1. The test material was Coorstek[1] CAP3 alumina with a nominal Young's modulus of 370 GPa and a nominal compressive fracture strength of 5 GPa.

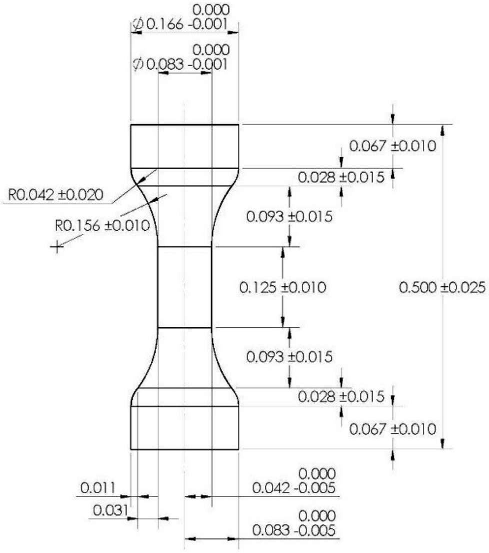

Fig. 1. Fabrication drawing for alumina dumbbell compression specimens. Dimensions in inches.

The NIST compression Kolsky Bar is pictured in Fig. 2 along with the results of a bar-to-bar test showing a small first reflection, indicative of imperfect interface alignment. Dimensions of the NIST Kolsky bar are given in Table 1 along with bar material properties and the longitudinal elastic wave speed in the bars. The Kolsky bar test was designed to fracture the samples in a single strike with a constant strain rate. For test design purposes, the breaking stress of this material was assumed to be 5 GPa, such that the fracture load of the specimens is estimated to be 17.8 kN. The fracture strain is estimated to be 0.0135 based on this fracture load and the nominal Young's modulus of 370 GPa. To break the sample, the striker length and impact velocity is selected to exceed both the peak load and the fracture strain. Based on a limited number of trials, a 203 mm long maraging steel striker bar (15 mm diameter) with an impact velocity of 9.9 m/s ± 0.1 m/s (± here is 2 standard deviations) were found to produce an adequate loading pulse. To achieve a constant strain rate, a ramped input pulse is created, following the recommendation in (1), with an annealed copper pulse shaper measuring 4.64 mm in diameter and 1.59 mm thick. Kolsky bar strain pulses are measured using dual 1000 Ω metal foil strain gages, one pair on each bar, located approximately midway along each bar. The strain gage bridge circuits are powered by a 24 V battery and the output is recorded at 2 MHz with a (14-bit) storage oscilloscope.

To protect the maraging steel bar ends from being damaged by ceramic fracture debris, square-shaped tungsten-carbide (WC) tool inserts (12 mm square by 3.22 mm thick) were placed on either side of the specimen as sacrificial protective elements. The WC tool inserts provided flat, hard surfaces that were well matched to the bar diameter. In some tests, round WC platens with stainless steel confining rings (12 mm diameter by 3 mm thick, impedance matched to the bars), leftover from previous studies, were used instead.

[1] Certain commercial equipment, instruments, or materials are identified in this paper to specify the experimental procedure adequately. Such identification is not intended to imply recommendation or endorsement by the National Institute of Standards and Technology, nor is it intended to imply that the materials or equipment identified are necessarily the best available for the purpose.

The spherical joint was constructed of 15 mm OD maraging steel. The mating surfaces, which were well matched and polished, had a radius of curvature of 17 mm, and the thickness of each piece was approximately 3 mm. The joint was placed directly behind the WC platen on the transmission side of the sample. The setup involving the spherical joints and a combination of square and round WC plates is shown in Fig. 3 (a). Interfaces between the bars and the spherical joint and WC platens were lubricated with heavy grease and the assembly was kept aligned with a small compressive force provided by elastic bands fixed between the bar and the bearing holders using capstan-style connectors.

Table 1. NIST Kolsky bar dimensions and materials.

Element	Quantity	Unit
Incident and Transmission Bar Length	1.5	m
Incident, Transmission & Striker Bar Diameter	0.015	m
Striker Bar Length	0.203	m
Bar Material	Maraging Steel (Un-Hardened)	
Bar Modulus	170	GPa
Bar Wave Speed	4600	m/s

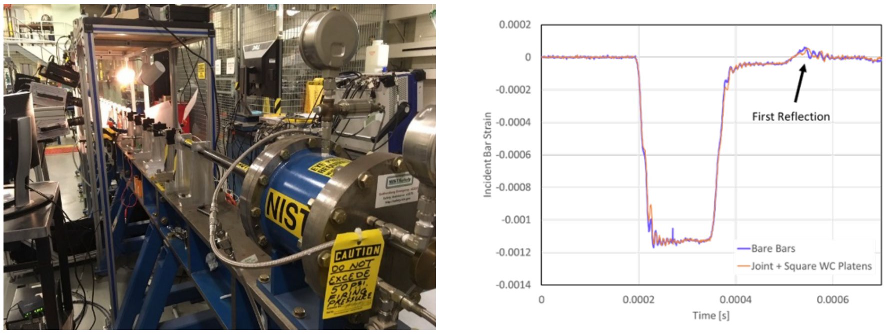

Fig. 2. Picture of the NIST compression Kolsky bar (left) and bar-to-bar test showing small first reflection indicative of imperfect interface alignment (right).

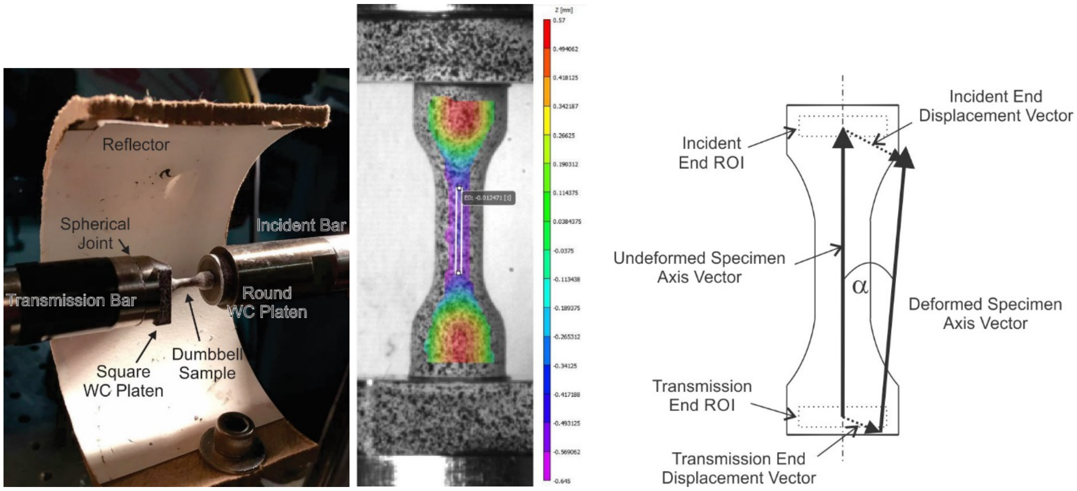
The imaging setup is pictured in Fig. **3** (a). Twin Photron SA1 high speed digital cameras with 90 mm macro lenses were used for 3D DIC measurements as well as to determine when and where the sample fails by videography. The lens apertures were set to the lowest setting (f/32) to maximize the image depth-of-field. The frame rate was 75 000 frames per second with a pixel resolution of 128 pixels by 352 pixels, and the exposure time was reduced to 1.76 µs using an electronic shutter on the cameras to eliminate motion blur prior to fracture. The geometric field of view was approximately 7.8 mm by 21.4 mm (about 16 pixels per mm), and the minimum object resolution, determined by the 1951 Air Force target method, was determined to be 0.0625 mm, indicating sharp focus. Illumination was provided by a single Photogenic PL2500 DR flash unit (871 W-s output over 0.001 s) positioned above the camera pair. A semi-circular diffuse reflector was added to improve illumination on the bottom side of the specimen and to provide a light background for the high-speed movies.

A sample DIC image is shown in Fig. 3 (b). Black speckles are produced on the while alumina sample using a fine, disperse spray of flat black spray paint. The included angle of the DIC cameras was 24 ° ± 2 °, and the working distance was 250 mm ± 25 mm. DIC measurements were obtained using Vic-3D from Correlated Solutions, with 15 pixel (0.94 mm) correlation windows (subsets) and a 3 pixel (0.19 mm) overlap. Correlations were determined using Gaussian subset weights with an optimized 6 tap interpolation scheme with normalized squared differences as the correlation criterion, according to the software settings. As this figure shows, the correlation region on the gage region is quite narrow, due to the high curvature of the specimen. Because of the limited number of DIC subsets available in the gage section, DIC measurements of sample strain in the gage section were obtained using the "virtual strain gage" method available in Vic-3D, which simply measures the relative displacement between two correlated subsets chosen along the gage section. The virtual gage is superimposed on the DIC image in Fig. 3 (b). The gage length in this example is 3.18 mm (51 pixels). The noise error for DIC displacement measurements, based on a set of 12 consecutive still images obtained under conditions identical to the real measurements, is a maximum of 1 µm and



(a) (b) (c)

Fig. 3. Sample, WC platens, spherical joint and reflector (a), DIC image of ceramic dumbbell showing correlation region and virtual gage used for strain measurement (b), and vector definitions for axis misorientation angle measurements (c).

is dominated by the out-of-plane displacement component. The noise is quite small compared to the typical maximum displacement measured prior to fracture (300 µm for the incident bell end, 160 µm for the trans bell end). Possible bias errors were not explored but are assumed to be small. The DIC parameters reported here are in partial fulfillment of the requirements laid out in the DIC Good Practice Guide (2).

RESULTS

Spherical Joint Tests with Ductile Metals

Experiments were conducted to ensure that the spherical joint and the WC protective platens did not introduce significant disturbance of the strain waves that might influence the data analysis in compression tests performed on actual samples. Previously, it was shown in bar-to-bar tests that the spherical joint and platens did not alter the wave transmission compared to tests without it (Fig. 2, right). Compression tests with and without the spherical joint and platens were conducted on samples of a brass alloy (26000) and on Ti-6Al-4V. Results of these tests are shown in Fig. 4. The results show that the presence of the additional elements does not change the stress-strain result for either material. We note that in these tests, the striker bar length and velocities were not identical, which caused the difference in total strains during the tests as evident in the figure. Regardless, the data agree quite well where they overlap in strain, indicating no significant disturbance of the waves through the joint and platens.

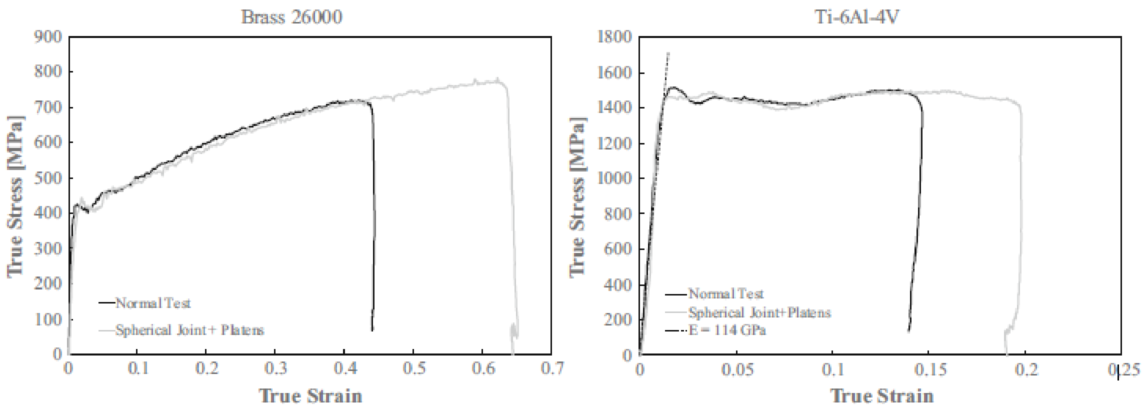


Fig. 4. Brass 26000 (left) and Ti-6Al-4V (right) measurements with and without spherical joint and WC platens. A nominal value of Young's Modulus (E) is plotted for Ti-6Al-4V for comparison with the data.

Alumina Dumbbell Compression Tests

The dynamic stress-strain response of the dumbbell samples is determined from the usual Kolsky bar strain wave analysis technique but with an adjustment to account for the strain concentration in the gage section of the dumbbell due to the reduced cross-sectional area there. Fig. 5 compares the strain-time data obtained from the adjusted wave analysis with DIC measurements directly on the gage section. Also shown in the figure is the platen strain, which is the overall dumbbell strain as determined from the measured displacements of the WC platens from DIC data. The DIC measurements indicated the gage strain is 1.4 times higher than the overall dumbbell strain due to the reduced cross-sectional area. In the case shown in Fig. 5, the adjusted wave strain is slightly higher than the adjusted platen strain, but the difference is within experimental uncertainty.

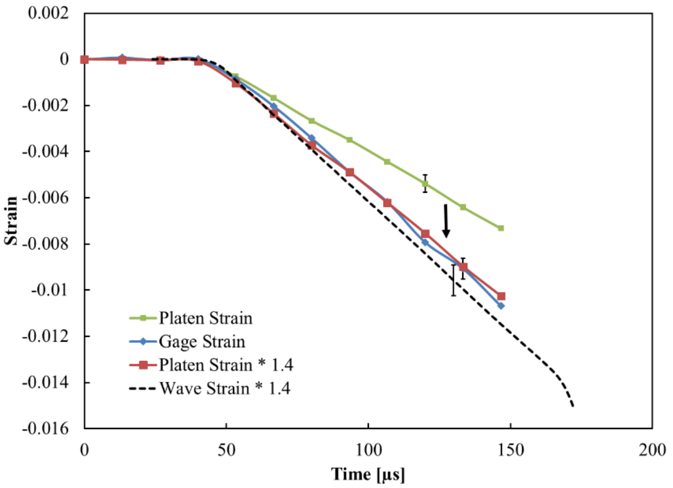

Fig. 5. Comparison of DIC Gage Strain (using the virtual gage method) with the overall strain of the dumbbell (Platen Strain from DIC-measured platen displacements), and the resulting correction factor of 1.4 applied to the Platen Strain data and the Wave Strain data. Error bars are determined using random error propagation and represent a coverage factor of 1.

Kolsky bar strain wave data showing the raw strain waves, equilibrium, strain-rate versus time and the stress-strain response for a dumbbell compression test that is considered valid (little obvious rotation observed from videography) are shown in Fig. 6. The apparent fracture stress, σ_{frac}, is determined from the peak load obtained from the Kolsky bar transmitted strain (ε_{frac}), and is determined from the following equation:

$$\sigma_{frac} = \frac{P_{frac}}{A_{gage}} = \frac{A_{bar}E_{bar}\varepsilon_{frac}}{\frac{\pi}{4}D_{gage}^{2}} \qquad (1)$$

P is load, E is Young's modulus, A is area. Subscript *gage* denotes dumbbell gage section properties, and *bar* denotes Kolsky bar properties. The uncertainty budget for the measurement of apparent fracture stress is given in Table 2, with the last entry being the calculated fractional uncertainty of the apparent fracture stress, considering independent, random error propagation. We note the apparent fracture stress uses the original cross-sectional area of the specimen, so it does not account for lateral expansion of the gage section due to Poisson effects.

Table 2. Uncertainty budget for fracture stress. Coverage factor = 1. δ denotes uncertainty.

Quantity	Uncertainty (Coverage Factor = 1)
$\delta A_{bar}/A_{bar}$	0.007
$\delta E_{bar}/E_{bar}$	0.012
$\delta\varepsilon_{frac}/\varepsilon_{frac}$	0.013
$\delta D_{gage}/D_{gage}$	0.004
$\delta\sigma_{frac}/\sigma_{frac}$	0.02

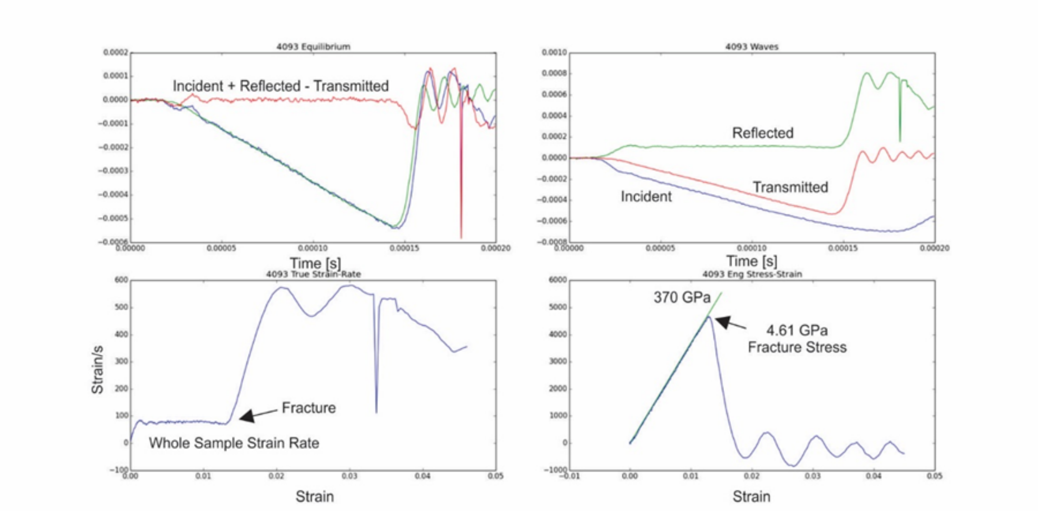

Fig. 6 Strain wave data from a dumbbell test that is considered valid. Upper left: comparison of incident, reflected and transmitted waves as a function of time. Upper right: raw incident, reflected and transmitted waves. Ordinate values of both plots in volts. Lower left: strain rate versus strain of the whole dumbbell sample, which is lower than the strain rate in the gage section by a factor of 1.4. Lower right: engineering stress-strain curve up to fracture (ordinate values in MPa).

Table 3 lists the results of the eight experiments where DIC data were available. Four tests used the spherical joint with WC platens and four tests used only WC platens. As the table shows, the apparent fracture stresses are generally lower when the spherical joint was employed, indicating that, rather than improving the test quality, the spherical joint actually makes things worse. Visual inspection of the high-speed movies revealed that the spherical joint appears to cause more significant rotation (bending) in the sample because of rotation in the joint. Fracture

strains, determined from the wave strain at fracture adjusted by the factor 1.4, are also listed in Table 3. A bias error in these strains is likely due to possible bending in the dumbbells during loading. Angles of rotation α are determined from DIC displacement data are also listed in Table 3, and their calculation is described below.

DIC measurements were used to quantify the deviation from uni-axial kinematics by measuring a misorientation angle, α, between the initial specimen axis and its axis just before fracture, as defined in Fig. 3 (c) and computed from the dot product of the two position vectors. Kinematically, in a uni-axial compression test of a dumbbell specimen, the axis of the dumbbell should remain parallel to the initial axis. If this is not the case, then the specimen is rotating and/or bending. Because the specimen is quite stiff, the amount of rotation and bending will be very small, even if bending stresses are high. As such, measuring rotation and/or bending requires very sensitive DIC displacement measurements. To examine whether rotation can be detected in our data, we compare the misorientation angle α with the apparent fracture stress, with the hypothesis being that the more the specimen rotates during the test, the larger the bending stress is likely to be, so that fracture strength should show a negative correlation with α (higher fracture stresses for lower misorientation angles). In addition, we expect, based on the visual assessment, that α will be larger for tests with the spherical joint compared to tests without the joint. Misorientation angles are reported in Table 3 just prior to fracture. The angles are quite small, as expected due to the high stiffness of the specimen and the Kolsky bar. While a random error analysis indicates that the uncertainty of the misorientation angle measurement is about two thousandths of a degree in the present case (based on the measured displacement noise components), bias errors have not been investigated, and a more thorough evaluation of the uncertainty magnitude is needed, for example using a very precise rotation stage. However, the results show larger misorientation angles when the spherical joint is used, confirming the earlier qualitative videography results. Further, as Fig. 7 shows, the apparent fracture stress increases as the misorientation angle decreases, which is also in-line with expectations. These results suggest that sensitive 3D DIC measurements may be able to provide useful information about the quality of a dynamic ceramic dumbbell compression test by measuring the degree of misorientation (bending) during the test. The simple misorientation analysis used here was motivated by the limited spatial and temporal resolution of the cameras on-hand; more advanced high-speed cameras with greater resolution at higher frame rates could provide other means to quantify bending, including a more accurate measure of the distortion of the dumbbell during loading and a more detailed measurement of the state of surface strain in the gage section. If bias sources can be more thoroughly quantified, a more definitive outlook on the usefulness of 3D DIC for improving the accuracy of dynamic compressive strength measurements of ceramic dumbbells can be made. The advantage of 3D DIC is rooted in the ability to measure out-of-plane displacements, which 2D DIC cannot provide. This capability could be used to guide the alignment of the Kolsky bar interface with dumbbell tests taken not quite to fracture, so allowing one to measure misorientation under load, saving valuable specimens until the bending is reduced to acceptable levels (possibly zero). The technique could also identify which fracture tests suffer from significant bending and should be discarded from the data set. Previously, the use of multiple gage-mounted strain gages has been suggested to monitor bending in dynamic compression tests on ceramics (1), although laboratories that already have access to very high-speed 3D DIC systems may consider using this optical method instead.

CONCLUSIONS

NIST's participation in a mini round robin involving dynamic fracture tests on dumbbell-shaped ceramic specimens has been described. A spherical joint was placed on the transmission side of the specimen to reduce bending loads on the specimen due to minor bar misalignment and thereby obtain more accurate fracture data. Instead, the joint resulted in lower apparent fracture strengths compared to tests performed without a joint. 3D DIC measurements of the specimen motion during testing showed a correlation between the amount of deviation from uni-axial kinematics and fracture strength, pointing to the possible usefulness of 3D DIC to monitor dynamic fracture test quality and improve overall test results by identifying invalid tests.

ACKNOWLEDGEMENTS

Dr. Jeffrey Swab, US Army RDECOM, for inviting us to participate in the round robin and for valuable discussions.

***Abstract*— We evaluate a method for estimating and removing local oscillator cable drift in transmission measurements using a network analyzer. The geometric mean of the measured forward and reverse transmission, including drift, can be used to estimate the actual transmission without drift. This requires the measurement of passive, symmetrical transmission measured with a bi-directional two-port remote-mixing down-converting measurement system. This method is being used in antenna measurements where cable movement is unavoidable. It is viable for other calibrations and measurements using remote-mixing systems and frequency extenders at higher frequencies.**

Keywords*— *antenna measurement; calibration; drift; local oscillator; network analyzer

I. Introduction

A method has been shown to effectively remove the phase effects of local oscillator (LO) cable drift from remote-mixing vector network analyzer (VNA) measurements [1]. We present the circuit basis for extending this analysis for correcting complex, amplitude and phase, LO drift in measurements [2].

Characterizations of antennas (gain-extrapolation, polarization, and patterns) require antenna movement. Cable drift and movement are direct contributors to errors and increased measurement uncertainties [1-3]. These adverse effects become more significant with increasing frequency and electrical cable length, so frequency conversion is often used to minimize the effect of loss, and cable stress [1,4,5].

Transmitting the signal at the operating radio frequency (RF) though long cables can have large dynamic-range-limiting losses and induce large phase errors which may be both temperature and movement dependent [6]. A reference at lower LO frequency is used to down-convert the higher test RF to a lower intermediate frequency (IF). This lower frequency LO reference and IF measurement can travel farther with better fidelity.

The downside of this approach is that using a remote LO creates a non-linear dependence between LO drift and the desired signal measurement. Ideally, keeping the LO drift small minimizes these errors. Complex systems have been built to measure and compensate for RF, LO and IF drift, which have dramatically reduced these effects [4]. Rather than treating LO drift as a random uncertainty, we estimate it through measurements [1,3,7]. We present a simple method using the geometric mean of forward and reverse measurements through a reciprocal system to estimate actual transmission.

II. Typical Antenna Measurements

Single direction measurement systems (i.e. only S_{21} or S_{12}) are typically used for antenna measurements as cost, speed and complexity are driving factors. Mixers and cabling for both directions can often be twice the cost, can add more hardware near the antenna (possibly increasing RF scattering) and may require more complex calibration to reduce systematic losses of the measurement system.

Fig. 1. shows several conventional RF setups used in antenna measurements. Fig. 1(a) depicts a common far-field range. Here differential changes in the LO feed network show up directly as differences in the measured IF signal. Fig. 1(b) shows no external frequency conversion. This can lead to excessive loss and RF amplitude phase changes due to the cabling, which become worse as frequency and/or range of movement increases. Fig. 1(c) depicts a single side down conversion. Fig. 1(d) shows a source and receiver conversion RF setup. The LO is split and may drift differently for the reference and antenna under test (AUT).

III. Dual-Direction Remote-Mixing

The National Institute of Standards and Technology (NIST) is using robotic systems to move antennas during the measurement of radiation characteristics from 1-500 GHz. To minimize cable transmission losses at higher frequencies and allow physical separation between the VNA and the antennas, we employ a remote-mixing, frequency-conversion scheme available from many manufacturers. Fig. 2(c) shows the signal

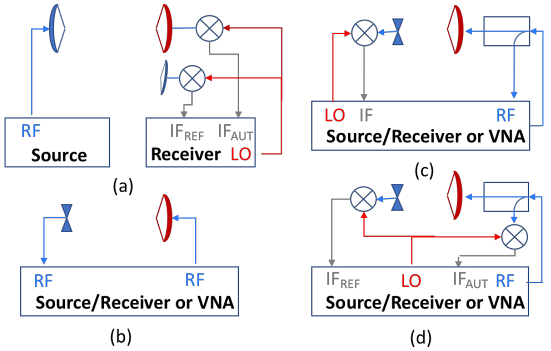

Figure 1. Typical single direction test setups used in antenna measurements. RF signal paths are shown in blue, LO reference paths are red, and IF signal paths are shown in gray.

Paper presented at 2019 Joint International Symposium on Electromagnetic Compatibility, Sapporo and Asia-Pacific International Symposium on Electromagnetic Compatibility (EMC Sapporo/APEMC), Sapporo, JP. June 03, 2019 - June 07, 2019.

block diagram of our measurement system. To determine the desired RF signal quantities, a_1, b_1, a_2, b_2, from the ideal VNA inputs, a_1', b_1', a_2', b_2', the error network, Fig. 2(a), needs to be characterized by a calibration. Large physical scans (>100λ) at these frequencies can stress cables that result in changes in receiver measurements not due to the actual antenna measurement. We will show that this is due largely to a mixer network which responds non-linearly to LO cable movement, Fig 2(b).

A. Assumptions, Limitations and Simplications

The major assumptions and limitations for the initial analysis are:

- Both directions are being measured and the antenna measurement is reciprocal, i.e. $S_{21}=S_{12}$. This limits the analysis for active antennas and usage of isolators/circulators.
- LO cable change is the dominant form of drift, i.e. we ignore thermal effects of the VNA or extender head.
- The IF cables are operating at a low enough frequency that amplitude and phase changes due to cable movement at IF can be ignored.
- The RF signal drift is removed by the ratioed S-parameter analysis.
- The system does not systematically change during the forward and reverse scattering parameter measurements. In practice, this is accomplished by limiting the movement of the antennas to no more than $\lambda_{RF}/50$ during the RF measurement.
- There is no movement/drift between the calibration plane and the antenna. This implies avoiding flexible connections between the frequency converter and the antenna. This drift effect can often be more significant than LO cable drift [3].

B. Signals to the Down-Converting Mixers

The standard error model for VNA calibration is dependent on a stable signal path between the test port and the VNA receivers. We assume the error networks in Fig. 2(c) are stable and the mixer networks transmit the coupler output signals, a_1', b_1', a_2', b_2', to the IF inputs of the VNA a_1'', b_1'', a_2'', b_2''.

We will propagate real-time signals from the coupler outputs through the mixer network to determine the effective loss and delay. The error network output signal, a_1', at the RF port of the mixer can be written as:

$$V_{A6}(t) = V_{RFa1}(t) = A_{a1}\sin(\omega_{RF}t + \phi_{a1}) \qquad (1)$$

Where ω_{RF} is the angular frequency of the RF test signal, t is time, and $A_{xi}$and ϕ_{xi} are the amplitude and phase of the signals impingent on the mixers for port i and wave direction x.

The LO signal at the port 1 frequency converter, A2, comes from source, A1, where it may be split and transmits through the LO cable to A2. The received LO signal at the frequency converter,$V_{A2}(t)$, is then sent to a limiting amplifier (depicted in Fig. 2(c) as a saturated amplifier and limiter) and typically filtered to reduce amplifier induced harmonics.

$$V_{A3}(t) = E_{lim1}(L_{LC1}A_{LO})\sin(\omega_{LO}t + \phi_{LO1} + \phi_{LC1} + \phi_{lim1}) \qquad (2)$$

where$L_{LC1}$and ϕ_{LC1}represent the LO cable loss and delay and $E_{lim1}(x)$ and ϕ_{lim1} are the amplitude transfer function and phase delay between the input to the frequency extender and the input to the *xn* LO up-converting mixer. The output of the up-converting mixer is split and sent to the down-converting mixers at A4, repented by:

$$V_{A4}(t) = C_{MUa1}E_{lim1}(L_{LC1}A_{LO}) \\ \sin[n(\omega_{LO}t + \phi_{LO1} + \phi_{LC1} + \phi_{lim1}) + \phi_{MUa1}] \qquad (3)$$

where C_{MUa1} and ϕ_{MUa1} represent the loss and phase delay, including the *xn* mixer's conversion and splitting loss, between the *xn* mixer and the input to the down-converting mixers. The *xn* mixer not only upconverts the LO frequency by a factor of *n*, but also multiplies any phase shifts after the mixer by the same factor.

The output of the down-converting mixer, A8, is the product of the two inputs to the mixer with a conversion loss:

$$V_{A8}(t) = \frac{C_{MDa1}A_{a1}C_{MUa1}E_{lim1}(L_{LC1}A_{LO})}{2} \qquad (4)$$
$$cos[(\omega_{RF} - n\omega_{LO})t - n(\phi_{LO1} + \phi_{LC1} + \phi_{lim1}) + \phi_{MUa1} \\ + \phi_{a1} + \phi_{MDa1}]$$

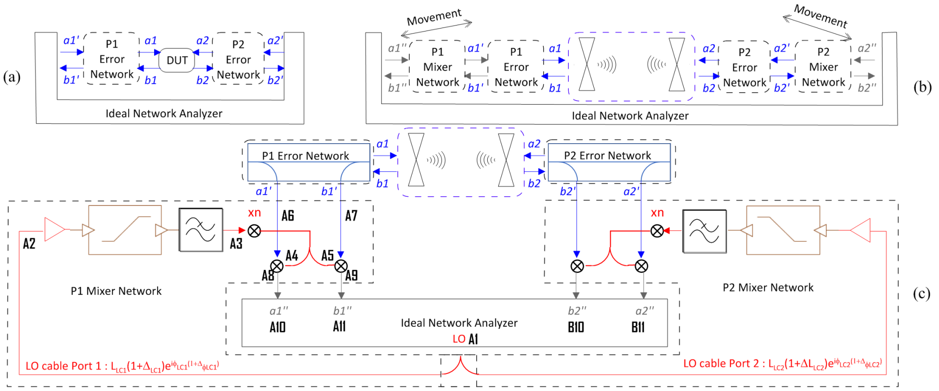

Figure 2. Block diagrams of the ideal VNA calibration with a static error network between the VNA and the test ports(a), (b) a changing error network due to movement such as during an antenna test, and (c) a signal flow model of the down-conversion to get the signal between the frequency extenders and the VNA.

Novotny, David. "Reducing Effects of LO Cable Movement in Antenna and Long Distance VNA Measurements." Paper presented at 2019 Joint International Symposium on Electromagnetic Compatibility, Sapporo and Asia-Pacific International Symposium on Electromagnetic Compatibility (EMC Sapporo/APEMC), Sapporo, JP. June 03, 2019 - June 07, 2019.

where C_{MDa1} and ϕ_{MDa1} are the mixer down-conversion loss and phase delay between A6 and A8. The upper mixing product, $(\omega_{RF} + n\omega_{LO})$, is filtered out by the mixer and the IF cabling leaving the IF signal $(\omega_{RF} - n\omega_{LO})$. The signal at A10 or the VNA receiver, a_1'', is the signal at A8 with the IF cable loss, L_{IFa1}, and phase delay, ϕ_{IFa1}, at the IF frequency.

$$V_{A10}(t) = a_1'' = \frac{L_{IFa1}C_{MDa1}A_{a1}C_{MUa1}E_{lim1}(L_{LC1}A_{LO})}{2} \\ cos[(\omega_{RF} - n\omega_{LO})t - n\phi_{LC1} + \phi_{a1} + \phi_{MUa1} + \phi_{MDa1} \\ + \phi_{IFa1}] \tag{5}$$

If we can assume thermal and mechanical stability except for the LO cable, and that at IF, the movement of the IF cables cause minimal change in complex loss, we can simply (5) to:

$$V_{A10}(t) = a_1'' = A_{a1}K_{a1}E_{lim1}(L_{LC1}A_{LO})\, cos[(\omega_{RF} - \\ n\omega_{LO})t - n\phi_{LC1} + \phi_{a1} + \phi_{Ka1}] \tag{6}$$

IV. How LO Changes Affect a Calibration

VNA calibration is accomplished by employing standards with “known” scattering parameters and measuring the response of the VNA with the attached error network and then removing the effects of the error network [8-10]. (6) shows a linear amplitude and phase relationship between the RF signal input and the VNA receivers as long as the LO cable stays constant. However, we see that LO cable changes in L_{LC1} and ϕ_{LC1} affect the relationship between a_1'' and a_1'.

A. Response Calibration

The simplest two-port error network characterization is using the response or “thru” calibration. The measurement ports are connected via a known transmission network, often a flush zero-loss device, and the source and transmission are measured relative to the“thru”.

To minimize notation, we can re-write (6) at the IF in amplitude and phase notation with the frequency suppressed:

$$\begin{aligned} a_1'' &= a_1'K_{a1}E_{lim1}(L_{LC1}A_{LO})\angle(-n\phi_{LC1} + \phi_{Ka1}) \\ b_1'' &= b_1'K_{b1}E_{lim1}(L_{LC1}A_{LO})\angle(-n\phi_{LC1} + \phi_{Kb1}) \\ a_2'' &= a_2'K_{a2}E_{lim2}(L_{LC2}A_{LO})\angle(-n\phi_{LC2} + \phi_{Ka2}) \\ b_2'' &= b_2'K_{b2}E_{lim2}(L_{LC2}A_{LO})\angle(-n\phi_{LC2} + \phi_{Kb2}) \quad . \end{aligned} \tag{7}$$

The reference value of the response calibration, with transmission $T\angle\phi_T$, is calculated at what is assumed to be the nominal state of the LO cables.

$$S_{21_{ref}} = \frac{b_2}{a_{1_{ref}}} = T\angle\phi_T = \frac{b_2''}{a_1''}_{ref} K_{21_{ref}} = \\ K_{21_{ref}} \frac{b_2'}{a_{1_{ref}}'} \frac{K_{b2}E_{lim2}(L_{LC2}A_{LO})\angle(-n\phi_{LC2}+\phi_{Kb2})}{K_{a1}E_{lim1}(L_{LC1}A_{LO})\angle(-n\phi_{LC1}+\phi_{Ka1})} \tag{8}$$

$$S_{12_{ref}} = \frac{b_2}{a_{1_{ref}}} = T\angle\phi_T = \frac{b_1''}{a_2''}_{ref} K_{12_{ref}} = \\ K_{12_{ref}} \frac{b_1'}{a_{2_{ref}}'} \frac{K_{b1}E_{lim1}(L_{LC1}A_{LO})\angle(-n\phi_{LC1}+\phi_{Kb1})}{K_{a2}E_{lim2}(L_{LC2}A_{LO})\angle(-n\phi_{LC2}+\phi_{Ka2})}$$

A calibrated response measurement can be made by solving for $K_{21_{ref}}$

$$K_{21_{ref}} = T\angle\phi_T / \left(\frac{b_2''}{a_1''}_{ref}\right), K_{12_{ref}} = T\angle\phi_T / \left(\frac{b_1''}{a_2''}_{ref}\right) \tag{9}$$

If a differential change is now added to the LO cables, as happens in moving antenna measurements, we see an amplitude and phase change (e.g. the port 1 LO cable transmission, $L_{LC1}\angle\phi_{LC1}$, becomes $L_{LC1}(1+\Delta_{LC1})\angle\phi_{LC1}(1+\Delta\phi_{LC1})$). This effects the single-direction measurement of S_{21}:

$$S_{21_{meas}} = \frac{b_2}{a_1} \sim \frac{b_2''}{a_1''} K_{21_{ref}} = \frac{b_2''}{a_1''} T\angle\phi_T / \left(\frac{b_2''}{a_1''}_{ref}\right) = \frac{b_2'}{a_1'} \\ \frac{K_{b2}E_{lim2}(L_{LC2}(1+\Delta_{LC2})A_{LO})\angle(-n\phi_{LC2}(1+\Delta\phi_{LC2})+\phi_{Kb2})}{K_{a1}E_{lim1}(L_{LC1}(1+\Delta_{LC1})A_{LO})\angle(-n\phi_{LC1}(1+\Delta\phi_{LC1})+\phi_{Ka1})} \\ T\angle\phi_T \frac{a_1'}{b_{2_{ref}}'} \left[\frac{K_{a1}E_{lim1}(L_{LC1}A_{LO})\angle(-n\phi_{LC1}+\phi_{Ka1})}{K_{b2}E_{lim2}(L_{LC2}A_{LO})\angle(-n\phi_{LC2}+\phi_{Kb2})}\right]. \tag{10}$$

If there are no changes in the LO cables, (10) reduces to the standard calibrated thru result. However, changes in either of the LO cables will directly translate into changes in the measured transmission: the standard side-effect of using a single-direction measurement. So, the measurement of just S_{21} or S_{12} using the VNA receivers may be compromised.

However, if we can assume that the antenna measurement is reciprocal, $S_{21} = S_{12}$, or $b_2/a_1 = b_1/a_2$, we can look at (10) and see that S_{12} has an inverse relationship with LO changes from S_{21}. If both directions are measured and the geometric mean of the results are taken, it can cancel out the LO drift effects:

$$\sqrt{S_{21_{meas}}S_{12_{meas}}} = \sqrt{\frac{b_2''}{a_1''}K_{21_{ref}} \frac{b_1''}{a_2''}K_{12_{ref}}} \\ = \sqrt{\frac{b_2''}{a_1''}\left(T/\left(\frac{b_2''}{a_1''}_{ref}\right)\right)\frac{b_1''}{a_2''}\left(T/\left(\frac{b_1''}{a_2''}_{ref}\right)\right)} = \left\{\frac{b_2'}{a_1'}\right. \\ \left[\frac{K_{b2}E_{lim2}(L_{LC2}(1+\Delta_{LC2})A_{LO})\angle(-n\phi_{LC2}(1+\Delta\phi_{LC2})+\phi_{Kb2})}{K_{a1}E_{lim1}(L_{LC1}(1+\Delta_{LC1})A_{LO})\angle(-n\phi_{LC1}(1+\Delta\phi_{LC1})+\phi_{Ka1})}\right] \\ T\angle\phi_T \frac{a_1'}{b_{2_{ref}}'} \left[\frac{K_{a1}E_{lim1}(L_{LC1}A_{LO})\angle(-n\phi_{LC1}+\phi_{Ka1})}{K_{b2}E_{lim2}(L_{LC2}A_{LO})\angle(-n\phi_{LC2}+\phi_{Kb2})}\right] \frac{b_1'}{a_2'}` \\ \left[\frac{K_{b1}E_{lim1}(L_{LC1}(1+\Delta_{LC1})A_{LO})\angle(-n\phi_{LC1}(1+\Delta\phi_{LC1})+\phi_{Kb1})}{K_{a2}E_{lim2}(L_{LC2}(1+\Delta_{LC2})A_{LO})\angle(-n\phi_{LC2}(1+\Delta\phi_{LC2})+\phi_{Ka2})}\right] \\ \left. T\angle\phi_T \frac{a_2'}{b_{1_{ref}}'} \frac{K_{a2}E_{lim1}(L_{LC2}A_{LO})\angle(-n\phi_{LC2}+\phi_{Ka2})}{K_{b1}E_{lim1}(L_{LC1}A_{LO})\angle(-n\phi_{LC1}+\phi_{Kb1})}\right\}^{\frac{1}{2}} \tag{11}$$

$$= \sqrt{\frac{b_2'}{a_1'}\left(T/\left(\frac{b_2'}{a_{1_{ref}}'}\right)\right)\frac{b_1'}{a_2'}\left(T/\left(\frac{b_1'}{a_{2_{ref}}'}\right)\right)} = \sqrt{\frac{b_2}{a_1}\frac{b_1}{a_2}} = \sqrt{S_{21}S_{12}} = S_{12} = S_{21}$$

B. Practial Implementation

Equation (11) shows that measured geometric mean of the forward and reverse measurements can be an estimate of the transmission through a passive, bi-directional, down-converting receiver setup. However, (11) has multiple solutions to the phase of the transmission signal [1]. If the net LO phase changes, $n(\Delta\phi_{LC1} - \Delta\phi_{LC2}) > \pi$, there can be an angle ambiguity, Fig. 3, because there are two solutions to square root in (11) that are separated by π. The correct branch can be found by keeping the movements small between RF measurements so to track the best branch, or by taking a broad frequency sweep so the correct solution can be chosen to keep the phase consistent.

Novotny, David. "Reducing Effects of LO Cable Movement in Antenna and Long Distance VNA Measurements." Paper presented at 2019 Joint International Symposium on Electromagnetic Compatibility, Sapporo and Asia-Pacific International Symposium on Electromagnetic Compatibility (EMC Sapporo/APEMC), Sapporo, JP. June 03, 2019 - June 07, 2019.

C. Reflection Measurments

Since reflection measurements use a single port, they only require one LO cable. Re-writing (11) for one-port results in:

$$S_{11} = \frac{b_1}{a_1} \propto \frac{b_1'}{a_1'} \frac{K_{a_1'} E_{limA}(L_{LOA} A_{LO}) \angle\left(-n\phi_{LOA} + \phi_{a_1'}\right)}{K_{b_1'} E_{limA}(L_{LOA} A_{LO}) \angle\left(-n\phi_{LOA} + \phi_{b_1'}\right)}. \quad (12)$$

(12) shows that the single-port scattering parameters are primarily dependent on one LO cable, so drift effects are normalized and reduced.

D. Other Calbration Methods

As the dominant term in the transmission error correction in most two-port calibrations is the transmission coefficient of the reference thru, a form of (10) is relevant in systems similar to Fig. 2(c). Estimating the transmission using $\sqrt{S_{21}S_{12}}$ with LO cable drift can be used for other two-port calibration methods such as TRL[9], SOLT, and “Unknown-Thru”[9]. A major advantage of using the “unknown-thru” in antenna measurements is that VNA calibrations can be done with the test antennas in place: this avoids the need for a mechanical-thru connection between the test ports, limiting port movement when measuring the standards during RF calibration.

V. Measured Data

We performed a two-port LRL calibration in WR-05 from 140-180 GHz. The *xn* up-conversion factor was 12 and the IF was set at 100 MHz. A power calibration was performed to ensure the LO was in the proper power range for the frequency converters. Fig 4. Shows the results viewing the flush-thru after calibration, so all data should be 0 dB and 0°. Moving the LO cable for each port shows minimal amplitude change but large phase changes. Using the measured $\sqrt{S_{21}S_{12}}$ to estimate S_{12} shows promise even when a 2-cm 2-dB pad is inserted into the LO line.

VI. Uncertainity Implications

The random sampling noise in $\sqrt{S_{21}S_{12}}$ has the potential to be larger than in S_{12} or S_{21}. So, for systems with small levels of LO stress this may increase uncertainty in the transmission results.

VII. Conclusion

The geometric mean of the measured forward and reverse transmission, in a system that has drift due to LO cable movement, can be used to estimate the actual drift-free transmission. This method requires a measurement of a passive and reciprocal system using a bi-directional remote down-converting receiver system. This method is especially useful when LO cable stresses are expected to be electrically large, as in antenna measurements and high-frequency measurements where movement of the test ports is much greater than a wavelength.

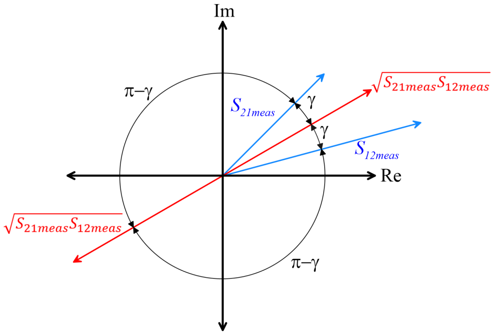

Figure 3. Geometric mean of the forward and reverse transmission measurement showing both solutions.

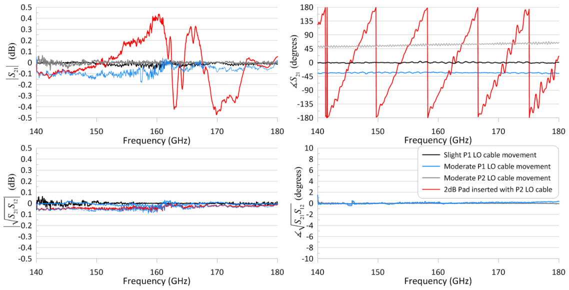

Figure 4. Transmission estimation of a flush thru using the measured $S_{21}$and $\sqrt{S_{21}S_{12}}$ with LO cable movement and inserting a 2 dB pad into the LO line. The majority of amplitude errors are reduced by the limiter in the converter, phase and residual amplitude errors are reduced by $\sqrt{S_{21}S_{12}}$.

***Abstract*—Previous work presented a theoretical model based on the implicit Bitcoin specification for how an entity might issue a protocol native cryptocurrency that mimics features of fiat currencies. Protocol native means that it is built into the blockchain platform itself and is not simply a token running on another platform. Novel to this work were mechanisms by which the issuing entity could manage the cryptocurrency but where their power was limited and transparency was enforced by the cryptocurrency being implemented using a publicly mined blockchain. In this work we demonstrate the feasibility of this theoretical model by implementing such a managed cryptocurrency architecture through forking the Bitcoin code base. We discovered that the theoretical model contains several vulnerabilities and security issues that needed to be mitigated. It also contains architectural features that presented significant implementation challenges; some aspects of the proposed changes to the Bitcoin specification were not practical or even workable. In this work we describe how we mitigated the security vulnerabilities and overcame the architectural hurdles to build a working prototype.**

***Index Terms*—Fiat Currency, Cryptocurrency, Bitcoin**

I. Introduction

The United States National Institute of Standards and Technology developed an architecture for a managed cryptocurrency that has many of the features of electronic fiat currencies and includes a governing entity [1]. It is intended to combine the strengths of both fiat currencies and cryptocurrencies. In doing this, it deviates from the goals of most cryptocurrencies by introducing concepts such as central banking, law enforcement, and identity proofed accounts. It also deviates from a government controlled fiat currency world in denying the currency administrator absolute power over financial controls. It enables a currency administrator to enact policy to create a specific cryptocurrency instance from the architecture, usually with immutable configurations that even the administrator cannot violate. This can promote public trust in the currency since the limits to the administrator's power are immutably recorded on the associated blockchain. The architecture uses a public permissionless blockchain approach whereby the administrator's actions are completely transparent. Furthermore, a public set of miners maintaining the blockchain can prevent the administrator from performing unauthorized actions. At the same time, the cryptocurrency is designed to prevent the public miners from taking control from the administrator or from preventing the administrator's transactions from being processed. This architecture thus creates a 'balance of power' between the administrator and the public miners. Additional features include adding role attributes to cryptocurrency acounts that represent fiat currency entities (e.g., commercial banks, central banks, and law enforcement) such that there is created a tree based hierarchy of nodes with roles for all users of the cryptocurrency.

A major limitation to the approach is that it was presented only as a theoretical architecture. It demonstrated what might be possible to create through modest forks to existing cryptocurrencies, specifically using Bitcoin [2] [3] [4] as an example. The empirical work was limited to proposing changes to the implicit Bitcoin specifications in [5] and [6] to add the features necessary for this 'balance of power' managed cryptocurrency approach. No code was developed and no implementation was tested. The ability of [1] to modify the Bitcoin specification to add the needed features indicated that a managed cryptocurrency might be able to be built through a modest fork of an existing cryptocurrency, but it lacked a proof-of-concept prototype built as a protocol native implementation.

In this work, we set out to build such a prototype as an applied research endeavor. We tested whether or not such a managed cryptocurrency system could be built through modest modifications to the code base of an existing cryptocurrency. In this way we explored how to create a protocol native managed cryptocurrency built into the blockchain platform itself and explore the advantages of this approach. This was non-trivial as we did not simply create a token on top of another cryptocurrency. We also wanted to see if this could be done efficiently, with only a modest amount of programming effort (we scoped using half a person year, in part due to resource constraints). We chose to use Bitcoin since [1] described their theoretical model through proposing changes to Bitcoin. We wanted to discover the complexity of modifying Bitcoin to require identity proofing of accounts, establish accounts with roles, enable law enforcement functions, enable central banking functions, and create and visualize a hierarchy tree of accounts that specifies the scope of control of the various management and law enforcement nodes.

An unattributed quote says that 'theory is when you know everything but nothing works.' Yogi Berra said, 'in theory there is no difference between theory and practice. But, in practice, there is.' We found these statements to be true with regard to our implementation of the theoretical work. We discovered that the theoretical model contains several

vulnerabilities and security issues that needed to be mitigated. It also contains architectural features that presented significant implementation challenges; some aspects of the proposed changes to the Bitcoin specification were not practical or even workable. We thus had to augment the material in [1] in order to achieve a functional and secure system, especially in areas such as preserving the balance of power, law enforcement powers, management node powers, bootstrapping the system, and the needed movement of accounts within the node hierarchy (e.g., when an account holder changes their account manager). We also encountered difficulties using the Bitcoin code base which necessitated design changes not foreseen in [1]. However, in the end we discovered that it was possible to modestly modify Bitcoin to implement this 'balance of power' managed cryptocurrency approach and to do it with a relatively low amount of programming effort.

In summary, we showed that the theoretical architecture provided by [1] works and can be implemented efficiently. However, we had to change, refine, and augment the original design in order to make it function. This paper describes these changes and the final prototype implementation which we have made publicly available on GitHub (any mention of commercial products is for information only; it does not imply recommendation or endorsement). Note that due to resource constraints, our prototype is not a full implementation. The largest limitation is that the cryptocurrency policy configuration is static, while the full design in [1] permits dynamic policy changes. While not all features were implemented, the core functionality was enabled to provide confidence that the system could be efficiently constructed.

The rest of this paper is organized as follows. Section II presents the theoretical architecture from [1] and discusses relevant Bitcoin architectural features. Section III discusses the vulnerabilities and security issues we discovered in the architecture. Section IV discusses the architectural hurdles that we had to overcome. Section V outlines how we created our prototype system and Section VI presents the related work. Section VII discusses our future plans for the system and Section VIII concludes.

II. Theoretical Architecture

The research in [1] provides an architecture that can be instantiated into a cryptocurrency instance through specifying a specific policy configuration. The policy parameters enable or disable feature sets while specifying parameters for cryptocurrency operation. The financially related parameters are just examples of what could be (e.g., limits on money production) and are not intended to be exhaustive given that the identification of financial controls is a related but separate research area. In this architecture, anyone can create an account, but an account cannot do anything unless it is granted one or more roles. The initial block on the blockchain has a 'genesis transaction' that grants roles to the root administrator account and all future role assignments spring from this initial root account. The root account grants roles to other accounts, and those accounts in turn may grant roles to accounts. This sets up a hierarchy of accounts in a tree structure with the root account (or node) being the most authoritative.

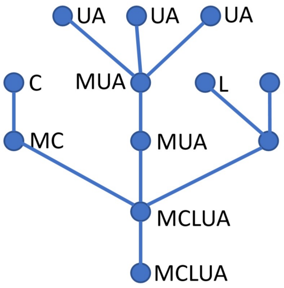

Fig. 1. Example Managed Cryptocurrency Hierarchy (from [1])

The initial root node is given all possible roles so that it can propagate these roles to other accounts. Of particular import is the 'M' currency manager role that enables an account to give its roles to other accounts (or withdraw granted roles) and to modify cryptocurrency policy. Other roles include 'U' user, 'A' account manager, 'C' central banker, and 'L' law enforcement. Their abilities are summarized in [1] as follows:

- 'The U role enables an account to receive and spend coins. An account for which the U role has been removed has its funds frozen.
- The A role enables a node to create accounts with the U role (and only the U role). It may also remove the U label for its descendants.
- The C role enables the creation of new coins (apart from the block mining rewards).
- The L role enables an account to forcibly move funds between accounts, to remove the U label, and to restore a previously removed U label. However, these actions can only be performed against nodes with the same or greater distance from the root.'

Note that in this model the currency administrator controls the root manager node and thus controls the privileges of all other nodes participating in the system. It can thus ensure that the A nodes perform identity proofing of U nodes (if desired). This can enable law enforcement, at least with a court order, to identify individuals within the system. This goes counter to the trend in cryptocurrencies where privacy and non-traceability are key objectives. An example node hierarchy tree with role assignments is shown in Figure 1.

There are three types of transactions that enable accounts with roles to perform their functions: coin transfer mode, role change mode, and policy change mode. A large portion of [1] specifies how to modify the nValue field in Bitcoin (which normally specifies the amount of coin to transfer) to enable the role and policy change functionality while still enabling coin transfer (but now only between accounts with the U role).

Lastly, there are two possible security models. There is an independent mining model where the miners are truly independent from the currency administrator, but they could then as a group deny the inclusion of management transactions (i.e., role changes and policy changes). This would be similar to a 51 % attack [7] being launched against Bitcoin. To prevent this there is also a dependent mining model where the miners must include a certain number of management transactions every so many blocks. This can prevent a large group of miners from being able to revolt and exclude management transactions as with the independent mining model. However, it shifts the balance of power slightly towards the currency administrator by allowing them to convey a small financial advantage to preferred miners. This risk can be arbitrarily diminished through making certain permanent policy settings.

The theoretical architecture defined in [1] proposed modifying Bitcoin for its implementation. The original Bitcoin whitepaper is available at [2] while detailed explanations can be found in [3], [4], and [5]. Of import to this work is that Bitcoin transfers coins using transactions. The coins are not stored in user accounts but are linked to the transactions themselves. Thus, each transaction has one or more inputs (Vin fields) that bring unspent coins into the transaction and one or more outputs (Vout fields) that declare who can next spend those coin outputs. As shown in Figure 2, a Vin field from some transaction x brings in an unspent Vout field from some transaction y. Figure 3 shows the format of a Bitcoin transaction.

III. Discovered Vulnerabilities and Security Issues

We discovered vulnerabilities and security issues in the theoretical architecture that needed to be mitigated in order to implement the prototype system. The vulnerabilities enabled violations of the balance of power, replay attacks, and attacks against miners. The security issues included improper scoping of manager and law enforcement powers as well as insecure bootstrapping for establishing cryptocurrency policy.

A. Preserving the Balance of Power

The research in [1] contains a 'dependent mining model' where the manager can specify that x number of management transactions must be included within each interval of y blocks. One can set x and y through issuing policy transactions. The idea is that this model forces the miners to periodically include management transactions.

However, we have discovered a vulnerability in which the manager can use this feature to take over the blockchain. The manager can initially set y to be high and wait for the community to fully adopt and use the cryptocurrency. Once a significant amount of value has been invested in the cryptocurrency, the manager can issue a policy transaction changing y to be very low. The manager then could, for example, require management transactions to be issued with every block and only send those management transactions to miners whom they favor or control. The miners receiving those transactions would then not propagate them to other miners, preventing the other miners from mining any blocks (since per policy all blocks would have to contain a management transaction). This way, only miners that the manager favored or controlled could publish blocks and the manager could effectively take over the blockchain with effects similar to that of a 51 % attack [8].

Our mitigation is to simply limit how tightly a manager can set y. If the specification and developed code reject policy transactions that set y values below some threshold, then the manager is prevented from using this method to take control of the blockchain. The manager could also voluntarily set a minimum threshold for these values using permanent policy transactions issued by the root manager node in order to create public confidence in the cryptocurrency. Even with minimums set, it should be noted that the manager can still implement this attack periodically, favoring their own miners every y blocks if they refuse to issue management transactions in the intervening blocks. This would give a periodic financial advantage to manager favored miners but would be highly visible to the community and would not result in the manager controlling the blockchain. To minimize the impact of this residual attack possibility, y should be required to be high enough to make the financial advantage minuscule. An alternative is to use the independent mining model discussed in II, but this opens up the possibility for the miners to revolt against the manager.

B. Preventing Replay Attacks

The research in [1] modifies the Bitcoin transactions to support roles because the architecture requires that all transactions include roles. They are brought into the transaction using a modified Vin field; in Bitcoin Vin fields are only used to bring coin into a transaction. Both uses of the Vin field use the same cryptographic protections and one would assume that they would inherit the same security properties. However, this is not the case and it results in a vulnerability in the architecture.

Since roles are spent like coins but never get used up (since you don't lose a role through using it), they can be spent an infinite number of times. This means that transactions that use a role might be able to be replayed. For the typical transactions also transferring coin (e.g., to pay a transaction fee), this is not a problem as the replayed transaction will be rejected because the coin would already have been spent. However, if the transaction does not involve coin it could be replayed. This might happen if the manager owns miners servers and issues management transactions without transaction fees with the intention that their miners will publish them. In this case, there would be no barriers to performing a replay attack. This might result in a situation where law enforcement unlocks an account but can never securely lock it again because the original unlocking transaction can be replayed by anyone.

There are several possible solutions. One approach is to require that all transactions pay some transaction fee while requiring transaction signatures to sign the entire transaction. In our attempt to modify Bitcoin as little as possible, our approach was to change the theoretical model to truly spend roles as if they were coin; once spent they can't be spent again. However, whenever we spend a role by including it in a Vin field we also re-create the same role in one of the Vout

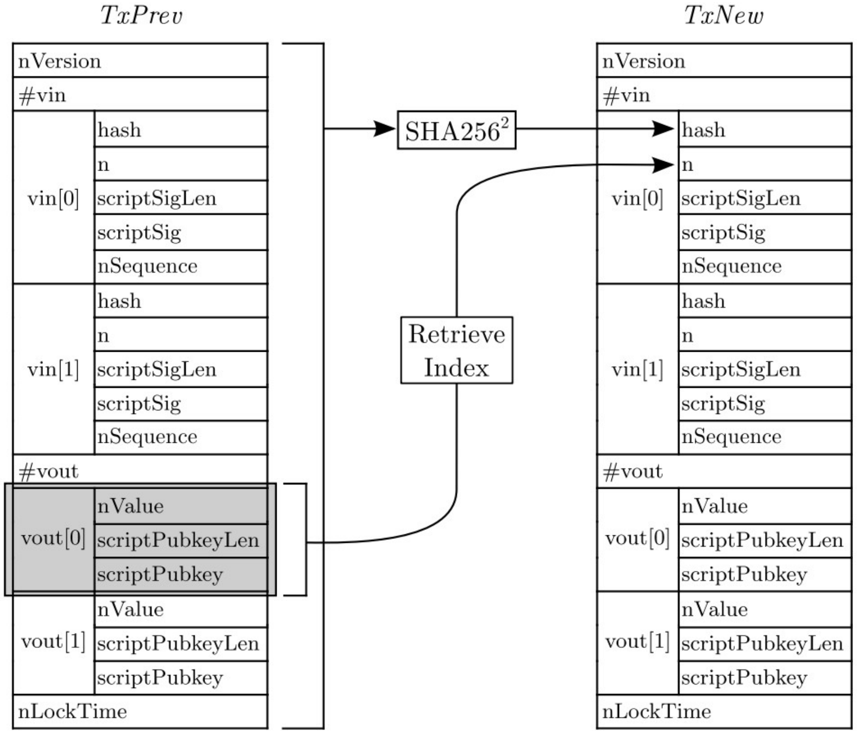

Fig. 2. Bitcoin Vin[] Field Reference to a Previous Transaction (copied from [5]).

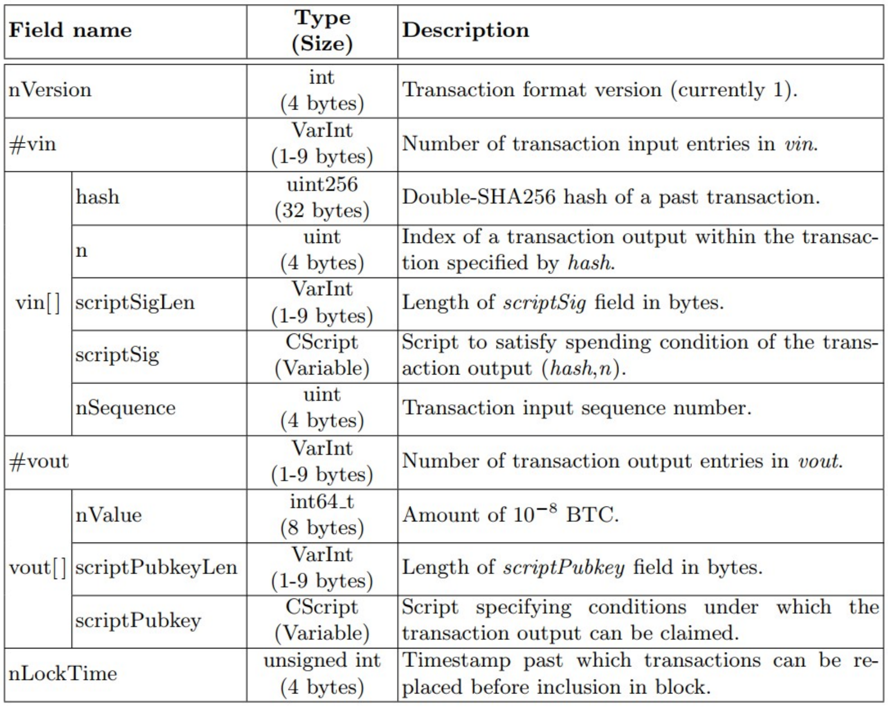

Field name		Type (Size)	Description
nVersion		int (4 bytes)	Transaction format version (currently 1).
#vin		VarInt (1-9 bytes)	Number of transaction input entries in *vin*.
vin[]	hash	uint256 (32 bytes)	Double-SHA256 hash of a past transaction.
	n	uint (4 bytes)	Index of a transaction output within the transaction specified by *hash*.
	scriptSigLen	VarInt (1-9 bytes)	Length of *scriptSig* field in bytes.
	scriptSig	CScript (Variable)	Script to satisfy spending condition of the transaction output (*hash*,*n*).
	nSequence	uint (4 bytes)	Transaction input sequence number.
#vout		VarInt (1-9 bytes)	Number of transaction output entries in *vout*.
vout[]	nValue	int64_t (8 bytes)	Amount of 10^{-8} BTC.
	scriptPubkeyLen	VarInt (1-9 bytes)	Length of *scriptPubkey* field in bytes.
	scriptPubkey	CScript (Variable)	Script specifying conditions under which the transaction output can be claimed.
nLockTime		unsigned int (4 bytes)	Timestamp past which transactions can be replaced before inclusion in block.

Fig. 3. Bitcoin Transaction Format for Sending Bitcoin (BTC), copied from [5].

fields. The effect is that an account keeps a role when it is spent but the transaction containing the active version of their role can change. Probably the most elegant approach would be to implement the architecture using a cryptocurrency with an accounts based model so that roles are not stored within transactions, but instead within a record associated with each account (discussed more below).

C. Preventing Managers from Attacking Miners

In [1] all accounts must have the U role for them to receive or spend coin. The purpose is to force all participants in the cryptocurrency to be identity proofed by an account manager in order to receive the U role. This in turn supports 'know your customer' laws, which have been a challenge for most cryptocurrencies [9]. However, this also creates a vulnerability. The manager could keep track of the accounts receiving block rewards and remove the U role from those accounts (thus freezing the funds). The public miners would then have no financial incentive to mine and then the manager's own mining servers could take over the majority of mining. This would give the manager the ability to launch a 51 % attack [8] and to a large degree control the blockchain.

Our solution is to enable miners to deposit block rewards into any account, regardless of whether or not it has been registered in the system or has any roles. Also, we handle the coin from these coinbase transactions (the mining reward transactions) specially such that it can be sent without the owning account needing the U role. This prevents the currency administrator from freezing the mining reward coinbase funds. However, once coinbase coin is sent away from the original account it becomes normal coin subject to the normal requirements (it can't be spent without the associated account having the U role).

D. Scoping Law Enforcement Powers

In [1] law enforcement powers are both too limited and too relaxed. They are too limited in that law enforcement can only lock accounts through removing the U label. Law enforcement nodes can't prevent an account using its other roles (M, C, A, or L). This is a major issue in the event that an account is stolen. On the other hand, law enforcement powers are too relaxed in that law enforcement nodes can effect any node higher in the account hierarchy tree regardless of whether or not it is on the same branch. This effectively gives law enforcement nodes a global reach (which is especially problematic if a law enforcement node is compromised).

Our solution is to reflect account locking not through the removal of the U role but by setting a locked flag. We use one of the unused bits in the nValue field for role change mode to set this flag. If the flag is set it temporarily disables all roles, not just the U role. This stops all activity by the targeted account, giving law enforcement the powers it needs to freeze stolen accounts. At the same time, we put additional restrictions on law enforcement nodes by only giving them authority over nodes farther from the root on the same branch of the node hierarchy tree. More precisely, we define the scope of control of a law enforcement node by traversing backwards until the first node is found with the manager role and then by performing a breadth first search to reveal all nodes within scope. This enables law enforcement nodes to 'hang' off of manager nodes in the tree (they don't have to be inline on each branch).

E. Management Node Powers

In [1] management nodes also had powers that were too relaxed. They were required to have any role that they would want to grant. This resulted in management nodes having powers that they had no intention of using. Also, their scope of control was the same as law enforcement giving each M node low down in the hierarchy tree an almost global reach.

Our solution was to limit their scope to nodes reachable by breadth first search and to limit management nodes to only having the M role. However, in our approach management nodes can add any role to other nodes. This gives more power to a manager node (which might be seen as decreasing security) but it limits that power to a more narrow scope creating what we believe is a rational compromise.

F. Policy Bootstrapping

In [1], it is not stated how the initial policy is defined for an instantiated cryptocurrency. It is implied that some configuration file, apart from the blockchain, must exist that provides the original parameter settings. These settings may or may not then be subsequently overridden through policy transactions on the blockchain. The result may be that some policy is defined on the blockchain and some through an original configuration file. Given that the configuration file wouldn't have the same cryptographic protections as blockchain transactions, the distributor of the node software for maintaining the blockchain could conceivably change policy using software updates through modifying the configuration file.

Our solution is to eliminate the need for the unsecured initial configuration file. We do this by specifying that all policy is initially defined as permissive as possible. We then require that all policy parameters be defined explicitly on the blockchain within the first x blocks (as defined in the full node software distribution). Thus early in the blockchain, ideally prior to it being released publicly, the manager will have to explicitly record all possible policy parameters within cryptographically secured blocks.

We also discovered that the original root management node should not be used to set the initial policy (except for policy settings intended to be permanent). This is because, per [1], management nodes closer to the root are more authoritative; any root manager node policy decisions will prevent any other management node from changing that policy. Also, the root management node account ideally should never be used after the initial few blocks and its keys should be physically stored in a vault to eliminate the possibility of it being compromised. Thus, if the root node is used to set policy it should only be used to set permanent policy that, by design, will never be changed.

IV. Architectural Challenges

Apart from mitigating vulnerabilities in the original design, we encountered several architectural challenges where it was not practical or even possible to directly implement the theoretical architecture. In this section we describe the primary challenges, how we modified the theoretical design to overcome them, and how we implemented those changes.

A. Dual Signature Requirements for Coin Transfer Transactions

In [1] an account must have the U role to both spend and receive coin. It specifies that these roles must be brought into each coin transfer transaction using two separate Vin fields. However, this requires both the sender and receiver to sign the transaction which would require off blockchain coordination and some unspecified infrastructure to support this.

This could be resolved by including the coin transfer recipient only in the Vout field (not the Vin) and requiring full nodes to check the U role on the account listed in the Vout field (without explicitly bringing it into the transaction using a Vin field), at the cost of additional tracking overhead. Our mitigation was to only require the U role for spending coin. Any account then can receive coin, but may not be able to spend it. This results in only a single account needing to sign coin transfer transactions and eliminates additional overhead.

B. Node Movement

In [1] there is no mention of how accounts can change position within the node hierarchy graph once they have been created. This is necessary, for example, for users that want to use different account managers. Besides moving nodes, edges in the graph may need to be moved in order to cut out compromised nodes but leave the rest of the node hierarchy intact.

To implement the needed functionality, we created the idea that if a node adds roles to an account that has no roles, this creates an edge in the node hierarchy graph from the node adding the roles to the node representing the account gaining the roles. If an edge already existed to the node gaining the roles (which would happen if an account received roles and then deleted them), the prior edge will be deleted in order to preserve the required tree structure.

To prepare a node to be moved, the relevant account can unilaterally remove its own roles or else a manager whose scope covers the node can remove the roles. Using this paradigm, nodes can be moved around the node hierarchy tree. It also doesn't require explicitly coding edge creation and deletion within the modified Bitcoin protocol, which would have been unnecessarily complicated. A drawback is that node movement requires a two step process: one transaction to remove roles and another to add them back in (thus removing the old edge and creating the new edge). In our future work we will design a format where a single transaction does this atomically. Complicating this may be the need for dually signed transactions to prevent security violations (which we are trying to avoid, see section IV-A). Our current two step approach ensures that the role removal, node movement, and edge addition only happens through transactions issued by nodes authorized to perform those activities.

C. Determining Transaction Types

The theoretical architecture in [1] uses the most significant bits of an nValue field to determine the type of transaction being processed: role change, policy change, or coin transfer. The nValue fields, in the original Bitcoin, specify the amount of coin to be spent. Using the leftmost bits as control bits is conceivably risky because a bug in the code might interpret the leftmost control bits as value bits for moving or create large amounts of coin. More problematic though is that the Bitcoin implementation uses the leftmost bit of the nValue field as a signed bit.

For these reasons, we chose to deviate from [1] and not use the leftmost bits of the nValue field to determine the type of transaction. Instead, we determined the type of transaction using the transaction version number; this then determines how the nValue fields within a transaction are handled. We created three transaction version numbers, each of which correspond to the three different modes for evaluating nValue fields (role change, policy change, and coin transfer). Lastly, we also changed to using the nValue low order bits for specifying roles and policy change types in case those nValue fields ever got interpreted as coin transfer fields through some bug or attack. This would then limit the damage done by having fewer coin inadvertently transferred or created.

D. Transaction Fees

Since we determine transaction type (role change, policy change, or coin transfer) through the transaction version number, it means that the mode of all the nValue fields in the Vout fields are determined by that number. However, it is usually necessary to pay a transaction fee for most transactions and there is usually change that must be sent back to the sender. This is not possible then for the role and policy change transactions because the nValue fields of the Vout fields change roles/policies; they don't send coin as in the original Bitcoin specification. We solved this simply by specifying which Vout field is always the change sent back to the originator of the transaction (which may be 0 coin on occasion).

V. Developed Prototype

Our prototype was developed publicly through Github and is available within the project 'usnistgov/managed-cryptocurrencies-bitcoin'. We built our prototype through forking and modifying the C++ Bitcoin codebase available on Github at 'bitcoin/bitcoin'.

For flexibility, efficiency, and portability we ran our modified bitcoin peer-to-peer network for development and testing on a local virtualized environment. For our testing, we thus had a single virtual machine (VM) executing the entire distributed Bitcoin network. We used the Vagrant virtual machine manager with Virtualbox as the VM provider. Within the VM, we used the Docker Engine to run a set of containers to represent the nodes on the modified Bitcoin network. This enabled us to simultaneously run five Bitcoin miners within a single VM to maintain our test blockchain. Note that we artificially reduced the mining difficulty to enable quick block production for testing and demonstration purposes. Lastly, we used the GraphViz library to enable us to visualize the node hierarchy tree. To make access control decisions for role and policy change transactions, it was inefficient to look up individual node roles using the tree. Thus, we separately maintained an associative array mapping node names to a list of their roles. The tree was only necessary for determining the scope of control of one node over others (e.g., for the law enforcement and manager nodes).

An example output tree is shown in Figure 4. Within each node in parenthesis is listed the roles activated for that node and its state (locked or unlocked). The labels are deciphered as follows: M-manager, C-central banker, L-law enforcement, U-registered user, A-account manager, D-disabled account) Node 0 is the root node created in the genesis block. It should normally never be used directly for security reasons and so Node 1 was created as the 'active' manager. Node 3 is the central banker; it could have hung off of Node 1 but it was useful for our example to have it as a child under Node 0. Node 2 is law enforcement with the scope of all that is reachable from Node 1 (all nodes except 0, 3, and 11). Nodes 4 and 5 are account managers. Node 6 is a user account that has been disabled by law enforcement. Nodes 7, 8, and 10 are ordinary users. Node 9 is a node who has had all its roles removed (either done by Node 9 itself, its account manager Node 5, or one of the manager nodes 0 or 1). This might have been done because Node 9 was compromised or because it is being prepared to move to another part of the tree under a different account manager. Node 11 is a node that has been active in the cryptocurrency but has no roles and has never had any roles (due to their being no edge to it). It represents an account created by a miner to store coinbase coins, that can be spent without needing any roles.

VI. Related Work

To our knowledge, [1] is the only work proposing a managed cryptocurrency that has a balance of power where the public can hold the manager accountable. There have been many government cryptocurrencies proposed but these differ in that they are often not managed, don't use roles, or don't have a balance of power.

Multichain [10] is a system that might appear to be similar in that it contains management features. However, Multichain enables a permissioned chain where what is managed is which entities have the privilege of mining. This is opposite of our prototype that enables open mining. That said, we may explore modifying Multichain to implement [1] while leveraging a permissioned chain whose membership is defined by the current members (not the manager).

There are many government cryptocurrencies proposed and in development (for example [11], more citations are in [1]). However, none of these have yet come to fruition except the Venezuelan Petro [12], which to our knowledge is the only existing government issued cryptocurrency.

There is research proposing a Fedcoin [13], a cryptocurrency that would support central banks with a permissioned blockchain that complies with 'know your customer' laws [9]. It is based on RS—Coin [14], one of many cryptocurrencies advertised to support central and commercial banks with international transaction handling. Others argue that central banks don't need a cryptocurrency, but instead a new form of electronic money [15]. There are also concerns with the amount of power a government could leverage through creating a Fedcoin [16].

VII. Future Work

There are two major changes to be made in future iterations of the implementation: using an account model and better handling of compromised nodes.

A. *Using an Account Model*

Bitcoin uses an unspent transaction output (UTXO) model. Coin is not stored within user accounts but within the transactions themselves. All transactions have outputs (representing coin) and any unspent output may be spent by another transaction. Who may spend a given output is determined by a script that usually specifies the public key of a particular account. There is no single data structure on the blockchain that shows the coin associated with a particular account.

This works well for Bitcoin, but immediately became awkward for the implementation of our managed cryptocurrency prototype. In the theoretical architecture, accounts have roles that specify their privileges in the system and these roles are specified in nValue fields. Without a central data structure for each account, the roles had to be treated like coin and be spent repeatedly as an account used those roles. In our system, an account's roles are transaction outputs and the active copy (the one that hasn't yet been spent) is temporarily in one particular transaction. We simplified this, compared to the theoretical architecture, by requiring that any role additions and removals repeat the remaining roles. Thus, all of an account's roles are always designated within a single transaction, not spread out among many transactions as would have occurred through a direct implementation of the theoretical architecture.

Our future approach will be to implement the system through forking cryptocurrency code that uses an account model instead of an UTXO model. This is possible because the theoretical architecture is not tied to any particular cryptocurrency. A likely candidate replacement cryptocurrency would be Ethereum due to its maturity, but this choice would bring in the added complexity of a codebase that supports smart contracts. A mature Bitcoin-like cryptocurrency without smart contract capabilities that uses an account model might be better suited.

B. *Handling Compromised Nodes*

In section III-D we expand the law enforcement powers to disable all the roles of an account to handle the case where

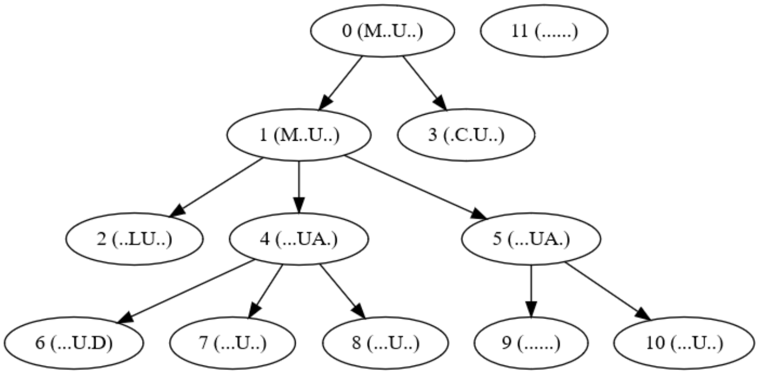

Fig. 4. Example Output Showing a Node Hierarchy.

a node is compromised (in [1] only the ability to send and receive coin was disabled). However, this does not allow the compromised node to be recovered. To do this, we propose that all nodes should have two sets of cryptographic key pairs. The first set is used for the daily signing of transactions for the associated account. The second set is stored offline and is used only to replace the first set. This enables account owners to unilaterally re-establish control over their accounts without having to involve a manager node (one with the M or A role). However, it will require the development and implementation of a new transaction type to enable this resetting of the first key pair.

VIII. Conclusion

The theoretical managed cryptocurrency architecture proposed in [1] can be efficiently developed from an existing cryptocurrency codebase and deployed (despite the many implementation issues that had to be overcome). An important result of this is that we have shown that the novel balance of power concept, whereby a manager and public miners jointly control a cryptocurrency, is a feasible mechanism to be explored for future cryptocurrencies. Another result of our work is to show the practicability of adding roles to cryptocurrency accounts and the capabilities that can be achieved through these roles (in particular for mimicking fiat currency mechanisms). Lastly, we note that building such a protocol native managed cryptocurrency within a blockchain platform itself was non-trivial but we showed that it could be accomplished with only a modest cost in programming effort.

In summary, we have shown that the theoretical system in [1] can be implemented in such a way as to not just leverage many of the strengths of modern cryptocurrencies, but also leverage the capabilities of traditional fiat currencies. While this goes against the goals and directions of most cryptocurrency efforts which are promoting greater privacy and autonomy from managing institutions, this result may be useful for large institutions (e.g., governments) investigating future electronic currency approaches. We do not necessarily believe that the architecture in [1] provides the answer for such a use case, but it and our applied research in this work may open up new research directions to better support large institutions issuing their own managed cryptocurrencies.

TMPS: Ticket-Mediated Password Strengthening

Abstract

We introduce the notion of Ticket-Mediated Password Strengthening (TMPS), a technique for allowing users to derive keys from passwords while imposing a strict limit on the number of guesses of their password any attacker can make, and strongly protecting the users' privacy. We describe the security requirements of TMPS, and then a set of efficient and practical protocols to implement a TMPS scheme, requiring only hash functions, CCA2-secure encryption, and blind signatures. We provide several variant protocols, including an offline symmetric-only protocol that uses a local trusted computing environment, and online variants that avoid the need for blind signatures in favor of group signatures or stronger trust assumptions. We formalize the security of our scheme by defining an ideal functionality in the Universal Composability (UC) framework, and by providing game-based definitions of security. We prove that our protocol realizes the ideal functionality in the random oracle model (ROM) under adaptive corruptions with erasures, and prove that security w.r.t. the ideal/real definition implies security w.r.t. the game-based definitions.

1 Introduction

In many real-world cryptosystems, the user's password is the greatest practical weakness. Commonly, the user enters a memorized password or passphrase, which is processed using a password-based key derivation function, to get a symmetric key. Knowledge of this key allows the attacker to completely violate the security of a system he has physically compromised–to read the user's files, sign arbitrary things with her private key, spend her bitcoins, etc.

Deriving a key from a password is an old, well-studied problem [18, 25, 30]. The practical difficulty comes from the ability of an attacker to run a parallel password search. After stealing the user's device, the attacker is able to run an offline attack, perhaps trying billions of different password guesses per second until the user's password is found. Few users can memorize a password capable of withstanding such an attack for long.

In this paper, we propose a novel method to approach this problem, called Ticket-Mediated Password Strengthening (TMPS). Informally, this works as follows: When the user wants to produce a new password-derived key, she creates and stores some local data, and runs a protocol with a server to produce a set of t *tickets*. Later, when she wants to unlock this key using her password, she runs another protocol with the server, providing (and discarding) one of these tickets. The password can only be used to unlock the user's key with the server's help, and the server will not provide this help without a ticket that has never before been used.

The result is that the user can establish a hard limit on the number of possible guesses of the password any attacker can make–if she has only 100 tickets on her device, then an attacker who compromises the device can never try more than 100 guesses of her password.

Our approach provides strong privacy guarantees for the user w.r.t. the server, and unlike many proposed password-hardening schemes in the literature, is focused on user-level key derivation problems, rather than on online authentication to some web service. We also provide a mechanism to allow the server to control which users it provides services to, without violating the users' privacy.

Among other advantages, our scheme gives users a security metric that is human-meaningful–the maximum number of guesses the attacker can ever have against their password. Hardness parameters of password hashes, or entropy estimates of a password, are meaningful only to security experts; the maximum number of attacker

guesses that will be allowed is much easier to understand. On the other hand, our scheme imposes the need to be online in order to unlock a key secured by a password. (Though we provide variant schemes which can be used offline.)

1.1 Our Results

- We introduce the notion of Ticket-Mediated Password Strengthening (TMPS), a mechanism for allowing users to derive keys from passwords while imposing a strict limit on the number of guesses of their password any attacker can make, and strongly protecting the users' privacy.
- We formalize the security requirements of our new notion of TMPS, both by introducing game-based definitions (See Appendix B) as well as defining a corresponding ideal functionality in the Universal Composability (UC) framework (See Section 5).
- We present efficient protocols realizing our new notion. Our basic protocol requires only hash functions, CCA2-secure encryption, and blind signatures (See Section 4).
- We prove that our protocol UC-realizes the aforementioned ideal functionality in the random oracle model (ROM) under adaptive corruptions with erasures (See Appendix C) and prove that security w.r.t. the Ideal/Real definition implies security w.r.t. the game-based definitions (See Appendix B).
- We present several variants of our protocol, including an offline version of our protocol using a local hardware security module (HSM) or trusted execution environment, and variants that make use of group signatures, proofs of work, or weaker security assumptions to ensure user privacy while still preventing overuse of server resources (See Section 6).
- Finally, we discuss efficient implementations and performance, and consider some questions left open by this research, in Section 7.

1.2 Related Work

A long list of work (e.g., [5,6,31]) focuses on Password Authenticated Key Exchange (PAKE) protocols where the user and server share a password to securely establish a session key. These protocols have some similarities to our scheme (in particular the use of a trusted server), but their details (key generation) and usage are quite different. Typically, the PAKE protocols are vulnerable to offline dictionary attacks after server compromise which has been tackled in recent proposals such as Qpaque protocol [16]. Another related concept known as Password Protected Secret Sharing (PPSS) as described in [15], requires many servers to hold some share of a key; a secret sharing scheme is used to reconstruct them, secured by a password.

Many significant works on password security focuses on password-based authentication systems. In [24], Mani describes a scheme that uses a server to assist in password hashing, but without any concern for user privacy–the goal in that scheme was to harden the password file by incorporating a PRF computed on a single-purpose machine. Similarly, [2,26,27] describe a scheme with a separately-stored secret key in a crypto-server to strengthen password hashing, an informal description of the concept of password hardening, later formally defined in [12,22,28]. Our scheme differs in goal; however, is related to *password hardening* in using a separate server or device, in order to limit (online) brute-force attacks.

Another significant proposal by Lai et al. [21] defines a *password hardening encryption* scheme which provides substantial protection from password-cracking attacks by rate-limiting password cracking attempts assuming the crypto server is not compromised. Our scheme differs in many ways, most notably in the use of tickets for decryption, and in the assurance of user privacy. Also, our scheme focuses on the setting of password-based key derivation on the user's device, rather than on a server the user trusts with her data.

Still another line of work introduces the notion of password-based threshold authentication [1] for token-based authentication in single sign-on setting–in their scheme, any subset of ℓ of n servers participate in verifying the user's password and generating a token.

There is also a rich literature in server-assisted computation [3,13,19,20] which preserves the user's privacy. Our scheme differs from most of this work in that we are not trying to offload computational work to the server, we are just using a server to limit the number of times some computation may be done. In our proposal, we use standard algorithms, and provide a great deal more flexibility to choose the underlying cryptographic functions than is available in these schemes.

2 Preliminaries

2.1 Notation

Let $k \in \mathbb{N}$. The set of bitstrings of length k is denoted as $\{0,1\}^k$. The concatenation of two bitstrings x and y is denoted by $x \parallel y$. The exclusive-OR of two bitstrings x

Kelsey, John M.; Dachman-Soled, Dana; Sonmez Turan, Meltem; Mishra, Sweta. "TMPS: Ticket-Mediated Password Strengthening." Paper presented at The Cryptographer's Track of the RSA Conference (CT-RSA 2020), San Francisco, CA, US. February 24, 2020 - February 28, 2020.

and y of same length is denoted as $x \oplus y$. We let b^k denote the string with k successive repetitions of bit b. If $\mathcal{X}$ is a set, we let $x \leftarrow_{\$} \mathcal{X}$ denote sampling a uniformly random element x from $\mathcal{X}$. The security parameter is denoted by $n \in \mathbb{N}$. Unless otherwise specified, we assume all symmetric keys and hash outputs to be n bits in length.

2.2 Underlying Primitives and Functions

We use the following primitives in our protocols:

- $\texttt{HASH}(X)$: The cryptographic hash of input X.
- $\texttt{HMAC}(K,X)$: The HMAC of X under key K.
- $\texttt{PH}(S,P)$: Hash of the password P using salt S.
- $\texttt{KDF}(K,D,\ell)$: ℓ-bit key derived from the secret value K and public value D.
- Π_{ENC} := (GEN, ENC, DEC): An encryption system where $\texttt{ENC}(K,X)$ is encryption of plaintext X under the key K, and $\texttt{DEC}(K,Y)$ is decryption of ciphertext Y under the key K.
- Π_{BSIG} := (GEN, BLIND, UBLIND, SIGN, BVERIFY): A 2-move blind signature scheme where
  - $M^* \leftarrow \texttt{BLIND}(M)$: The user blinds the message M to obtain M^* and sends to the signer.
  - $\sigma^* \leftarrow \texttt{SIGN}_{SK}(M^*)$: The signer outputs a signature σ^* on input of message M^* and private key SK and sends to the user.
  - $F \leftarrow \texttt{UBLIND}(\sigma^*)$: The user unblinds the signature σ^* to obtain F. Note that the user inputs additional private state to the UBLIND algorithm, which we leave implicit.
  - $\texttt{BVERIFY}_{PK}(M,F)$: Verification of signature F on message M under public key PK as valid/invalid.

Next, we define two internal functions: $\texttt{VE}(D,K_P)$ provides verifiable encryption of K_P with D and $\texttt{DV}(D,Z)$ decrypts K_P after checking the correctness of D. Both functions assume that D, K_P and hash outputs are n bits long.

Algorithm 1 Verifiably encrypt K_P with D.

```
function VE($D, K_P$)
    $Z \leftarrow \texttt{HASH}(0 \parallel D) \parallel (\texttt{HASH}(1 \parallel D) \oplus K_P)$
    return($Z$)
```

Algorithm 2 Verifiably decrypt Z with D.

```
function DV($D, Z$)
    $X \leftarrow Z_{0\ldots n-1}$
    $Y \leftarrow Z_{n\ldots 2n-1}$
    $X^* = \texttt{HASH}(0 \parallel D)$
    if $X == X^*$ then
        return($\texttt{HASH}(1 \parallel D) \oplus Y$)
    else
        return($\perp$)
```

3 Ticket-Mediated Password Strengthening

In *Ticket-Mediated Password Strengthening*, or TMPS, users first interact with a server to get a set of *tickets*. Each ticket entitles the user to assistance from the server with one attempt to unlock a master secret (called the *payload key*) using a password. Later, users (or anyone else with access to the tickets) may use the tickets to attempt to unlock the payload key using the password.

TMPS requires a setup phase, and two protocols: REQUEST and UNLOCK. During setup, the server establishes public encryption and signing keys and makes them available to its users.

In order to get tickets, the user chooses a payload key and a password, and runs the REQUEST protocol with the server, requesting t tickets. If the protocol terminates successfully, the user ends up with t tickets, each of which entitles her to one run of the UNLOCK protocol.

In order to use a password to unlock the payload key, the user must consume a ticket–she runs the UNLOCK protocol with the server, passing the server some information from the ticket and some information derived from her ticket and her password. When the protocol runs successfully, the user recovers the payload key.

The security requirements of a TMPS scheme are:

1. REQUEST
   (a) The server learns nothing about the password or payload key from the REQUEST protocol.
   (b) There is no way to get a ticket the server will accept, except by running the REQUEST protocol.
   (c) Each ticket is generated for a specific password and payload key; tickets generated for one password and payload key give no help in unlocking or learning any other password or payload key.
2. UNLOCK

(a) An UNLOCK run will be successful (it will return the correct K_P) if and only if:

i. This ticket came from a successful run of the REQUEST protocol.
ii. This ticket has never been used in another UNLOCK call.
iii. The same password used to request the ticket is used to UNLOCK it.

(b) From an unsuccessful run of the UNLOCK protocol, the user gains no information about the payload key.

(c) From an unsuccessful run of the UNLOCK protocol, the user learns (at most) that the password used to run the protocol was incorrect.

(d) The server learns nothing about the payload key or password from the UNLOCK protocol.

(e) The server learns nothing about which user ran the UNLOCK protocol with it at any given time.

Note that these requirements don't describe the generation of the payload key or the selection of the password. If the payload key is known or easily guessed, then TMPS can do nothing to improve the situation. In any real-world use, the payload key should be generated using a high-quality cryptographic random number generator.

The strength of the password matters for the security of ticket-mediated password strengthening, but in a very limited way–each run of UNLOCK consumes one ticket and allows the user to check one guess of the password. An attacker given N equally-likely passwords and t tickets thus has at most a t/N probability of successfully learning the password.

3.1 Discussion

The usual way password-based key derivation fails is that an offline attacker tries a huge number of candidate passwords, until he finally happens upon the user's password. He then derives the same key as the user derived, and may decrypt her files. A TMPS scheme avoids this attack by requiring the involvement of the server in each password guess, and (more importantly) by limiting the number of guesses that will ever be allowed. If the user of a TMPS scheme requests only 100 tickets from the server, then an attacker who compromises her machine and learns the tickets will never get more than 100 guesses of her password. If he cannot guess the password in his first 100 guesses, then he will never learn either the password or the payload key. Even if he is given the correct password after he has used up all the tickets, he cannot use that password to learn anything about the payload key.

The security of a TMPS scheme relies on the server being unwilling to allow anyone to reuse a ticket, and the inability of anyone to unlock a payload key with a password *without* running the UNLOCK protocol with a server, and consuming a fresh ticket in the process.

A corrupt server can weaken the security of TMPS, but only in limited ways. It cannot learn anything about the password or payload key. It cannot determine which user is associated with which ticket, or link REQUEST and UNLOCK runs. But it *can* enable an attacker who has already compromised a user's tickets to reuse those tickets as many times as he likes.

4 The Basic Protocol

In this section, we describe a set of protocols that implement Ticket-Mediated Password Strengthening in a concrete way. Our protocols require a secure cryptographic hash function, a public key encryption scheme providing CCA2 security[1], and a blind signature scheme. (Note that there are variants that do not need a blind signature scheme described in Section 6.)

A *ticket* gives a user enough information to enlist the server in helping carry out one password-based key derivation. Each ticket contains an *inside* part (which the user retains and does not share with the server) and an *outside* part (which the user sends to the server). The different parts of a ticket are bound together with each other and with the specific password and key derivation being carried out, and can't be used for a different key derivation.

We make two assumptions about this protocol: First, all messages in this protocol take place over an encrypted and authenticated channel. Second, the user somehow demonstrates that he is entitled to be given tickets by the server; we assume the user has already done this before the REQUEST protocol is run. There are many plausible ways this might be done, such as:

1. The user may pay per ticket.
2. The user may demonstrate his membership in some group to whom the server provides this service.
3. The server may simply provide this service for all comers.

The specific method used is outside our scope. However the user demonstrates his authorization to receive tickets, it is very likely to involve revealing her identity. In

[1] An attacker who can alter a ciphertext to get a new valid ciphertext for the same plaintext can attack our scheme.

order to protect the user's privacy from the server, the REQUEST protocol must thus prevent the server linking tickets with this identifying information, or linking tickets issued together.

4.1 Server Setup

The steps given below are done once by the server (though presumably the server rolls over keys from time to time).

- The server establishes an encryption keypair PK_S, SK_S for some algorithm that supports CCA2 security. Server distributes its public key to all users.
- The server establishes a signature keypair PK'_S, SK'_S for some algorithm that supports blind signatures.
- The server establishes a list to store previously-seen tickets.

4.2 REQUEST: Protocol for Requesting Tickets

The basic ticket requesting protocol is illustrated below. The user starts out with a password P and a payload key K_P, and generates t tickets with the assistance of the server.

In order to create a ticket without revealing any identifying information to the server, the user will do the following steps:

1. Randomly generate an n-bit salt S and an n-bit secret value B.
2. Encrypt B using the public encryption key PK_S of the server, producing E.
3. Run a protocol to get a blind signature on E from the server–this is F.
4. Derive a one-time key from the password and the secret B:
$$D \leftarrow \mathtt{HMAC}(B, \mathtt{PH}(S, P))$$
5. Encrypt the payload key under the one-time key: $X \leftarrow \mathtt{VE}(D, K_P)$

The ticket will consist of (S, E, F, Z); the user must irretrievably delete all the intermediate values above. The user repeats the steps t times to get t tickets. Below, we show the REQUEST protocol:

```
Protocol: REQUEST$(P, K_P, t)$:

User                                   Server
for $i = 1 \ldots t$
    $S \leftarrow_{\$} \{0,1\}^n$
    $B \leftarrow_{\$} \{0,1\}^n$
    $E \leftarrow \mathtt{ENC}(PK_S, B)$
    $E^* \leftarrow \mathtt{BLIND}(E)$
                        $\xrightarrow{E^*}$
                                       $\sigma^* \leftarrow \mathtt{SIGN}_{SK'_S}(E^*)$
                        $\xleftarrow{\sigma^*}$
    $F \leftarrow \mathtt{UBLIND}(\sigma^*)$
    $C \leftarrow \mathtt{PH}(S, P)$
    $D \leftarrow \mathtt{HMAC}(B, C)$
    $Z \leftarrow \mathtt{VE}(D, K_P)$
    Forget $B, C, D, E^*, \sigma^*$
    $T_i \leftarrow (S, E, F, Z)$
endfor
return$(T_{1,2,\ldots,t})$
```

At the end of this protocol, the user constructs t tickets she can use to run the UNLOCK protocol. The server, on the other hand, knows only that it has issued t tickets–it knows nothing else about them!

4.3 UNLOCK: Protocol for Unlocking a Ticket

In order to use a ticket along with a password $\hat{P}$ to unlock K_P, the user does the following steps:

1. Hash the password: $\hat{C} \leftarrow \mathtt{PH}(S, \hat{P})$.
2. Send $(E, F, \hat{C})$ to the server.
3. If the signature is invalid or E is being reused, then the server returns $\perp$.
4. Otherwise:
   (a) The server stores E, F as a used ticket.
   (b) $B \leftarrow \mathtt{DEC}(SK_S, E)$
   (c) $D \leftarrow \mathtt{HMAC}(B, \hat{C})$
   (d) The server sends back D.
5. The user tries to decrypt Z with D. If this succeeds, she learns K_P. Otherwise, she learns that $\hat{P}$ was not the right password.

Protocol: $\textsc{Unlock}(S, E, F, Z, \hat{P})$:

```
User                                    Server
$\hat{C} \leftarrow \texttt{PH}(S, \hat{P})$
                  $\xrightarrow{E, F, \hat{C}}$
                                        IF
                                          $E$ fresh AND
                                          $\texttt{VERIFY}_{SK'_S}(E, F)$
                                        THEN
                                          $B \leftarrow \texttt{DEC}(SK_S, E)$
                                          $D \leftarrow \texttt{HMAC}(B, \hat{C})$
                                        ELSE
                                          $D \leftarrow \perp$
                  $\xleftarrow{D}$
$K_P \leftarrow \texttt{DV}(D, Z)$
return$(K_P)$
```

Note that in these two protocols, the server never learns anything about K_P, P, or $\hat{P}$, and has no way of linking a ticket between REQUEST and UNLOCK calls.

5 Security Analysis

In this section, we provide a security analysis and some security proofs for our basic protocol. Our approach comes in three separate parts: First, we define an *ideal functionality* for the system. Second, we prove that our basic protocol is indistinguishable from the ideal functionality in the UC framework. Finally, we provide several game-based security definitions, and prove bounds on an attacker's probability of winning the games when they are interacting with the ideal functionality. These game-based definitions show that the ideal functionality we've defined actually provides the practical security we need from this scheme.

The ideal functionality makes use of a table τ–a key-value database indexed by a ticket T. T can be any n-bit string, or the special values $\perp$ and $*$.

A user calls REQUEST to get a new ticket[2]. We assume a two-sided authenticated and secure channel for REQUEST–the ideal functionality knows the user's identity, and the user knows she is talking with the ideal functionality. Also, REQUEST requires an interaction with the server, in which the server also learns the user's identity. At the end of the REQUEST call, the user either has a valid ticket, or knows she did not get a valid ticket.

Algorithm 3 Ideal Functionality: Initialize and REQUEST

```
function INITIALIZE(SID)
    $\textsc{sid}.\tau \leftarrow \{\}$
function REQUEST$(U, \textsc{sid}, P, K_P)$
    $T \leftarrow_\$ \{0,1\}^n$
    $\textsc{sid}.\tau[T] \leftarrow (P, K_P, \perp)$
    Send to server SID: $(\textsc{sid}, \textsc{Request}, U)$
    if server SID compromised then
        Wait for response $(\textsc{sid}, \textsc{Request}, U, R)$.
    else
        $R \leftarrow 1$
    if $R = 1$ then
        Send to source $U$: $(\textsc{sid}, \textsc{Request}, T)$
    else
        Send to source $U$: $(\textsc{sid}, \textsc{Request}, \perp)$
```

The user makes use of a ticket and a password to recover her payload key with an UNLOCK call. We assume the UNLOCK call is made over a secure channel which is authenticated on one side–the user knows she is talking with the ideal functionality, but the ideal functionality doesn't know who is talking to it. UNLOCK also requires an interaction with the server, in which the server is not told the identity of the user. At the end of the UNLOCK call, the user either learns the payload key associated with the ticket she has used, or receives an error message ($\perp$) and knows the UNLOCK call has failed.

Before stating our theorem, we note that we assume that the protocols for REQUEST and UNLOCK given in Sections 4.2 and 4.3 are executed in a hybrid model, where an ideal functionality for secure, two (resp. one)-sided authenticated channels, $\mathcal{F}_{\mathsf{ac}}$ (resp. $\mathcal{F}_{\mathsf{osac}}$), (see e.g. [8]) is invoked each time a message is sent. We require that the VE scheme used is the one given in Algorithms 1 and 2. We assume three independent random oracles: $H_{\mathsf{pw}}, H_{\mathsf{KD}}, H_{\mathsf{VE}}$. H_{pw} is the password hash. H_{KD} is used to model the HMAC key derivation as a random oracle and H_{VE} is the random oracle for the verifiable encryption scheme given in Algorithms 1, 2.

Theorem 5.1. Under the assumption that Π_{ENC} is a CCA2-secure encryption scheme (see Definition A.5), Π_{BSIG} is a 2-move blind signature scheme (see Definition A.7) and the assumptions listed above, the protocols for SETUP, REQUEST and UNLOCK given in Sections 4.1, 4.2 and 4.3, UC-realize the ideal functionality

[2] The ideal functionality is defined for one ticket, but in our protocol, we define REQUEST to return t tickets at a time. This is equivalent to just rerunning the REQUEST ideal functionality t times.

Algorithm 4 Ideal Functionality: UNLOCK

```
# If ticket and password good, return $K_P$.
# Otherwise, return $\perp$.
function UNLOCK($\text{SID}, T, \hat{P}$)
    if $T \in \text{SID}.\tau$ then
        $(P, K_P, \alpha) \leftarrow \text{SID}.\tau[T]$
    else
    # $\alpha = *$ signals invalid ticket.
        $(P, K_P, \alpha) \leftarrow (\perp, \perp, *)$
        $R \leftarrow 0$
    if $\alpha = \perp$ then
    # Fresh ticket
        $\alpha \leftarrow_{\$} \{0,1\}^n$
        $R \leftarrow 1$
    else
    # Reused or invalid ticket
        $R \leftarrow 0$
    # Server can see whether it's getting invalid,
    # repeated, or fresh ticket.
    Send to server SID: $(\text{SID}, \text{UNLOCK}, \alpha)$
    # If server is NOT compromised, we know R.
    # If server IS compromised, we must ask it
    # how to respond.
    if Server SID compromised then
        Wait for $(\text{SID}, \text{UNLOCK}, R)$  # $R \in \{0,1\}$
    # Send back the right response to the user.
    if $R = 0$ then
    # Server returns $\perp$, no decryption possible.
        Respond to caller: $(\text{SID}, \text{UNLOCK}, \perp)$
    else if $R = 1$ then
    # Server plays straight.
        if $\hat{P} = P$ then
            Respond to caller: $(\text{SID}, \text{UNLOCK}, K_P)$
        else
    # Server returns value, decryption fails.
            Respond to caller: $(\text{SID}, \text{UNLOCK}, \perp)$
```

provided in Algorithms 3 and 4 under adaptive corruptions, with erasures.

We note that our protocols can be generalized to work with multi-round blind signature schemes, and the same security proof goes through.

The proof of this theorem appears in Appendix C.

6 Variants of the Basic Protocol

In this section we discuss some variants and modifications of the basic protocol which may be useful in specific situations.

6.1 Limiting Password Attempts

Ticket-mediated password strengthening permits a user to request a large number of tickets at once, and this may make sense for reasons of efficiency or convenience. However, if the user has chosen a very weak password, it would be helpful to limit any attacker who compromises the user's machine to a very small number of password guesses. For example, many systems have a limit of ten password attempts before locking an account. There is a straightforward way to get this same limit with ticket-mediated password strengthening, even when requesting hundreds or even thousands of tickets at a time.

Suppose the user has successfully created 1000 password-hashing tickets, $T_{0,1,2,\ldots,999}$. Each successful use of a password ticket derives the payload key, K_P. In order to implement a limit of at most ten password guesses, we do the following steps:

1. Setup:
   (a) $K_T \leftarrow \texttt{KDF}(K_P, \text{“ticket encryption”}, n)$
   (b) Using any AEAD scheme, individually encrypt all but ten tickets under the key K_T
2. Each time a ticket is successfully used to unlock K_P
   (a) $K_T \leftarrow \texttt{KDF}(K_P, \text{“ticket encryption”}, n)$
   (b) Decrypt the next few encrypted tickets with key K_T, until we have ten tickets left unencrypted.

Consider an attacker who gets access to the stored data at some point. He has only ten tickets available. Assuming the KDF is secure, he cannot decrypt any other tickets without access to K_P, which he can get only by successfully using a ticket.

This technique can be used with our basic protocol or with any of our variants, described below.

6.2 Adding Offline Access

It is possible to add a second offline mode of access to the payload key. This may be a practical requirement in many cases, where a user needs to have access even when internet access is not available. However, this represents an explicit tradeoff between security and usability–the number of tickets no longer provides a limit on how many passwords may be guessed by an attacker who compromises the user's device.

If offline access is added, the first question is: how much computation should be required to unlock the payload key offline? We propose the following steps for adding offline access, if this is necessary, making use of the "pepper" idea of Abadi et al. [25]:

1. Determine the largest acceptable amount of computing time on the device that would be acceptable to get offline access. Let this parameter be W. For example, we might require ten minutes' continuous computing on the user's device in order to unlock the offline access. (Note that in many cases, the constraint may be battery life rather than time.)
2. Determine an acceptable time for the initial generation of the offline access information, I, such that $I \times 2^q = W$ for some integer q. For example, I might be 15 seconds on the user's device.
3. Calculate $q \leftarrow \lg(W/I)$.
4. Generate a random salt $S^* \leftarrow_{\$} \{0,1\}^n$ for offline access.
5. Compute $D \leftarrow \mathtt{PH}(S^*, P)$, using parameters for the password hash that require I seconds to compute.
6. Store $Z^* \leftarrow \mathtt{VE}(D, K_P)$
7. Set the low q bits of S^* to zeros.
8. Forget D.

If this is done, we strongly suggest using a memory-hard function for PH, with parameters set to the largest memory requirements that can be reasonably accommodated on the user device–this will make the offline attack more expensive and difficult, and may prevent the attacker using commodity graphics cards to parallelize the attack. Throwing away a few bits of the salt (following Abadi et al.) allows us to only do the work necessary to compute *one* instance of PH during setup, while still requiring an offline user (or attacker) to compute 2^q instances of PH.

6.2.1 Analysis

Consider a user who provides offline access requiring W work, alongside a TPMS scheme for online access. If the user's device is compromised, the attacker is no longer limited to t password guesses–instead, he first makes t password guesses "for free," and then does W work per additional password guess.

Providing offline access throws away one of the major usability advantages available with ticket-mediated password strengthening: the ability of a user to choose a relatively low-entropy password safely. A random dictionary word or six-digit number provides substantial security against an attacker who has only ten guesses. Further, most users can probably understand what kind of passwords are necessary to withstand an attacker who is limited to ten guesses; few can properly estimate whether their password will survive an offline attack given the attacker's budget and the value of W.

The advantage of using a TMPS scheme in this situation is that it allows the work per offline guess to be set to some extremely high value, hopefully making the offline guessing attack too expensive for an attacker in practice, while the user can still get access her data with very little delay as long as she has internet access.

This technique can be used with our basic protocol, or with any of the variants described below. (Though it would not make much sense for the Offline Variant with HSM.)

6.3 An Offline Variant with HSM

Consider the situation where a user has a trusted computing environment or trusted hardware security module (HSM). We define an offline variant of ticket granting and unlocking protocol which uses an HSM and does not need any external server. However, we emphasize that this variant is secure only if the HSM is secure–an attacker who can extract the secret from or reload past states into the HSM can recover the K_P with a simple password search.

6.3.1 Starting Assumptions

We assume that the HSM can be loaded up with a secret value, B, which can not be released from the HSM afterward. We further assume that the HSM supports one-time use of the value B which is updated at each interface as described in Algorithm 5. Note that HSM_Step must be an atomic operation–if any value of D is returned, then B *must* be updated.

We also assume that the user can load a new value of B into the HSM at any time which overwrites the previous existing value.

Algorithm 5 Access Secret and Update HSM Internal State

```
function HSM_STEP($C$)
    $D \leftarrow \mathtt{HMAC}(B, C)$
    $B \leftarrow \mathtt{HASH}(B)$
    return($D$)
```

6.3.2 HSM REQUEST Protocol

In order to generate t tickets, the user first chooses a password, P and generates a random payload key K_P, and then follows the steps listed in Algorithm 6.

Algorithm 6 Create Tickets for the HSM Protocol

```
function HSM_REQUEST($P, K_P, t$)
    $S \leftarrow \{0,1\}^n$
    $B \leftarrow \{0,1\}^n$
    $C \leftarrow \mathtt{PH}(S, P)$
    Load $B$ into the HSM as the new secret value.
    for $i \leftarrow 1 \dots t$ do
        $D_i \leftarrow \mathtt{HMAC}(B, C)$
        $Z_i \leftarrow \mathtt{VE}(D_i, K_P)$
        $B \leftarrow \mathtt{HASH}(B)$
    Forget $D_{1,2,\dots,t}$, $C$, $B$
    return($S, Z_{1,2,\dots,t}$)
```

The protocol uses a fixed random salt S for generating all t tickets. As we do not need privacy from the HSM, reusing the salt and getting same C is acceptable. Similarly, there is no need for public key encryptions or signatures. Guessing the password is equally difficult as the password-derived value C is never stored. The value B is updated after each computation of Z_i, resulting t-different D_i's. The t-tickets $\{Z_1, Z_2, \dots, Z_t\}$ consist *only* of the encryptions of K_P under different keys D_i. As a result, the user storage as single S and $Z_{1,2,\dots,t}$.

Note that the same protocol can be used to generate new tickets when the old ones are running out. In that case, the user simply runs the HSM_UNLOCK algorithm (Algorithm 7) to recover K_P, and then runs the HSM_REQUEST algorithm (Algorithm 6) with P and K_P to get more tickets for the same password and payload key.

6.3.3 HSM UNLOCK Protocol

The process of unlocking the tickets is straightforward; however, it needs sequential run of the protocol starting from ticket number 1 to t and hence, requires a strong synchronization between the HSM and the user. Specifically, the synchronization ensures the computation of the correct value of B and finally the K_P when correct password is provided. The protocol as shown in Algorithm 7 starts with accepting a password $\hat{P}$ from the user, which is used to derive a challenge value $\hat{C}$. The HMAC of this challenge value along with the current value of B inside the HSM is computed by the HSM and returned to the user as $\hat{D}$, and then B is again updated by the HSM. These computations inside the HSM follows the steps of Algorithm 5. Finally, the correctness of $\hat{D}$ is verified by analyzing the output K obtained at Step 4 of the Algorithm 7. The correct value of $\hat{D}$ implies K is the desired K_P.

Algorithm 7 Use an HSM Ticket to Unlock K_P

```
1: function HSM_UNLOCK($\hat{P}, S, Z$)
2:     $\hat{C} \leftarrow \mathtt{PH}(S, \hat{P})$
3:     $\hat{D} \leftarrow$ HSM_Step($\hat{C}$)
4:     $K \leftarrow \mathtt{DV}(\hat{D}, Z_i)$
5:     if $K = \perp$ then
6:         return($\perp$)
7:     else
8:         return($K$)
```

The user must delete all old values of Z, in order to ensure that he can always determine which ticket is to be used next.

It is possible that some software error will lead to the HSM and user software getting out-of-synch. The best strategy for handling this is to attempt to unlock the payload key using the password and the final ticket, and to keep trying until the payload key is unlocked.

6.3.4 Analysis

Note that this scheme is not covered by our security proofs. Here, we provide some arguments for the security of the scheme.

Consider the situation where the user has produced t tickets, and then her laptop was stolen by an attacker who cannot violate the security of the HSM. Informally, what can we say about the attacker's chances of learning K_P?

The attacker needs to guess the correct value of $C = \mathtt{PH}(S, P)$. Each guess of the password leads to a guess of C.

The user has tickets corresponding to the next t values of B that will be used by the HSM. For $i = 1, 2, \dots, t$, a ticket Z_i is used as follows:

$$\begin{aligned} D_i &= \texttt{HMAC}(B_i, C) \\ Z_i &= \texttt{VE}(D_i, K_P) \\ B_{i+1} &= \texttt{HASH}(B_i) \end{aligned}$$

The HSM will only carry out one computation with each value of B_i–this can be used to derive the decryption key D_i, but only if the attacker guesses the right value of C. Each value of B_i inside the HSM allows a new guess of C, and each value of Z_i in the attacker's hands allows the guess to be checked.

After t guesses, the HSM has a value of B for which the attacker has no corresponding values of Z. At this point, the attacker can learn nothing about K_P from interacting with the HSM. Since he also cannot break the encryption, this imposes a hard limit–the attacker gets only t guesses of the password.

In this setting, we have no privacy concerns w.r.t. the HSM. However, it's worth noting that the HSM never sees the password or any value it could use to check a password guess. (Though if the HSM was also used to generate the salt S, this would no longer be true.).

We assume that the HSM is able to securely keep B secret. Along with whatever tamper-resistance features are incorporated into the HSM, since B is updated each time it is used, side-channel attacks are very unlikely to succeed.

6.4 Different Ways to Authorize Tickets

In the basic protocol, we assume that the server issues blind signatures to allow the server to limit how much assistance it is required to provide. (That is, the server's owner presumably wants it to only provide TMPS services to users who have paid for them, or to users who are somehow affiliated with the entity running the server.). A blind signature works well to protect the user's privacy, but makes strong demands on the signature scheme used. In particular, most proposed post-quantum signature schemes have no known blind signature defined. Below, we discuss alternative ways for the server to limit access to its services *without* the need for a blind signature.

Our possible approaches fall into two broad categories:

1. Offline–the REQUEST operation is done without any interaction with the server or any other party.
2. Online–the REQUEST protocol is almost unchanged, but some other operation is substituted for the blind signature protocol.

Note that the security proof on our basic protocol doesn't cover these variants, though we believe it could be modified to cover them without too much difficulty. For each variant, we provide a short sketch of why we believe the variant is secure. Also note that we still assume that the public key encryption used below is CCA2–specifically, it must not be possible to modify a ciphertext without changing the plaintext.

6.4.1 Third Party Signer (Online)

A very lightweight (but imperfect) technique for ensuring user privacy from the server is simply to separate the authorization of getting a ticket from the unlocking of tickets. Suppose we have two trusted parties: the Bank and the Server. The Bank authorizes tickets, and can recognize a ticket, but is never shown tickets by the Server; the Server unlocks tickets but can't recognize them. In this protocol, we need an ordinary signature, nothing more.

The REQUEST protocol works as follows. Note that this is almost the same protocol as with the blind signatures, except it is done with the Banker instead of the Server.

```
Protocol: ThirdParty_REQUEST$(P, K_P, t)$:
User                                   Banker
for $i = 1 \ldots t$
    $B \leftarrow_{\$} \{0,1\}^n$
    $E \leftarrow \texttt{ENC}(PK_S, B)$
                          $\xrightarrow{E}$
                                           $F \leftarrow \text{sign}(SK_B, E)$
                          $\xleftarrow{F}$
    $S \leftarrow_{\$} \{0,1\}^n$
    $C \leftarrow \texttt{PH}(S, P)$
    $D \leftarrow \texttt{HMAC}(B, C)$
    $Z \leftarrow \texttt{VE}(D, K_P)$
    Forget $B, C, D, E^*, \sigma^*$
    $T_i \leftarrow (S, E, F, Z)$
endfor
return$(T_{1,2,\ldots,t})$
```

The unlocking protocol is exactly the same except for the public key used to verify the signature.

Security This scheme is almost identical to the basic protocol–the only difference is that the REQUEST protocol is run with a different server, and no blind signature is used. The user's privacy from the server is ensured by separation of information–the banker knows the signatures it issued to the user, but doesn't share that information with the server. An attacker who compromises the user's device has exactly the same probability of success in this scheme as in the main protocol.

6.4.2 Group Signatures (Offline)

If we want to use TMPS with a signature scheme which doesn't allow blind signatures, but allows group or ring signatures, then a small variation of the protocol can be done. We assume here that the user has a group public key PK and a personal private key SK_U for the group signature scheme. We also assume that the server knows PK.

Algorithm 8 Use Group Signature to Create Tickets

```
function GROUP_REQUEST($P, K_P, t$)
    for $i \leftarrow 1 \dots t$ do
        $B \leftarrow_{\$} \{0,1\}^n$
        $E \leftarrow \mathtt{ENC}(PK_S, B)$
        $F \leftarrow \mathrm{GroupSign}(SK_U, E)$
        $S \leftarrow_{\$} \{0,1\}^n$
        $C \leftarrow \mathtt{PH}(S, P)$
        $D \leftarrow \mathtt{HMAC}(B, C)$
        $Z \leftarrow \mathtt{VE}(D_i, K_P)$
        Forget $D_{1,2,\dots,N}$, $C$, $B$
        $T_i \leftarrow (S, E, F, Z)$
    return($T_{1,2,\dots,t}$)
```

The corresponding UNLOCK protocol is almost unchanged–the server simply verifies that F signs E using the group public key PK rather than its own signature public key PK'_S.

Security Consider an attacker who compromises the user's device, and thus learns his tickets and his signing key. The attacks possible to him are the same as in the basic protocol–he can request new tickets, but without knowing K_P or P, these will give him no help in learning the correct value of P or K_P. Despite knowing the signing key, he cannot alter tickets to give himself more guesses, because the public key encryption used is CCA2.

The server can't learn which user is UNLOCKing her key at any given time, because the group signature tells the server only that she is a member of the group.

6.4.3 Proof of Work (Offline)

If the server's main concern is having its resources wasted rather than being paid for its services, a simple alternative is to require a proof of work for each new ticket. Let's add two new functions:

$y \leftarrow \mathtt{MakePOW(x,W)}$ does approximately W work to create a proof of work, y, associated with input value x.

$\mathtt{CheckPOW(x,y,W)}$ returns 1 if the proof of work is valid, and 0 otherwise.

With these two, we can define an entirely offline proof-of-work version of our protocol, where W is assumed to be a known systemwide parameter.

Algorithm 9 Use Proof of Work to Create Tickets

```
function POW_REQUEST($P, K_P, t$)
    for $i \leftarrow 1 \dots t$ do
        $B \leftarrow_{\$} \{0,1\}^n$
        $E \leftarrow \mathtt{ENC}(PK_S, B)$
        $F \leftarrow \mathtt{MakePOW}(E, W)$
        $S \leftarrow_{\$} \{0,1\}^n$
        $C \leftarrow \mathtt{PH}(S, P)$
        $D \leftarrow \mathtt{HMAC}(B, C)$
        $Z \leftarrow \mathtt{VE}(D_i, K_P)$
        Forget $D_{1,2,\dots,N}$, $C$, $B$
        $T_i \leftarrow (S, E, F, Z)$
    return($T_{1,2,\dots,t}$)
```

Protocol: POW_UNLOCK($S, E, F, Z, \hat{P}$):

```
User                                   Server
$\hat{C} \leftarrow \mathtt{PH}(S, \hat{P})$
                $\xrightarrow{E, F, \hat{C}}$
                                       IF
                                           $E$ fresh AND
                                           $\mathtt{CheckPOW}(F, E, W)$
                                       THEN
                                           $B \leftarrow \mathtt{DEC}(SK_S, E)$
                                           $D \leftarrow \mathtt{HMAC}(B, \hat{C})$
                                       ELSE
                                           $D \leftarrow \perp$
                $\xleftarrow{D}$
$K_P \leftarrow \mathtt{DV}(D, Z)$
return($K_P$)
```

Security The use of the proof of work eliminates any information about the user in the ticket, and in fact, makes the REQUEST protocol non-interactive.

An attacker who compromises the user's device can make up additional tickets, but without knowing K_P or P, these do not help him learn the correct values of P or K_P. Again, the attacker cannot alter the value of E, because the public key encryption is CCA2 secure.

7 Implementation

The TMPS protocol requires the use of a public key encryption scheme (e.g. RSA or El Gamal), a hash function (e.g. SHA2, SHA3, or Blake2) and an HMAC computation, a password-hashing scheme (e.g. PBKDF2, scrypt, or Argon2), a blind signature protocol (e.g. RSA or El Gamal). The protocol permits a great deal of flexibility in choice of underlying cryptographic primitives. Notably, all of these (except possibly the last) can be accomplished using existing quantum-resistant algorithms.

We implemented our protocol in Python [3], using the Cryptography module, which provides a Python frontend for OpenSSL calls. The protocol allows a choice of underlying primitives; we used RSA with 3072-bit moduli for signing and public key encryption, along with SHA256 for hashing, and PBKDF2_HMAC_SHA2 for password-hashing.

All measurements were performed on a Macbook Pro (3.5 GHz Intel Core i7).While this is not an optimized implementation, it allows us to obtain concrete performance numbers.

Requesting 1000 tickets took a total of 83.9 seconds, of which 76.3 was taken up by the server. This was mostly the work of doing an RSA blind signature–the library we used didn't have a blind signature call, so we implemented one ourselves–this is much slower than the library call. In our implementation, each ticket took about 0.0763 seconds to produce on the server side, and about 0.0076 seconds on the user side. The blind signature done on the server side consists of a modular exponentiation with the exponent d, and should take no more time than a normal RSA signature. A better estimate for an optimized Python implementation's server work would be about 1.6 seconds for 1000 tickets, or about 0.0016 seconds per requested ticket. Unlocking 1000 tickets took a total of 6.7 seconds, of which 1.8 seconds was taken up by the server. Thus, the server required 0.0018 seconds to assist in the unlocking of a ticket, while the user needed about 0.0049 seconds. We provide these performance numbers to demonstrate that the protocol is practical–even with an unoptimized Python implementation.

8 Conclusion and Open Questions

In this paper, we have proposed a new mechanism for strengthening password-based key derivations, called TMPS (Ticket-Mediated Password Strengthening). We have also proposed a set of protocols that implements a TMPS scheme, proved its security in the UC model, and provided a number of variant schemes which allow for different implementation constraints and tradeoffs.

There are several questions left open by this research.

First, whether it is possible to construct TMPS schemes which provide privacy for the user, allow the server to restrict access to only authorized users, and do not need blind or group signatures. The variant protocols in Section 6 that avoided these primitives imposed other requirements–either a willingness to trust a third party with user privacy, a willingness to provide the service to all comers, or the use of group signatures.

Second, investigating other settings where one can use tickets bound to a computation to obtain a novel functionality. For example, it may be possible to use this kind of mechanism to limit accesses to a local encrypted database, or computations of a key derivation function.

Third, whether there are more elaborate restrictions that can be imposed on these tickets, without losing the users' privacy. For example, is it be possible to rate-limit UNLOCK requests from a given user without revealing which user was using the scheme?

Finally, incorporating a mechanism for key rollover, for situations where a server's key may have been compromised, would be a useful addition to the scheme. At present, our solution would be to REQUEST a large set of replacement tickets using the server's new public key.

A Definitions

In this section, we mention the key definitions used in the security analysis of our protocol to facilitate better understanding. Our exposition closely follows [4, 14, 17, 29].

Definition A.1. [Encryption System] An encryption system can be defined as a tuple of probabilistic polynomial-time algorithms $\Pi_{\texttt{ENC}}(\texttt{GEN}, \texttt{ENC}, \texttt{DEC})$ such that:

1. The key-generation algorithm $\texttt{GEN}$ takes as input the security parameter 1^n and outputs a key K.
2. The encryption algorithm $\texttt{ENC}$ takes as input a key K and a plaintext message $M \in \{0,1\}^*$, and outputs a ciphertext C where $C \leftarrow \texttt{ENC}_K(M)$.
3. The decryption algorithm $\texttt{DEC}$ takes as input a key and a ciphertext, and outputs a message. We assume without loss of generality that the decryption algorithm corresponding $\texttt{ENC}_K$ is $\texttt{DEC}_K$ such that $M = \texttt{DEC}_K(C)$ and for every n, every key K output by $\texttt{GEN}(1^n)$, and every $M \in \{0,1\}^*$, it holds that $\texttt{DEC}_K(\texttt{ENC}_K(M)) = M$.

The Chosen-Ciphertext Attack (CCA) security experiment $PrivK^{cca}_{\mathcal{A},\Pi_{\texttt{ENC}}}(n)$**:** Consider the following experiment for an encryption system $\Pi_{\texttt{ENC}} = (\texttt{GEN}, \texttt{ENC}, \texttt{DEC})$, adversary $\mathcal{A}$, and value n for the security parameter.

1. A random key K is generated by running $\texttt{GEN}(1^n)$.
2. The adversary $\mathcal{A}$ is given input 1^n and oracle access to $\texttt{ENC}_K(\cdot)$ and $\texttt{DEC}_K(\cdot)$. It outputs a pair of messages M_0, M_1 of the same length.
3. A random bit $b \leftarrow \{0,1\}$ is chosen, and then a ciphertext $C \leftarrow \texttt{ENC}_K(M_b)$ is computed and given to $\mathcal{A}$. We call C the challenge ciphertext.
4. The adversary $\mathcal{A}$ continues to have oracle access to $\texttt{ENC}_K(\cdot)$ and $\texttt{DEC}_K(\cdot)$, but is not allowed to query the latter on the challenge ciphertext itself. Eventually, $\mathcal{A}$ outputs a bit b'

5. The output of the experiment is defined to be 1 if $b' = b$, and 0 otherwise.

Definition A.2. [CCA Security] An encryption system $\Pi_{\mathtt{ENC}}$ has indistinguishable encryptions under a chosen-ciphertext attack (or is CCA-secure) if for all probabilistic polynomial-time adversaries $\mathcal{A}$ there exists a negligible function negl such that:

$$Pr[PrivK^{cca}_{\mathcal{A},\Pi_{\mathtt{ENC}}}(n) = 1] \leq \frac{1}{2} + negl(n),$$

where the probability is taken over all random coins used in the experiment.

Other variants of the CCA Security definition are defined below.

Definition A.3. [Chosen Plaintext Attack (CPA) Security] Similar to the security experiment of CCA except that the Adversary $\mathcal{A}$ is not given access to decryption oracle at step 2 and step 4.

Definition A.4. [Non-adaptive CCA or CCA1 Security] Similar to the security experiment of CCA except that the Adversary $\mathcal{A}$ is not given access to decryption oracle at step 4.

Definition A.5. [Adaptive CCA or CCA2 Security] Similar to the security experiment of CCA where the Adversary $\mathcal{A}$ is allowed to perform a polynomially bounded number of encryptions, decryptions or other calculations over inputs of its choice except on the challenge ciphertext.

Definition A.6. [Signature Scheme]: A signature scheme is a tuple of probabilistic polynomial-time algorithms $\Pi_{SIG}(\mathtt{GEN}, \mathtt{SIGN}, \mathtt{VERIFY})$ such that:

1. The key-generation algorithm GEN takes as input a security parameter 1^n and outputs a pair of keys (PK, SK). These are called the public key and the private key, respectively.
2. The signing algorithm SIGN takes as input a private key SK and a message M from some underlying message space. It outputs a signature F represented as $F \leftarrow \mathtt{SIGN}_{SK}(M)$.
3. The deterministic verification algorithm VERIFY takes as input a public key PK, a message M, and a signature F. It outputs a bit b represented as $b = \mathtt{VERIFY}_{PK}(M, F)$ where $b = 1$ means valid and $b = 0$ means invalid.

We require that for every n, every (PK, SK) output by $\mathtt{GEN}(1^n)$, and every message M in the appropriate underlying plaintext space, it holds that

$$\mathtt{VERIFY}_{PK}(M, \mathtt{SIGN}_{SK}(M)) = 1.$$

We say F is a valid signature on a message M if $\mathtt{VERIFY}_{PK}(M, F) = 1$.

Definition A.7. [Blind Signature] A 2-move blind signature scheme is an interactive signature scheme with signer $\mathcal{S}$ and user $\mathcal{U}$ and can be defined as a tuple of probabilistic polynomial-time algorithms $\Pi_{BSIG} = (\mathtt{GEN}, \mathtt{BLIND}, \mathtt{UBLIND}, \mathtt{SIGN}, \mathtt{BVERIFY})$ such that:

1. The key-generation algorithm Gen takes as input a security parameter 1^n and outputs a pair of keys (PK, SK). These are called the public key and the private key, respectively.
2. Signature Issuing. The parties execute the following protocol, denoted $\langle \mathcal{U}(PK, M), \mathcal{S}(SK) \rangle$:
   (a) $M^* \leftarrow \mathtt{BLIND}(M)$: The user blinds the message M to obtain M^* and sends to the signer.
   (b) $F^* \leftarrow \mathtt{SIGN}_{SK}(M^*)$: The signer outputs a signature F^* on input of message M^* and private key SK and sends to the user.
   (c) $F \leftarrow \mathtt{UBLIND}(F^*)$: The user unblinds the signature F^* to obtain F. Note that the user inputs additional private state to the UBLIND algorithm, which we leave implicit.
3. The deterministic verification algorithm BVERIFY takes as input a public key PK, a message M, and a signature F. It outputs a bit b where $b = 1$ means valid and $b = 0$ means invalid.

We require that for every n, every (PK, SK) output by $\mathtt{GEN}(1^n)$, and every message $M \in \{0, 1\}^n$ and any F output by $\mathcal{U}$ in the joint execution of $\langle \mathcal{U}(PK, M), \mathcal{S}(SK) \rangle$, it holds that

$$\mathtt{BVERIFY}_{PK}(M, F) = 1.$$

The security of blind signature schemes requires two properties, namely unforgeability and blindness.

Definition A.8. [Unforgeability] A 2-move blind signature scheme $\Pi_{BSIG} = (\mathtt{GEN}, \mathtt{BLIND}, \mathtt{UBLIND}, \mathtt{SIGN}, \mathtt{BVERIFY})$ is called unforgeable if for any efficient algorithm $\mathcal{A}$ the probability that experiment $\mathrm{Unforge}^{\Pi_{BSIG}}_{\mathcal{A}}(n)$ evaluates to 1 is negligible (as a function of n) where

Experiment $\mathbf{Forge}^{\mathcal{A}}_{\Pi_{BSIG}}$

1. $(SK, PK) \leftarrow \texttt{GEN}(1^n)$
2. $((M_1,F_1),\cdots,(M_{k+1},F_{k+1})) \leftarrow \mathcal{A}^{\langle\cdot,\mathcal{S}(SK)\rangle^{\infty}}(PK)$ Return 1 iff
   (a) $M_i \neq M_j$ for $1 \leq i < j \leq k+1$ and
   (b) $\texttt{BVERIFY}_{PK}(M_i, F_i) = 1$ for all $i = 1, 2, \cdots, k+1$, and
   (c) at most k interactions with $\langle\cdot,\mathcal{S}(SK)\rangle^{\infty}$ were completed.

Definition A.9. [Blindness] A 2-move blind signature scheme $\Pi_{BSIG} = (\texttt{GEN}, \texttt{BLIND}, \texttt{UBLIND}, \texttt{SIGN}, \texttt{BVERIFY})$ is called blind if for any efficient algorithm $\mathcal{A}$ the probability that experiment $Blind^{\Pi_{BSIG}}_{\texttt{BSIGN}^*}(n)$ evaluates to 1 is negligibly close to $\frac{1}{2}$ where

Experiment Blind$^{\Pi_{BSIG}}_{\texttt{BSIGN}^*}$

1. $(PK, M_0, M_1, st_{find}) \leftarrow \mathcal{A}(find, 1^n)$
2. $b \leftarrow \{0,1\}$
3. $st_{issue} \leftarrow \mathcal{A}^{\langle\mathcal{U}(PK,M_b),\cdot\rangle^1,\langle\mathcal{U}(PK,M_{1-b}),\cdot\rangle^1}(issue, st_{find})$ and let F_b, F_{1-b} denote the (possibly undefined) local outputs of $\mathcal{U}(PK, M_b)$ resp. $\mathcal{U}(PK, M_{1-b})$
4. set $(F_0, F_1) = (\perp, \perp)$ if $F_0 = \perp$ or $F_1 = \perp$
5. $b^* = \mathcal{A}(guess, F_0, F_1, st_{issue})$
6. return 1 iff $b = b^*$.

Definition A.10. [Group Signature] A group signature scheme $\Pi_{GSIG} = (GK_g, \texttt{GSIGN}, \texttt{GVERIFY}, \texttt{OPEN})$ consists of four polynomial-time algorithms:

1. The randomized group key generation algorithm GK_g takes input a security parameter 1^n and 1^m where $m \in \mathbb{N}$ is the group size and outputs a tuple $(gPK, gmSK, gSK)$, where gPK is the group public key, $gmSK$ is the group manager's secret key, and gSK is an n-vector of keys with $gSK[i]$ being a secret signing key for player $i \in [m]$.
2. The randomized group signing algorithm GSIGN takes as input a secret signing key $gSK[i]$ and a message M to return a signature of M under $gSK[i]$ $i \in [m]$.
3. The deterministic group signature verification algorithm GVERIFY takes as input the group public key gPK, a message M, and a candidate signature F for M to return either 1 or 0.
4. The deterministic opening algorithm OPEN takes as input the group manager secret key $gmSK$, a message M, and a signature F of M to return an identity i or the symbol $\perp$ to indicate failure.

Correctness: The scheme must satisfy the following correctness requirement. For all $n, m \in \mathbb{N}$, all $(gPK, gmSK, gSK) \in [GK_g(1^n, 1^m)]$, all $i \in [n]$ and all $M \in \{0,1\}^*$

$$\texttt{GVERIFY}(gPK, M, \texttt{GSIGN}(gSK[i], M)) = 1 \text{ and}$$

$$\texttt{OPEN}(gmSK, M, \texttt{GSIGN}(gSK[i], M)) = i$$

Definitions of security in the Universal Composability (UC) framework. We refer to previous work [9, 10, 23] for definitions of UC secure computation in the adaptive-corruption setting.

B Game-Based Security Definitions and Proofs

Theorem 5.1 ensures that the basic protocol behaves like the ideal functionality, but does not tell us exactly what security properties the ideal functionality provides. In this section, we consider some game-based security definitions, and show that the ideal functionality makes it easy to prove a bound on an attacker's probability of winning these games. Combined with Theorem 5.1, we thus prove that no attacker interacting with our basic protocol can win these games with probability more than negligibly higher than these bounds.

B.1 User Compromise: Stealing Tickets

The most practically important attack to consider involves the compromise of a user's data. For example, Bob steals Alice's laptop with an encrypted hard drive; he knows all her tickets, and can impersonate her to the server, but he doesn't know Alice's password. The security goal of our scheme in this case is straightforward: after Bob steals Alice's t tickets, he gets only t guesses for her password. We can define this in terms of the following game:

Security Game: User Compromise

1. The game is parametrized by security parameter n, dictionary size N and number of tickets t, where $t < N$.
2. The challenger generates a list of N distinct passwords, $P_{1,\ldots,N}$.
3. The challenger randomly generates a payload key, $K_P \leftarrow \{0,1\}^n$.

4. The challenger chooses a random $\ell \in \{1,\ldots,N\}$.
5. The challenger honestly runs `ServerSetup` and `RequestTickets` the to generate t tickets $T_{1,\ldots,t}$ using password P_ℓ and payload key K_P.
6. The challenger provides the attacker with the list of N passwords and t tickets.
7. The attacker may send any messages he likes to the server, and may do any computation he likes, up to some very generous limits.
8. The attacker may request new tickets by running `RequestTickets` with the challenger.
9. The attacker must return a guess of K_P. If his guess is correct, he wins; otherwise he loses.

In this game, we explicitly assume that the server being used is *not* compromised.

Consider an attacker allowed to make at most 2^k queries to the server, and at most 2^k trial decryption attempts to `DV`. The protocol meets its security target against this attacker if he wins the game with probability at most $\frac{t}{N} + \mathsf{negl}(n-k)$.

B.1.1 Practical Relevance

This game directly relates to the attack we are most concerned with in this system–the one where Bob learns all of Alice's stored information, and tries to guess her password so he can decrypt all her files. If Alice keeps only t tickets on her computer, this must translate to Bob getting no more than t guesses at her password, in order for our system to be secure.

B.1.2 Proof

We now will prove that an adversary interacting with the ideal functionality and limited to at most 2^k trial decryptions with `DV` has at most a $\frac{t}{N} + 2^{k-n}$ probability of winning this game.

Definition B.1. *Winning Transcript*
An attacker has a *winning transcript* (WT) when the transcript of his interactions with the ideal functionality includes at least one response to an UNLOCK request which contains the correct value of K_P.

A *losing transcript* (LT) is any transcript which is not a winning transcript.

Fact. Given a winning transcript, the attacker has (at most) a probability of one of winning the game.

This is trivially true of any condition, though an attacker with a winning transcript actually has *exactly* a probability of one of winning the game.

We write $Pr[WT]$ to denote the probability of getting a winning transcript, and $Pr[WT|A]$ to denote the probability of adversary A getting a winning transcript.

Definition B.2. *Well-Behaved Adversary*
Consider an adversary given tickets $T_{1,2,\ldots,t}$ and passwords $P_{1,2,\ldots,N}$. A well-behaved adversary (WBA) makes queries to the ideal functionality according to the following rules:

1. Never make a REQUEST query.
2. For each UNLOCK query:
   (a) Use a ticket $T \in T_{1,\ldots,t}$.
   (b) Never use the same ticket in more than one UNLOCK query.
   (c) Use a password $\hat{P} \in P_{1,\ldots,N}$.
   (d) Never use the same password in more than one UNLOCK query.

Lemma B.1. A WBA has a probability of at most $\frac{t}{N}$ of having a winning transcript.

Proof:

1. Every WBA UNLOCK query has a valid ticket. (Definition of WBA (a,b) and Definition of Game (step 5))
2. Every WBA UNLOCK query returns $(1,\perp)$ if its password is incorrect, and $(1,K_P)$ if its password is correct. (Ideal functionality, lines 26 and 29)
3. WBA makes at most t queries. (WBA definition, (a,b))
4. $P[GT] = P[$ correct password appears in one of WBA's UNLOCK queries$]$. (Implication of step 2.)
5. $P[$correct password appears in one of WBA's queries$] \leq \frac{t}{N}$
   (a) WBA makes t queries, each with a different password.
   (b) One password is correct, but adversary has no information about which.

(c) Thus, WBA has at best a $\frac{t}{N}$ chance of including the right password in one of its queries.

6. Thus, a WBA has at most a $\frac{t}{N}$ probability of having a winning transcript. (Previous two steps.)

Lemma B.2. There is no adversary A such that $Pr[WT|A] > Pr[WT|WBA] + 2 \times 2^{k-n}$.

Proof: By showing that violating any of the five conditions of being a WBA can never raise $P[WT]$ by more than a negligible amount.

1. Making a REQUEST call never raises $P[WT]$.
   (a) A WT is a transcript in which an UNLOCK returns K_P.
   (b) Tickets generated by a REQUEST permit an UNLOCK with the same payload key as appeared in the REQUEST.
   (c) The value of K_P is selected randomly from all possible n-bit strings.
   (d) The adversary may make at most 2^k REQUEST calls.
   (e) Thus, the probability of the adversary putting the right value of K_P in one of those REQUEST calls (which will enable an UNLOCK call with the right value of K_P) is no greater than 2^{k-n}.
2. Using a ticket that's not in the valid set of tickets never raises $P[WT]$. (Only tickets $T_{1,2,...,t}$ have payload key K_P.
3. Reusing a ticket never raises $P[WT]$. (A reused ticket always gets $(\perp, \perp)$.
4. Using a password that's not in $P_{1,...,N}$ never raises $P[WT]$. (Only an UNLOCK with P_ℓ will get back $(1, K_P)$, any other password will get $(1, \perp)$.)
5. Reusing a password never raises $P[WT]$. (If the password was used with a valid fresh ticket in a previous UNLOCK call, then future UNLOCK calls with fresh tickets will get the same result. Thus, the probability of K_P appearing in the transcript is never raised.)
6. Thus, $P[WT|\text{non-}WBA] \leq P[WT|WBA] + 2^{k-n}$.

□

Theorem B.3. With the ideal functionality and an uncompromised server, no adversary who can make at most 2^k queries to `DV` or the ideal functionality can win this game with probability higher than $\frac{t}{N} + 2 \times 2^{k-n}$.

Proof:

1. **GT:** No adversary has more than $\frac{t}{N} + 2 \times 2^{k-n}$ probability of getting a winning transcript when interacting with the ideal functionality. (Lemma B.2.)
2. **LT:** Given a losing transcript, an adversary who can make no more than 2^k trial decryptions with `DV` has a probability of at most 2^{k-n} of determining K_P. (Game definition with K_P chosen randomly.)
3. **Union Bound:** The probability of the attacker knowing K_P is thus no higher than $\frac{t}{N} + 3 \times 2^{k-n}$ (Summing GT and LT conditions.)

□

B.2 Server Compromise: Learning the User's Password

Another critical security property of this scheme is that the server must never learn anything about the user's password. We capture this with the following game, in which we assume the server is corrupted:

Security Game: Learn User's Password

1. The game is parametrized by security parameter n, dictionary size N and number of tickets t, where $t < N$.
2. The challenger generates two random passwords, P_1, P_2.
3. The challenger randomly generates a payload key, $K_P \leftarrow \{0,1\}^n$.
4. The attacker is allowed to play the role of the server in the protocol.
5. The challenger honestly runs `ServerSetup` and `RequestTickets` with the attacker playing the role of the server, using password P_1 and payload key K_P. to generate t tickets $T_{1,...,t}$.
6. The challenger runs UNLOCK using password P_1 and each ticket in succession.
7. The challenger generates a random bit b, and sends the attacker $P_b, P_{b\oplus 1}$.
8. The attacker must guess b to win the game.

Kelsey, John M.; Dachman-Soled, Dana; Sonmez Turan, Meltem; Mishra, Sweta. "TMPS: Ticket-Mediated Password Strengthening." Paper presented at The Cryptographer's Track of the RSA Conference (CT-RSA 2020), San Francisco, CA, US. February 24, 2020 - February 28, 2020.

B.2.1 Practical Relevance

If a compromised server can learn anything about the user's password, then it becomes a major security threat–a single server being compromised might lead to the leak of thousands of users' passwords. If there's no attacker who can win this game with probability more than $\frac{1}{2}$, then the server learns nothing at all about the user's password–not even enough to distinguish the correct password from an incorrect one when given both values. An attacker who can't distinguish correct and incorrect passwords also cannot mount a brute-force password search.

B.2.2 Proof

Theorem B.4. No attacker can win the Learn User's Password game when the attacker and challenger are interacting via the ideal functionality with probability higher than $\frac{1}{2}$.

Proof: In the ideal functionality, the server never receives any information about the password P provided by the user. With no information about the correct password, the attacker has no strategy better than a random guess for determining b. □

B.3 Server Compromise: Violating the User's Privacy

The user trusts the server to assist her in key derivation, but may not want the server to be able to determine when she is deriving her key. This game captures a critical privacy property–the server must not be able to determine which user is unlocking her key at any given time.

Security Game: Violate User Privacy

1. The game is parametrized by security parameter n, and number of tickets t.
2. The challenger generates two random passwords, P_1, P_2, and two payload keys K_P1 and K_P2.
3. The attacker is allowed to play the role of the server in the protocol.
4. The challenger honestly runs `ServerSetup`.
5. The challenger honestly runs REQUEST to generate t tickets with password P_1 and payload key K_P1, identifying itself as user 1.
6. The challenger honestly runs REQUEST to generate t tickets with password P_2 and payload key K_P2, identifying itself as user 2.
7. For $i = 1 \dots t-1$:
   (a) The challenger asks the attacker which user should make the next UNLOCK call, and whether he should use the right password or not.
   (b) The challenger makes the UNLOCK call as directed.
8. The challenger generates a random bit b.
9. The challenger runs UNLOCK using password P_b and one of user $b+1$'s tickets.
10. The attacker must guess b to win the game.

B.3.1 Practical Relevance

We want to guarantee that the user retains privacy from the server–she doesn't give the server the power to track each time she decrypts her hard drive. This game captures the user's privacy goal–an attacker who has compromised the server cannot learn which user ran the UNLOCK protocol with him in any given instance, even if he knows which user requested each ticket and has observed many other uses of the same password. Note that this assumes that the server isn't able to simply track the user by IP address–network-level anonymization of the user is outside the scope of our work.

B.3.2 Proof

The proof is trivial: the ideal functionality does not inform the server which user is making an UNLOCK call, so the server dealing with the ideal functionality never learns this information.

C Proof of Theorem 5.1

Before re-stating our theorem, we note that the only random oracle that gets programmed in the proof is H_{VE}.[4]

[4] We note that for UC composition to hold in the programmable random oracle model, one must, in general, assume that an independent random oracle is used for each SID instance. In our case, we essentially use the programmability of the random oracle to implement a non-committing encryption scheme (see [11]), by adjusting the outcome of H_{VE} to ensure that the string Z_i decrypts to the correct K_P value.

We also assume that honest users securely erase their tickets after an unlock attempt with that ticket has been made (as well as any other part of their state which no longer needs to be stored).

Theorem 5.1. Under the assumption that Π_{ENC} is a CCA2-secure encryption scheme (see Definition A.5), Π_{SIG} is a 2-move blind signature scheme (see Definition A.7) and the assumptions listed in Section 5, the protocols for SETUP, REQUEST and UNLOCK given in Sections 4.1, 4.2 and 4.3, UC-realize the ideal functionality provided in Algorithms 3 and 4 under adaptive corruptions, with erasures.

To prove the theorem, we provide a simulator Sim and prove that the resulting Ideal and Real distributions are computationally indistinguishable. Throughout, we assume that the same ticket (resp. alias) is never issued twice during a REQUEST (resp. UNLOCK) procedure in an Ideal execution with a single SID. Since each of these events occurs with at most $\lambda'^2/2^n$ probability, where λ' is the total number of tickets issued, this assumption can only reduce the adversarial distinguishing probability by at most $2 \cdot \lambda'^2/2^n$, which is negligible.

C.1 Description of Simulator Sim

Simulator Sim under adaptive corruptions of parties

Note that since we assume secure channels, Sim only needs to begin simulating the view at the moment that some party is corrupted.

Fix an environment Env, Server Server, users $\mathcal{U}_1, \ldots, \mathcal{U}_m$ and adversary $\mathcal{A}$. Recall that we allow the environment Env to choose the inputs of all parties. Simulator Sim does the following:

1. Initialization: Initialize tables $\mathcal{B}, \mathcal{E}, \mathcal{S}, \mathcal{Z}, \mathcal{T}_{\mathsf{gen}}, \mathcal{T}_{\mathsf{used}}$ to empty and counters count_i for $i \in [m]$ to 0.

2. Preprocessing: Let λ'_i be the maximum number of tickets for each party $\mathcal{U}_i$. For $i \in [m]$, $j \in [\lambda'_i]$: Generate $B^i_j \leftarrow \{0,1\}^n$, $S^i_j \leftarrow \{0,1\}^n$, $Z^i_j \leftarrow \{0,1\}^{2n}$. Add all generated B^i_j (resp. S^i_j, Z^i_j) values to $\mathcal{B}$ (resp. $\mathcal{S}, \mathcal{Z}$). Let λ' be the total number of (B^i_j, S^i_j, Z^i_j) tuples generated.

3. Responding to corruption requests:

   Corruption of a party $\mathcal{U}_i$: Sim corrupts the corresponding ideal party and obtains its internal state, consisting of unused tickets $t^i_1, \ldots, t^i_{\lambda_i}$. For $j \in [\mathsf{count}_i]$, modify entry $(U^i, S^i_j, B^i_j, E^i_j, F^i_j, Z^i_j, \perp) \in \mathcal{T}$ to $(U^i, S^i_j, B^i_j, E^i_j, F^i_j, Z^i_j, t^i_j)$. For $j \in \{\mathsf{count}_i + 1, \ldots, \lambda_i\}$:

   (a) Generate $E^i_j = \mathtt{ENC}_{PK_S}(B^i_j)$ and F^i_j as a blind signature of E^i_j using SK_S (note that since $\lambda_i - \mathsf{count}_i > 0$, Sim must have already generated $(PK_S, SK_S, PK'_S, SK'_S)$).

   (b) Add $(U^i, S^i_j, E^i_j, F^i_j, Z^i_j, t^i_j)$ to $\mathcal{T}$ and E^i_j to set $\mathcal{E}$.

   Sim releases tickets $(S^i_j, E^i_j, F^i_j, Z^i_j)$.

   Corruption of Server: Sim corrupts the corresponding ideal party and obtains its ideal internal state If an Initialize query has not yet been submitted to the ideal functionality, Sim returns $\perp$. Otherwise, if the server's keys have not yet been sampled, Sim samples $(PK_S, SK_S, PK'_S, SK'_S)$. Let $\alpha_1, \ldots, \alpha_\lambda$ be the aliases in the ideal internal state (if any). Associate each row in $\mathcal{T}_{\mathsf{used}}$ with a random alias so each entry in $\mathcal{T}_{\mathsf{used}}$ contains a value from $\{\alpha_1, \ldots, \alpha_\lambda\}$ in its final column. For $i \in [\lambda - |\mathcal{T}_{\mathsf{used}}|]$, Generate $B_i \leftarrow \{0,1\}^n$, $E_i = \mathtt{ENC}_{PK_S}(B_i)$ and F_i as a blind signature of E_i. Add all tuples $(B_i, E_i, F_i, \alpha_i)$ to $\mathcal{T}_{\mathsf{used}}$. For each row of $\mathcal{T}_{\mathsf{used}}$, release (E_i, F_i).

4. Responding to random oracle queries to $H_{\mathsf{pw}}, H_{\mathsf{KD}}$: Sim forwards the query to the oracle and forwards the response back.

5. Responding to random oracle queries to H_{VE}: Sim maintains a table $\mathcal{T}_{H_{\mathsf{VE}}}$. The table is initialized as empty. Each time $\mathcal{A}$ queries H_{VE} on input x, Sim checks the table to see if an entry of the form (x, y) appears in the table for some y. If yes, Sim returns y. Otherwise, Sim chooses a random y, adds entry (x, y) to $\mathcal{T}_{H_{\mathsf{VE}}}$ and returns y to A.

6. When responding to oracle queries, Sim also does the following:

   - **Bad Event 1:** If Server is corrupted and $\mathcal{A}$ makes a query to H_{pw} with input of the form

Camenisch et al. [7] showed that some natural non-committing encryption schemes in the programmable random oracle model can be proven secure in the UC setting, since the simulator only needs to program the random oracle at random inputs, which have negligible chance of being already queried or programmed. We anticipate that a similar argument would work for our scheme, since D^i_j is unpredictable and with very high probability will not be queried in any other session before being programmed in the target session. However, our formal proof is only for the case where an independent random oracle is assumed for each session.

$S^i_j||\hat{P}^i_j$, where $S^i_j \in \mathcal{S}$ and $(S^i_j,\cdot,\cdot,\cdot,t^i_j) \notin \mathcal{T}$ (for $t^i_j \neq \perp$) then Sim aborts.

- **Bad Event 2:** If Server is not corrupted and $\mathcal{A}$ makes a query to H_{KD} with input of the form $(B^i_j||\hat{C}^i_j)$, where $B^i_j \in \mathcal{B}$, then Sim aborts.
- If Server is corrupted and $\mathcal{A}$ makes a query to H_{pw} with input of the form $S^i_j||\hat{P}^i_j$ where $S^i_j \in \mathcal{S}$, Sim finds the tuple of the form $(S^i_j,\cdot,\cdot,\cdot,t^i_j) \in \mathcal{T}$ and submits $\textsc{Unlock}(\textsc{sid},t^i_j,\hat{P}^i_j)$ to the ideal functionality. Sim receives $(\textsc{Unlock},\textsc{sid},\alpha)$ from the ideal functionality, and returns $(\textsc{sid},\textsc{Unlock},1)$. If the ideal functionality returns $\perp$, Sim forwards $\hat{C}^i_j = H_{\mathsf{pw}}(S^i_j||\hat{P}^i_j)$ to $\mathcal{A}$. If the ideal functionality returns K_P, Sim computes $\hat{C}^i_j = H_{\mathsf{pw}}(S^i_j||\hat{P}^i_j)$, $D^i_j = H_{\mathsf{KD}}(B^i_j||\hat{C}^i_j)$ and entries for $(0||D^i_j,y_1),(1||D^i_j,y_2)$ such that $y_1||y_2 = Z^i_j \oplus (0^n,K_P))$ to $\mathcal{T}_{H_{\mathsf{VE}}}$. Sim returns $\hat{C}^i_j$ to A. **Bad Event 3:** If at this point $0||D^i_j$ or $1||D^i_j$ have already been queried to H_{VE}, Sim aborts.

7. Responding to messages from the $\textsc{Request}$ protocol issued by a corrupted $\mathcal{U}_i$ when Server is not corrupted. Sim does the following:

   (a) Generate (PK_S,SK_S,PK'_S,SK'_S) if not yet generated.

   (b) Submit $\textsc{Request}(\mathcal{U}_i,\textsc{sid},0,0)$ to the ideal functionality and receive back ticket t.

   (c) Place $(U_i,*,*,*,*,t) \in \mathcal{T}_{\mathsf{gen}}$.

   (d) Play the part of an honest signer with secret key SK'_S in the blind signature protocol with the corrupted user.

8. Responding to $(\textsc{sid},\textsc{Request},U_i)$ messages from Ideal Functionality. Sim does the following:

   (a) Set $\mathsf{count}_i := \mathsf{count}_i + 1$ and $j := \mathsf{count}_i$.

   (b) Generate $E^i_j := \mathtt{ENC}_{PK_S}(B^i_j)$.

   (c) Participate in a blind signature protocol on message E^i_j with the corrupted Server to obtain signature F^i_j.

   (d) Store $(U_i,S^i_j,B^i_j,E^i_j,F^i_j,Z^i_j,\perp) \in \mathcal{T}_{\mathsf{gen}}$.

9. Responding to messages from the $\textsc{Unlock}$ protocol issued by adversary $\mathcal{A}$ when Server is not corrupted. $\mathcal{A}$ sends $(\hat{E},\hat{F},\hat{C})$ to the server.

   - If a tuple of the form $(\cdot,\hat{E},\cdot,\hat{t},*) \in \mathcal{T}_{\mathsf{used}}$, then send $\textsc{Unlock}(\textsc{sid},\hat{t},\perp)$ to the ideal functionality.
   - Otherwise, if the signature does not verify submit $\textsc{Unlock}(\textsc{sid},\perp,\perp)$ to the ideal functionality.
   - Otherwise, if $\hat{E} = E^i_j \in \mathcal{E}$:

     (a) Find an entry of the form $(\cdot,\cdot,\hat{E},\cdot,\hat{t}) \in \mathcal{T}$. Add $(\hat{B},\hat{E},\hat{F},t,*)$ to $\mathcal{T}_{\mathsf{used}}$.

     (b) **Bad Event 4:** If there is more than one oracle query that returned $\hat{C}$, Sim aborts.

     (c) If the unique query exists, extract the password guess $\hat{P}$ (with bit length at most n'). If it does not exist, set $\hat{P}$ to $\perp$. Send $\textsc{Unlock}(\textsc{sid},\hat{t},\hat{P})$ to the ideal functionality. **Bad Event 5:** If $\hat{C} = H_{\mathsf{pw}}(S^i_j,*)$, for some $S^i_j \in \mathcal{S}$, but $\mathcal{A}$ did not make an oracle query returning $\hat{C}$, Sim aborts.

     (d) If the ideal functionality returns a value K_P, then set $D^i_j = H_{\mathsf{KD}}(B^i_j||\hat{C})$. Add $(0||D^i_j,y_1),(1||D^i_j,y_2)$ to $\mathcal{T}_{H_{\mathsf{VE}}}$ such that $y_1||y_2 = Z^i_j \oplus (0^n,K_P))$ Return D_j to $\mathcal{A}$. **Bad Event 6:** If $\mathcal{A}$ has already queried H_{VE} on $0||D^i_j$ or $1||D^i_j$, Sim aborts.

     (e) Otherwise, return $D^i_j = H_{\mathsf{KD}}(B^i_j||\hat{C}^i_j)$.

   - Otherwise if $\hat{E} \notin \mathcal{E}$, Sim does the following:

     (a) **Bad Event 7:** If there is no entry of the form $(*,*,*,*,\hat{t}) \in \mathcal{T}$, Sim aborts.

     (b) Find an entry of the form $(*,*,*,*,\hat{t}) \in \mathcal{T}$ and remove it.

     (c) Decrypt $\hat{E}$ using SK_S to obtain $\hat{B}$. **Bad Event 8:** If $\hat{B} \in \mathcal{B}$, Sim aborts.

     (d) Make an $\textsc{Unlock}$ request to the ideal functionality $\textsc{Unlock}(\textsc{sid},\hat{t},\perp)$

     (e) Continue the execution honestly to recover $\hat{D} = H_{\mathsf{KD}}(\hat{B}||\hat{C})$. Return $\hat{D}$ to $\mathcal{A}$.

10. Responding to $(\textsc{Unlock},\textsc{sid},\alpha)$ messages from Ideal Functionality. If Sim receives a message $(\textsc{sid},\textsc{Unlock},\alpha)$ (which does not stem from an $\textsc{Unlock}$ request submitted by Sim) then Sim does the following:

    (a) If there is some $(\hat{B},\hat{E},\hat{F},*,\alpha) \in \mathcal{T}_{\mathsf{used}}$. Then Sim forwards $(\hat{E},\hat{F})$ to Server, along with a random value for $\hat{C}$.

    (b) If not, update the next tuple of the form $(\hat{B},\hat{E},\hat{F},*,\perp) \in \mathcal{T}_{\mathsf{used}}$, to $(\hat{B},\hat{E},\hat{F},*,\alpha)$. Forward $(\hat{E},\hat{F})$ to Server, along with a random value for $\hat{C}$.

(c) If Sim returns $\bot$, then return 0 to the ideal functionality.

(d) Otherwise, Sim receives back a D value from Server and checks whether D was computed correctly with respect to $\hat{B}$ and $\hat{C}$. If yes, Sim sends $(\textsc{sid}, \textsc{Unlock}, 1)$ to the ideal functionality. Otherwise, Sim sends $(\textsc{sid}, \textsc{Unlock}, 0)$ to the ideal functionality. If tuples of the form $(0||D, y_1), (1||D, y_2)$ are not in $\mathcal{T}_{H_{\mathsf{VE}}}$, Sim chooses random y_1, y_2 and adds $(0||D, y_1), (1||D, y_2)$ to $\mathcal{T}_{H_{\mathsf{VE}}}$. **Bad Event 9:** If $y_1||y_2 \oplus Z = 0^n||*$, for some $Z \in \mathcal{Z}$, Sim aborts.

We begin by bounding the probability that the Bad Events occur. It is clear by inspection that Bad Event 1 occurs with probability at most $q \cdot \lambda'/2^n$, and that Bad Event 4 occurs with probability at most $q^2/2^n$, where q is the total number of oracle queries made by the adversary and Sim. Moreover, it is clear that if Bad Event 2 does not occur, then Bad Events 3 and 6 occur with probability at most $q^2/2^n$ each. We proceed to bound the remaining events (Events 2, 5, 7, 8).

Lemma C.1. Bad Event 5 occurs with at most negligible probability in the Ideal experiment.

We upper bound the probability of Bad Event 5 by analyzing the probability that $\hat{C} = H(S^i_j, x)$, for some value of $x \in \{0,1\}^{n'}$. This probability can be upper bounded by $\frac{2^{n'}}{2^n}$, since there are $2^{n'}$ possible strings of the form $S^i_j||x$ and each of these gets mapped to a particular string $\hat{C}$ with probability $\frac{1}{2^n}$. Setting parameters appropriately, we have that $\frac{2^{n'}}{2^n}$ is negligible.

Lemma C.2. Assuming the CCA2 security of encryption scheme $\texttt{ENC}$ (see Definition A.5), the probability that Bad Event 2 or Bad Event 8 occurs is at most negligible in the Ideal experiment.

The proof proceeds by showing that if Bad Event 2 or Bad Event 8 occurs with non-negligible probability, then there must be some $i \in [m]$, $j \in [\lambda'_i]$ and efficient Env, $\mathcal{A}$ (who did not corrupt Server) such that $\mathcal{A}$ queries H_{KD} on the value, B^i_j, or, in an $\textsc{Unlock}$ request, sends an encryption $\hat{E} \notin \mathcal{E}$ that decrypts to B^i_j, with non-negligible probability. We will use Env, $\mathcal{A}$ to obtain another efficient adversary $\mathcal{A}'$ who breaks the security of the CCA2 encryption scheme $\texttt{ENC}$.

The adversary $\mathcal{A}'$ breaking the CCA2 security of the encryption scheme $\texttt{ENC}$ proceeds as follows: $\mathcal{A}'$ plays the part of Sim in the Ideal experiment, with the exception that (1) It knows all the honest users passwords and keys (since it controls Env); (2) It receives PK_S externally from its CCA2 challenger (and does not know the corresponding SK_S), (3) It aborts and outputs $0, 1$ with probability $1/2$ if $\mathcal{A}$ requests a Server corruption. Sim chooses random strings $B^i_j, B'^i_j \mathcal{B}$. Upon corruption of party $\mathcal{U}_i$, $\mathcal{A}'$ Sim sends B^i_j, B'^i_j back to its CCA2 challenger. The CCA2 challenger chooses $\tilde{b} \leftarrow \{0,1\}$ and returns an encryption of B^i_j if $\tilde{b} = 0$ and an encryption of B'^i_j if $\tilde{b} = 1$. Let E^* denote the challenge ciphertext that $\mathcal{A}'$ receives in return. $\mathcal{A}'$ continues to play the part of Sim, but includes challenge ciphertext E^* in the information returned for the corruption request for party $\mathcal{U}_i$, instead of a newly generated ciphertext. When responding to $\textsc{Unlock}$ queries $(\hat{E}, \hat{F})$, Sim must decrypt using SK_S if $\hat{E} \notin \mathcal{E}$. But in this case, either (1) $\mathcal{A}'$ has not yet requested/received its challenge ciphertext from the CCA2 challenger or (2) $\hat{E} \neq E^*$, since $E^* \in \mathcal{E}$. So $\mathcal{A}'$ forwards the decryption query $\hat{E}$ to its CCA2 oracle. Recall that throughout the experiment, $\mathcal{A}'$ (playing the part of Sim) monitors all queries made to the random oracles. If an $\textsc{Unlock}$ request is made with a valid ticket that includes E^* and a $\hat{C}^i_j$ value corresponding to the correct password, $\mathcal{A}'$ chooses a value for D^i_j at random (without querying oracle H_{KD}). If, at any point, **Case 1:** a query to H_{KD} of the form $(B^i_j, *)$ is made or some CCA2 decryption oracle query yields value B^i_j, then $\mathcal{A}'$ aborts the experiment and returns 0 to its challenger. If, at any point, **Case 2:** a query to H_{KD} of the form $(B'^i_j, *)$ is made or some CCA2 decryption oracle query yields value B'^i_j, then $\mathcal{A}'$ aborts the experiment and returns 1 to its challenger. If the experiment completes without the above cases occurring, $\mathcal{A}'$ flips a coin and returns the outcome to its challenger.

Now, note that if Bad Event 2 or 8 occur with non-negligible probability $\rho = \rho(n)$, then we must have that $\Pr[\tilde{b} = 0 \wedge$ **Case 1** occurs $] = \Pr[\tilde{b} = 1 \wedge$ **Case 2** occurs $] = \rho/2$.

On the other hand, it is always the case that $\Pr[\tilde{b} = 0 \wedge$ **Case 2** occurs $] = \Pr[\tilde{b} = 1 \wedge$ **Case 1** occurs $] = q/2^{n+1} + \lambda'/2^{n+1}$, where q is the total number of distinct oracle queries made during the experiment. This is because when $\tilde{b} = 0$, there is no information at all about B'^i_j contained in adversary $\mathcal{A}$'s view (unless $B'^i_j = B^{i'}_{j'}$ for some $(i', j') \neq (i, j)$, which occurs with probability at most $\lambda'/2^{n+1}$) and so $\mathcal{A}$ can only happen to query the oracle on B'^i_j at random. The case for $\tilde{b} = 1$ follows by identical reasoning.

Thus, the distinguishing advantage of CCA2 adversary $\mathcal{A}'$ is $\rho/2 - q/2^{n+1} - \lambda'/2^{n+1}$, which is non-negligible, since ρ is non-negligible. This implies a contradiction to the CCA2 security of the underlying encryption scheme.

Lemma C.3. Assuming the unforgeability of the blind signature scheme (see Definition A.7), Bad Event 7 occurs with at most negligible probability in the Ideal experiment.

The proof proceeds by showing that if Bad Event 7 occurs with non-negligible probability for some efficient adversary A, then, by definition, we obtain an efficient adversary $\mathcal{A}'$ who submits a larger number of valid UNLOCK requests than there are valid tickets obtained from the ideal functionality. But note that each valid UNLOCK request is accompanied by a fresh blind signature $\hat{F}$. Moreover, the number of valid signatures obtained from the signer corresponds to the number of valid tickets obtained. Thus, adversary $\mathcal{A}$ can be used to obtain adversary $\mathcal{A}'$ such that, according to Definition A.7, breaks the security of the blind signature scheme.

Conditioned on the Bad Events not occurring, the only difference between a Real and Ideal execution, is that in the Ideal execution in Step (10b) the simulator submits the next available $(\hat{E}, \hat{F})$ pair, whereas in the Real execution the order of submitted $(\hat{E}, \hat{F})$ pairs depends on which party is making the UNLOCK request. However, the blindness property of the blind signature scheme ensures that given a set of interactions and message signature pairs, the signer cannot tell in which order the message signature pairs were generated. Indeed, this is the case even when (PK_S', SK_S') are adversarially generated. Thus, the view of the adversary is indistinguishable in the two cases. We therefore conclude with the following lemma.

Lemma C.4. Assuming the blindness of the blind signature scheme (see Definition A.7), the Ideal and Real output distributions are computationally indistinguishable.

Optimization of a magnetostatic cavity for a ^{3}He spin analyzer on the CANDOR polychromatic reflectometer

Abstract.

A new instrument, the CANDOR (Chromatic Analysis Neutron Diffractometer or Reflectometer) polychromatic beam reflectometer is being built at the National Institute of Standards and Technology Center for Neutron Research. CANDOR will have a capability of polarization analysis for both specular and off-specular scattering, and allow for measuring the magnetic structures of magnetic thin films with a significantly shortened measurement time as compared to a conventional monochromatic beam reflectometer at a continuous neutron source. A critical component of the polarization analysis capability is to develop a ^{3}He neutron spin filter (NSF) for polarization analysis for both specular and off-specular scattering for a continuous wavelength range between 4 Å and 6 Å and a large solid angle coverage for up to 20 energy dispersive detector channels. For *ex-situ* spin-exchange optical pumping (SEOP) operation, a magnetically shielded solenoid (MSS) will be employed to provide a volume averaged field gradient, $|\vec{\nabla} B_\perp/B|$, better than 5×10^{-4} cm^{-1} to maintain ^{3}He polarization relaxation times of at least a few hundred hours on the beam line even when there are significant stray fields from a magnet operating at a field up to 3 T at the sample position. We describe a procedure to design, construct, and optimize a MSS with non-identical compensation coil dimensions on the ends to match the scattered neutron beam rays. The volume averaged field gradient is quantified and optimized over a cell for a MSS using the finite-element software package RADIA and compared with that from the experiment.

Key words: polychromatic reflectometer, CANDOR, SEOP, ^{3}He neutron spin filter, field gradient

1. Introduction

A conventional monochromatic reflectometer at a continuous source utilizes either a pyrolytic graphite (PG) crystal or a velocity selector to monochromatize the incident beam and detects neutrons elastically scattered from the sample without energy analysis. At the National Institute of Standards and Technology (NIST) Center for Neutron Research a novel instrument, the CANDOR (Chromatic Analysis Neutron Diffractometer or Reflectometer) polychromatic beam reflectometer is being built and is expected to be commissioned soon. CANDOR utilizes a polychromatic beam with incident neutron wavelengths (energies) between 4 Å (5.113 meV) and 6 Å (2.272 meV) that are closely matched to the peak flux of the neutron spectra from the NCNR's cold neutron source [1]. The energy determination is accomplished at the scattered

Hassan, Md.; Chen, Wangchun. "Optimization of a Magnetostatic Cavity for a u3He Spin Analyzer on the CANDOR Polychromatic Reflectometer." Paper presented at 12th International Conference on Polarised Neutrons for Condensed Matter Investigations, Milton Hill, GB. July 03, 2018 - July 06, 2018.

beam side using a linear array of PG crystals, similar to the Continuous Angle Multiple Energy Analysis (CAMEA) concept of the multi-analyzer module MultiFlexx of the cold triple axis spectrometer FLEXX [2]. The analyzer system employs a bank of 18 energy dispersive detector channels, each covering an angular range of 0.355 °, each containing 54 graphite analyzer crystals in series with corresponding scintillation detector plates. The total angular coverage for the scattered beam will be 6.4 °. The neutron detection system after the PG crystals is one of the most critical units for the CANDOR development and has been accomplished using a slab of LiF:ZnS(Ag) scintillator with embedded wavelength shifting fibers and a silicon photomultiplier used as a photosensor [3]. It is expected that CANDOR will provide significantly higher usable intensity incident on sample, hence reducing measurement times significantly for a given sample size over a conventional continuous source-based monochromatic reflectometer.

CANDOR will be equipped with a longitudinal polarization analysis capability for both specular and off-specular reflectivity measurements. For the polarized beam configuration, a double-V supermirror made by SwissNeutronics [4] is used to polarize the incident neutron beam and is expected to provide a neutron polarization of 98 % or higher for the entire wavelength range from 4 Å to 6 Å. An adiabatic radio-frequency (RF) spin flipper located immediately following the monochromator is used to flip the neutron spin over a large cross sectional beam with a flipping efficiency better than 99.5 % [5]. To spin analyze the neutron polarization of the scattered beam, it is necessary to have a spin analyzer able to cover the entire 6.4 ° angular range for the entire energy range and provide a spatially uniform analyzing power higher than 98 %, and have a second broadband spin flipper with a flipping efficiency higher than 99.5 % over a large cross sectional scattered neutron beam. Given the space of 60 cm available for both the spin analyzer and the broadband spin flipper, a ^{3}He neutron spin filter (NSF) was chosen for the following reasons. A ^{3}He NSF can (1) polarize a broad wavelength band of neutrons effectively; (2) polarize large area and widely divergent neutron beams; and (3) efficiently flip the neutron polarization by reversing the ^{3}He nuclear polarization using the adiabatic fast passage (AFP) nuclear magnetic resonance (NMR) technique [6], hence integrating the analyzer and flipper into a single device. The advantage of integration of the analyzer and the broadband flipper into a single neutron polarizing device is a unique feature of the ^{3}He analyzer since no other conventional neutron spin analyzer and flipper together can be fit into a 60-cm space along the beam path for the CANDOR scattered beam configuration. At the NCNR, ^{3}He NSFs have been routinely applied to small-angle neutron scattering, triple-axis spectrometry, and wide-angle polarization analysis [7]. A ^{3}He NSF has been demonstrated previously for polarization analysis of the diffusely reflected neutrons on the polarized neutron reflectometer at the NCNR [8, 9].

For ^{3}He NSF applications in polarized neutron scattering, a cylindrical geometric shape is generally chosen for a ^{3}He cell. For the CANDOR analyzer, a cylindrical ^{3}He cell with a diameter of 13 cm or larger is necessary for covering the scattering angle subtended by the entire detector bank. For this large ^{3}He cell, we plan to operate the ^{3}He NSF in the *ex-situ* spin exchange optical pumping (SEOP) operation mode. The ^{3}He gas is polarized in sealed cells in an off-line lab using the SEOP method, and the cells are transported to the beam line in a portable solenoid. In the *ex-situ* SEOP operation mode, it is critical to maintain the relaxation time of nuclear-polarized ^{3}He gas as long as possible. The relaxation time T_1 of the polarized ^{3}He gas has three contributions 1) dipole-dipole interactions [10], T_1^{dd}, 2) wall relaxation [11], T_1^{w}, 3) magnetic field gradients [12], T_1^{fg}, and is given by

$$\frac{1}{T_1} = \frac{1}{T_1^{\mathrm{dd}}} + \frac{1}{T_1^{\mathrm{w}}} + \frac{1}{T_1^{\mathrm{fg}}} \tag{1}$$

The dipole-dipole relaxation rate increases linearly with the partial pressure of ^{3}He gas and has been determined to be $p/807$ (h^{-1}) for p in bar [10]. The relaxation rate due to magnetic-field gradients is directly proportional to the square of the fractional transverse field gradients and inversely proportional to the ^{3}He pressure [12]. As discussed in Eq. 2 later, for a cell at a pressure of one bar in a uniform gradient of $|\vec{\nabla}B_\perp/B|$=5 × 10^{-4} cm^{-1} the gradient-induced relaxation time is ≈600 h. For a given ^{3}He polarization of 85 %, which can be routinely achieved at NIST with the SEOP method using the spectrally narrowed high power diode bar lasers [13], it is desired to have a ^{3}He partial pressure of ≈1 bar for the CANDOR ^{3}He analyzer for optimizing the analyzing power and transmission. This implies a dipole-dipole relaxation time of ≈800 h. The current best ^{3}He cell fabrication practice has nearly eliminated the wall relaxation rate (with the wall relaxation time longer than 3000 h) in certain ^{3}He cells [14, 15]. Specifically we have successfully developed ^{3}He cells for CANDOR with relaxation times between 450 h and 690 h, measured under a homogeneous magnetic field with the field gradient $|\vec{\nabla}B_\perp/B|$ better than 1×10^{-4} cm^{-1}. For the best cell, this implies a wall relaxation time longer than 5000 h. In order to achieve a relaxation time of 250 h or longer for the ^{3}He analyzer, a volume averaged field gradient upper limit of 5×10^{-4} cm^{-1} is required.

The polarization analysis capability on CANDOR will likely use a hybrid 3 T superconducting magnet at the sample with the field along the vertical direction. In order to effectively shield stray fields from the 3 T magnet, we will employ a magnetically shielded solenoid (MSS) to maintain the ^{3}He polarization on the CANDOR beam line. Several different magnetically shielded solenoids have been developed to maintain the ^{3}He polarization for several polarized beam instruments at the NCNR, and are able to shield stray fields of approximately a few mT, produced from either an electromagnet or even a superconducting magnet [7]. Furthermore, it is necessary to implement a neutron spin rotation device to adiabatically rotate the spin from the vertical to longitudinal direction. Under such an operating configuration, it is still necessary to maintain volume average field gradient better than 5×10^{-4} cm^{-1}. In this paper we describe modeling of the field gradients, design and construction of the CANDOR MSS, and characterization of field gradients for the ^{3}He spin analyzer on CANDOR.

2. Modeling

Similar to our previous designs of solenoids [7, 9, 16, 17, 18], the 16 AWG (American Wire Gauge) 1.31 mm diameter copper wire was wound on an aluminum cylinder which was nested inside a Conetic mu-metal [19] cylinder. The gap between the two cylinders is typically 7 mm. On each end of the mu-metal solenoid, a Conetic mu-metal end cap is tightly attached to the mu-metal cylinder body with an overlap of 2.5 cm. The overlap protects the mu-metal from saturation even when applying a modest current to the aluminum solenoid. A hole in each end cap lets neutrons pass through without neutron depolarization. Fig. 1 shows a schematic of the CANDOR MSS. Notable features in Fig. 1 include a RF coil structure that is used to invert the ^{3}He polarization, compensation coils centered to each end cap hole, and borated aluminum neutron shields attached to both the upstream end cap and the downstream compensation coil frame. We began by determining the dimensions of the CANDOR MSS with the aim of designing the solenoid to be as compact as possible, while still achieving a volume averaged field gradient better than 5×10^{-4} cm^{-1}. Based on the ^{3}He cell diameter requirement, we determined the diameters of the aluminum cylinder and mu-metal cylinder to be 261 mm and 279 mm, respectively. The length of the mu-metal solenoid was determined to be 356 mm by taking the following facts into consideration: (1) the total space available, (2) the space necessary for a device to accomplish an adiabatic $\pi/2$ spin rotation, (3) the effect of the magnetic field from the adiabatic spin rotation device on the field gradient of the MSS. Unlike magnetically shielded solenoids developed earlier at the NCNR [7] where the same number of ampere-turns in two identical compensation coils have been used, we used compensation coils with different diameters and hence different number of ampere-turns in order to further improve the field gradient and/or make it more compact for the CANDOR MSS. The diameters for the compensation coils were determined to be 117 mm and 143 mm attached to the upstream and downstream end caps, respectively. The compensation coils were wound on a 5.8 mm wide and 4 mm deep aluminum groove structure that was attached to the mu-metal end cap as shown in Fig. 1. The groove structure displaced the compensation coils by 3 mm along z and 2.8 mm in the radial direction from the end cap hole. As discussed later, the field gradient induced relaxation rate with non-identical compensation coils will be reduced by a factor of 1.88 over the conventional identical compensation coils. An additional benefit of using non-identical compensation coils is a possibility of reducing the diameter of the ^{3}He analyzer cell since the field homogeneity center is shifted closer to the upstream end cap as described later.

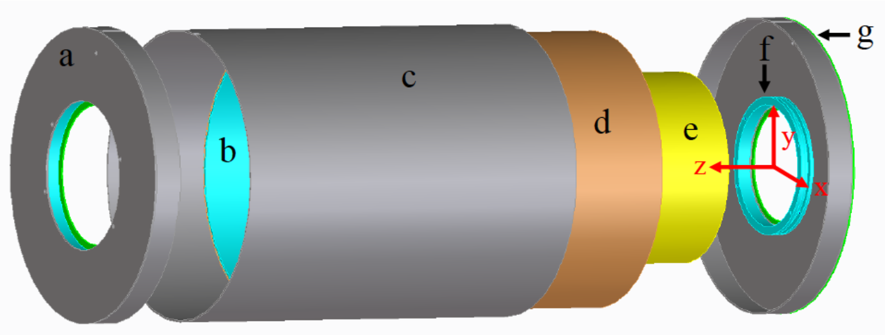

Figure 1. (Color online) Schematic of a magnetically shielded solenoid with circular holes in the end caps. The MSS is 279 mm in diameter, 356 mm long, with different sizes (117 mm diameter and 143 mm diameter) of holes on the end caps as described in the text. The MSS has the following components, (a) Conetic [19] mu-metal end caps, (b) aluminum cylinder with a wall thickness of 2.4 mm for support of the copper winding, (c) Conetic [19] mu-metal cylinder, (d) copper winding, (e) RF coil structure, (f) compensation coils centered to the end cap hole, (g) borated aluminum neutron shielding piece attached to the end cap in the upstream direction. The thickness for all mu-metal pieces is 1.6 mm.

We proceed to discuss the simulation of the magnetic field profile, the resulting field gradients, and optimization of compensation coils of the CANDOR MSS. A similar simulation and modeling has been completely described for our earlier development of a compact end-compensated magic box [20]. The field gradients relevant to the relaxation of polarized ^{3}He gas are $\vec{\nabla} B_x$ and $\vec{\nabla} B_y$, using the coordinate system in Fig. 1. These six gradients of field components, all perpendicular to the applied field, contribute over the volume, V, of a cell to the relaxation time of the polarized ^{3}He gas. At room temperature, the relaxation rate $1/T_1^{\text{fg}}$ due to field gradients is given by

$$\frac{1}{T_1^{\text{fg}}} = \frac{6700}{pV} \iiint_V \left(\frac{|\vec{\nabla} B_x|^2}{B^2} + \frac{|\vec{\nabla} B_y|^2}{B^2} \right) dx\,dy\,dz \;\; \text{h}^{-1} \equiv \frac{6700}{p} |\vec{\nabla} B_\perp / B|^2 \;\; \text{h}^{-1} \qquad (2)$$

where p is the gas pressure in bar and $\frac{\vec{\nabla} B_x}{B}$ and $\frac{\vec{\nabla} B_y}{B}$ are the gradients in the transverse components of the magnetic field (for nuclear polarization along the z-axis) normalized to the central field, B, in units of cm^{-1}[21]. $|\vec{\nabla} B_\perp / B|$ is the normalized volume-averaged transverse gradient over the cell volume, V. In practice, these transverse components are too tiny ($< 0.1\mu$T) to measure experimentally for a field gradient level of 10^{-4} cm^{-1} using conventional means. As demonstrated in an earlier publication [20], the conveniently measurable gradient component along the applied field $|\partial B_z / \partial z| / B$ was a good indicator of the normalized volume-averaged transverse field gradient.

We used the finite-element software package RADIA [22] for the field profile and the Mathematica [23] interface for analytical calculation of the magnetic field gradients. We modeled and optimized the CANDOR MSS with three different configurations: (i) the upstream compensation coil with an inner diameter of 117 mm and downstream compensation coil with an inner diameter of 143 mm, both upstream and downstream compensation coils with a diameter of 117 mm (ii) and 143 mm (iii). The criterion for convergence of the RADIA simulation iterations was that the magnetization of all segments changed by less than 10 nT. The segment size was determined to be about 4.6 mm (78 sections) along z and 6.67 ° (54 sections) radially in the x-y plane by confirming the normalized volume-averaged field gradients changed by less than 10^{-5} cm^{-1}.

We began to model the MSS with two identical compensation coils with an inner diameter of 117 mm and 143 cm as it is more straightforward and has been done for earlier development of the MSSs [7]. For the simulations, no air gap was used between the mu-metal cylinder body and each end cap in the 2.5 cm overlap section. The main coil winding section on the aluminum cylinder was extended to be in contact with each mu-metal cap. The compensation coil winding was fixed at 3 layers and 4.5 turns per layer in the groove. Changing the compensation coil was done via a change of the current dennsity. This closely matched to the experimentally field mapped condition since varying the number of the compensation coils was impractical during mapping. Other geometric dimensions for the simulation are identical to that from Fig. 1. The field in the center of the solenoid was fixed at about 2.73 mT. We found that at the optimized conditions the number of the compensation coils were 12 turns and 16 turns, corresponding to a ratio of ampere-turn of 0.044 and 0.059 between the compensation coil of an inner diameter of 117 mm and the main coil, and between the compensation coil of an inner diameter of 143 mm and the main coil, respectively. The volume averaged gradients $|\vec{\nabla} B_{\perp}/B|$ were calculated over a cylindrical ^{3}He cell, 120 mm in diameter and 100 mm long with a cylindrical axis along z. These gradients were determined to be 2.6×10^{-4} cm^{-1} and $4.8\ \times10^{-4}$ cm^{-1}, for compensation coils of inner diameters 117 mm and 143 mm, respectively. Although the volume averaged field gradient for the MSS with the compensation coil of an inner diameter of 143 mm was already better than $5\ \times10^{-4}$ cm^{-1} and was acceptable, it is expected that the field gradient for the MSS with non-identical compensation coils as shown in Fig. 1 would be even smaller. The simulation of the MSS with identical compensation coils gave a good indicator for the simulation of the CANDOR solenoid with non-identical compensation coils as the simulation for the MSS with non-identical compensation coils requires more complicated optimization of each individual compensation coil.

To optimize the field homogeneity of the CANDOR MSS with non-identical compensation coils, we began to tune the smaller compensation coil while fixing the larger compensation coil at 16 turns as determined from simulation with identical compensation coils. The optimal condition was determined to be 16 turns for the smaller compensation coil. The smaller compensation coil was then set to 16 turns and the procedure was repeated for the larger compensation coil. The optimal condition was determined to be 19 turns for the larger compensation coil. The volume averaged field gradient was calculated in every step. The above procedure was reiterated until the calculated volume averaged field gradient changed by less than 10^{-5} cm^{-1}. Fig. 2 shows an example of the calculated field B_{z} profiles by varying the number of turns of the smaller compensation coil while fixing the larger compensation coil to 19 turns. It appeared that 16 turns of the smaller compensation coil yielded the smallest volume averaged transverse field gradient.

Fig. 3 shows contour plots of the simulated B_{z} in the central plane (x=0). Shown in Fig. 3b is a contour plot zoomed from Fig. 3a centered around the most homogenous field region. The field in the center was about 2.73 mT and chosen to not saturate the mu-metal, provide a reasonably high field so that the effect from any external field to the field inside the MSS is minimal, and to achieve a very efficient AFP inversion of the ^{3}He polarization. The effect of compensation coils

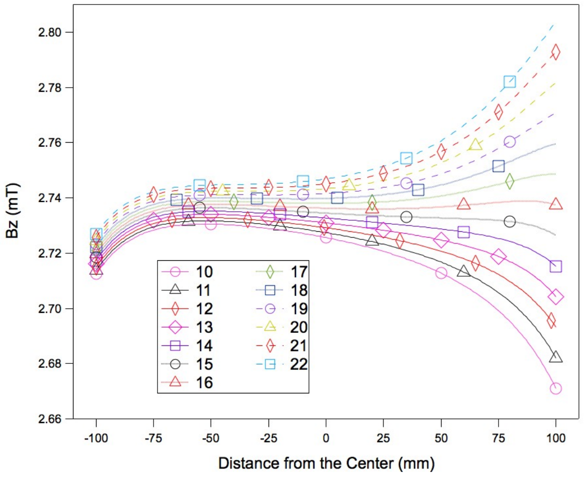

Figure 2. (Color online) Calculated B_z field profiles for different numbers of turns of compensation coils centered on the 117 mm diameter hole end cap with the compensation coil centered on the 143 mm diameter hole fixed to 19 turns. Lines are to guide the eye.

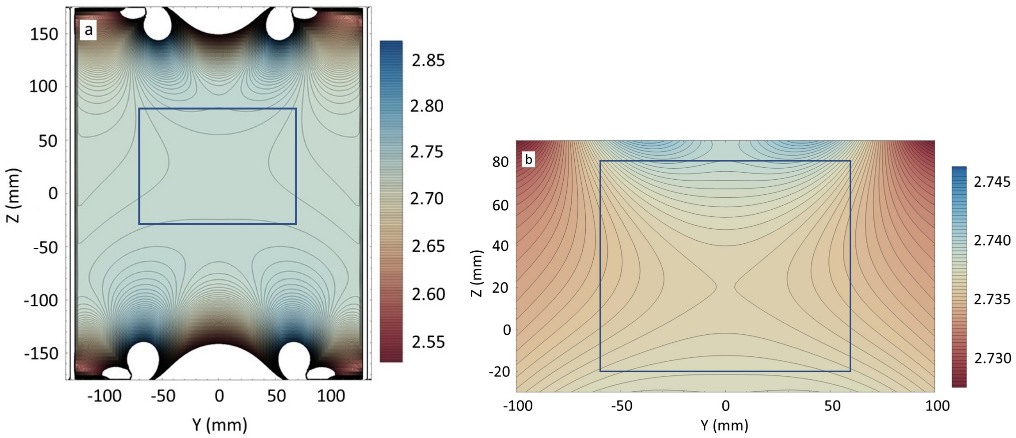

Figure 3. (Color online) Contour plots of the calculated B_z profile in the central plane (x=0) for the full size solenoid (a) and for the zoomed part centered around the most homogenous field region (b) at the optimized configuration of 16 turns and 19 turns of compensation windings attached to the small and large end cap hole, respectively. The field is in the unit of mT. The boxes in Fig. 3 indicates where the ^{3}He analyzer cell should be positioned.

Hassan, Md.; Chen, Wangchun. "Optimization of a Magnetostatic Cavity for a u3He Spin Analyzer on the CANDOR Polychromatic Reflectometer." Paper presented at 12th International Conference on Polarised Neutrons for Condensed Matter Investigations, Milton Hill, GB. July 03, 2018 - July 06, 2018.

was visible in Fig. 3a around the end cap holes and no magnetic flux saturation was observed near the main and compensation coils. The boxes in Fig. 3 represent a region with a minimal volume averaged field gradient and a region where the ^{3}He analyzer cell should be located. The field homogeneity center is shifted about 30 mm along z, as the center is expected at z=0 for a solenoid with identical compensation coils and holes in the end caps. In Fig. 3a, the two most inner magnetic flux lines represent a field difference of 2.2 μT, corresponding to a fractional field change $|\Delta B_z|/B$ of no worse than $8{\times}10^{-4}$ over a cross sectional area of 150 mm by 120 mm. In Fig. 3b the two most inner flux lines represent a field difference of 0.27 μT, corresponding to a fractional field change $|\Delta B_z|/B$ of $1{\times}10^{-4}$. The region of good field homogeneity with $|\Delta B_z|/B \approx 1{\times}10^{-4}$ was about 70 mm along the z-axis and nearly 120 mm along the y-axis. We calculated the volume averaged field gradient $|\vec{\nabla} B_\perp/B|$ over the volume of a cylindrical ^{3}He cell, 120 mm diameter and 100 mm long, and obtained $|\vec{\nabla} B_\perp/B|\approx 3.5{\times}10^{-4}$ cm^{-1} at the optimized configuration with ampere-turn ratios of 0.059 between the smaller compensation coil and the main coil and 0.070 between the larger compensation coil and the main coil, respectively. This gradient was a factor of 1.37 smaller than that for the MSS with the identical larger compensation coils of a diameter of 143 mm, implying an improvement of a factor of 1.88 in the field gradient induced relaxation time. This improvement of the field gradient was obtained without sacrificing the scattering angle coverage. At the optimized condition, simulations yielded 16 turns and 19 turns of 16 AWG wire for the smaller and larger compensation coils, respectively.

After obtaining an improved field gradient, we explored more contour maps for the off-center regions along both x and z directions. It was observed that the calculated $B_{\rm z}$ field homogeneity is still good at x=60 mm that corresponds to the edge of the cell and is only slightly worse than that in the center. Fig. 4 shows contour plots of the calculated $B_{\rm z}$ profile along the radial direction at z=30 mm and at z=80 mm. In Fig. 4 (a) and (b), the two most inner flux lines represented a field difference of 0.27 μT, corresponding to a fractional field change $|\Delta B_z|/B$ of $1{\times}10^{-4}$.

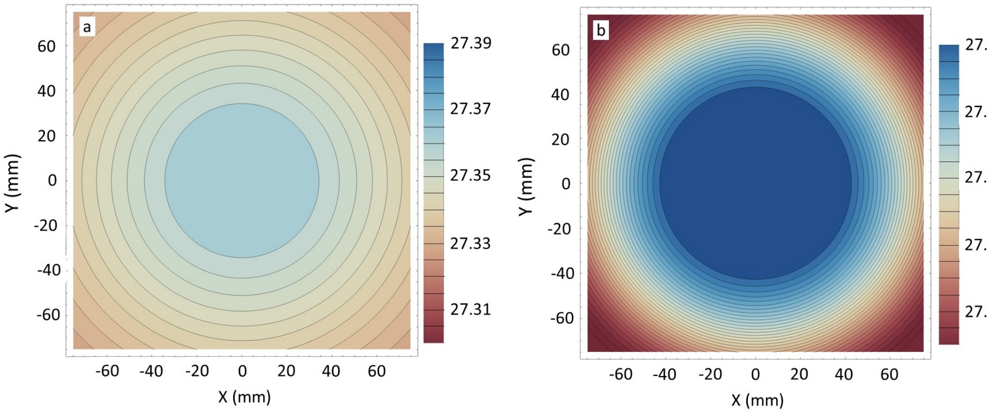

Figure 4. (Color online) Contour plots of the calculated $B_{\rm z}$ profile along the radial direction at z=30 mm (a) and at z=80 mm (b). The field is in the unit of mT.

3. Experimental results and discussion

We have designed and constructed a MSS based on modeling with the dimensions shown in Fig. 1. Each compensation coil was wound on an aluminum frame that was centered around the hole of the corresponding end cap. Both the main and compensation coils used 16 AWG wire. The main coil consisted of 270 turns. A computer controlled mapping system was used for field mapping at different compensation coil conditions. A 3-axis Hall probe (Lakeshore 460 3-channel Gaussmeter with a HSE probe) and a 3-axis fluxgate magnetometer (Bartington MG-03MS) were used to measure the field. The fluxgate has a resolution of 1 nT and was used for measurements of magnetic fields lower than 1 mT. The hall probe has a resolution of 10 nT and was used for measurements of fields higher than 1 mT. The mapper could translate along both y and z directions. Many field maps were taken on the axis of the MSS with varying turns for both compensation coils as discussed in the modeling section. Fig. 5 shows an example of a set of measured B_{z} field profiles in the central plane x=0, which was in good agreement with the simulation. We measured the line averaged gradient along z over a 100 mm length centered at the most homogenous region for each field map and found that the line-averaged gradient $|\Delta B_z/\partial z|/B$ was minimized at 20 turns of compensation coils on the 143 mm diameter hole and 11 turns of compensation coils on the 117 mm diameter hole. At this configuration, the linearly averaged gradient was 9.3×10^{-5} cm^{-1}. Off-center axis field maps were also taken to check the field homogeneity at the different compensation coil configurations. The experimentally determined compensation coil configuration at the 143 mm end cap was in good agreement with the model. However it was 11 turns of compensation coil at the 117 mm end cap, somewhat deviated from the simulation. Any tiny air gap between the Conetic mu-metal cylinder and end cap occurring during fabrication would cause perturbation of the magnetic field, while no gap was assumed for the simulation. We have checked the effect of the air gap between the Conetic mu-metal cylinder and end cap for two conditions and found an air gap of 1 mm (0.5 mm) can change the optimized configuration for the smaller compensation coil from 16 turns with no air gap to 6 (10) turns. It was determined that an $\sim$ 0.35 mm air gap would be required to change the optimized smaller compensation coil from 16 turns to 11 turns. This would result in a nearly negligible change of the volume averaged gradient $|\vec{\nabla} B_\perp/B|$ (from 3.5×10^{-4} cm^{-1} to 3.6×10^{-4} cm^{-1}). In practice, each mu-metal end cap was designed to be snugly fitted onto the mu-metal cylinder body to allow for convenient and quick ^{3}He cell exchange (on the order of several seconds) to minimize ^{3}He polarization loss. It is likely that a tiny gap exists due to the fabrication process. We speculate this air gap is likely the main reason for the discrepancy between the experiment and simulation. However, other non-ideal geometric factors such as a small difference of compensation coil location, inhomogeneous permeability in the mu-metal, roundness of the mu-metal cylinder and end caps, and parallelism of the end cap might make additional contributions to the discrepancy.

After optimization of the CANDOR MSS, we measured the relaxation time of the CANDOR ^{3}He analyzer cell Sundown. Sundown has a diameter of 132 mm and a neutron path length of 92 mm, and is able to cover the scattering angle from the entire detector assembly. Sundown was filled to a partial ^{3}He pressure of 0.95 bar. We obtained a relaxation time of 690 h in a pair of large Helmholtz coils that yielded a field gradient $|\vec{\nabla} B_\perp/B|$ better than 1×10^{-4} cm^{-1}, corresponding to a field gradient induced relaxation time of about 14000 h [20]. The relaxation time measurement was done in the CANDOR MSS after optimization on the PHADES (Polarized ^{3}He And Detector Experiment Station) beam line at the NCNR. The ^{3}He polarization was determined using the neutron transmission method [24]. Fig. 6 shows the time-dependent ^{3}He polarization. The ^{3}He polarization decays exponentially with time and is given by $P_{\mathrm{He}}(t) = P^0_{\mathrm{He}} exp(-t/T_1)$, where P^0_{He} is the initial ^{3}He polarization. We obtained a ^{3}He polarization relaxation time of 414.6 h ± 2.4 h in Fig. 6. The extrapolated volume averaged field gradient $|\vec{\nabla} B_\perp/B|$ is $(3.7\pm0.2)\times10^{-4}$ cm^{-1}, in good agreement with that from the simulation. The initial ^{3}He polarization was 85 %. The final time averaged ^{3}He polarizations would 82.6 %, 80.3 %, and 78.0 % for experiments of 24 h, 48 h and 72 h duration, respectively.

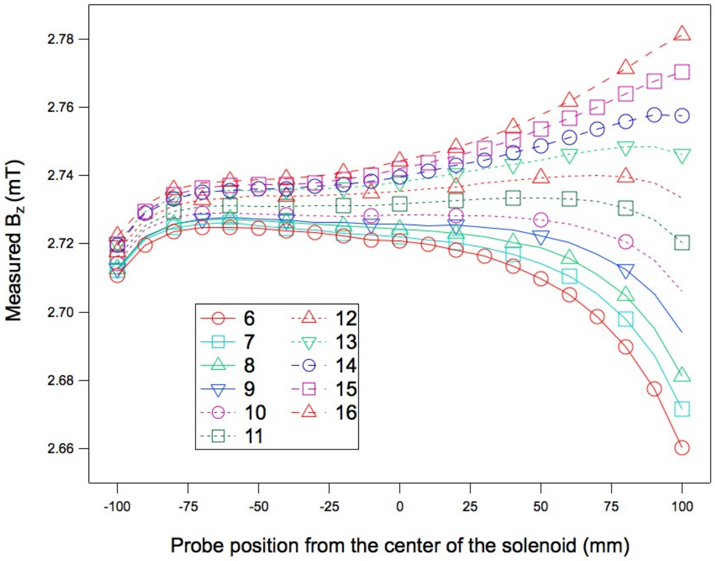

Figure 5. (Color online) Measured B_z field profiles for different numbers of turns of compensation coils centered on the 117 mm diameter hole end cap with the compensation coil centered on the 143 mm diameter hole fixed to 20 turns. The hall probe was used for these measurements. Lines are to guide the eye. Error bars are smaller than the data points.

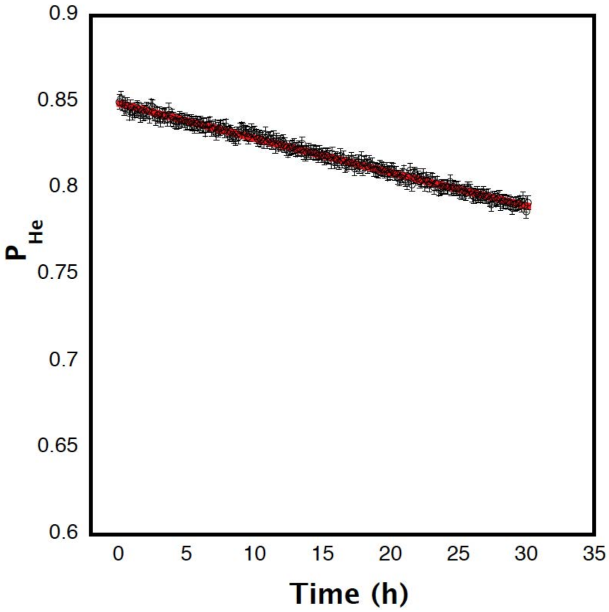

Figure 6. (Color online) The ^{3}He polarization P_{He} decay with time for the cell Sundown that will be used on CANDOR after optimization of the CANDOR MSS. The red solid line is the best fit to an exponential decay of ^{3}He polarization, yielding a relaxation time T_1 of 414.6 h ± 2.4 h. Error bars and uncertainties represent one standard deviation.

4. Conclusions

We have simulated and optimized the magnetic field gradients of a magnetically shielded solenoid (MSS) for the ^{3}He neutron spin filter that will be used as a spin analyzer on the new polychromatic reflectometer CANDOR at the NCNR. We have calculated the volume-averaged transverse field gradient which is directly linked to the field gradient-induced ^{3}He polarization relaxation time. Based on the simulation, we have constructed and characterized a compact MSS that has a dimension of 279 mm in diameter and 356 mm long. The MSS has a Conetic mu-metal cylindrical solenoid with an end cap attached to either end. By applying non-identical compensation coils centered to the hole on each end cap, we have found that the center where the field is most homogenous shifted ≈30 mm closer to the end with a smaller compensation coil. Hence the ^{3}He analyzer cell should be placed closer to the sample, which allows its diameter to be reduced. We have also shown that the volume-averaged field gradient over the cell was reduced by a factor of 1.37, hence the field gradient induced relaxation time was improved by a factor of 1.88 compared to that with identical compensation coils. We have obtained a ^{3}He polarization relaxation time of 414.6 h ± 2.4 h for a ^{3}He cell 132 mm in diameter and 92 mm long after optimization of the CANDOR MSS. After correction to the intrinsic relaxation time of 690 h, the volume averaged field gradient was determined to be $(3.7 \pm 0.2) \times 10^{-4}$ cm^{-1}, agreeing well with the calculation (3.5×10^{-4} cm^{-1}). In the near future, we will develop a ^{3}He adiabatic fast passage NMR flipper that is integrated into the ^{3}He analyzer. We plan to characterize the overall polarization analysis capability as soon as CANDOR is available.

Abstract

This paper synthesizes a theory from industrial best practices codified in recent standards. Recent editions of ASME and ISO standards codify the evolving industrial best practices in defining and modeling the information about products made from fibrous composite materials. A theory of constructive composite geometry and topology is synthesized from these practices. Major features of this theory include (1) a constructive composite geometry tree that is equivalent to the ply/laminate tables of the standards, (2) an adjacency graph that captures a crucial aspect of the topology of the geometric cell complex structure of composite products, and (3) conformal mapping of ply surfaces using rosettes in the lay-up process. It also addresses the geometrical and topological structure of fiber arrangements inside the plies. The goal of the theory is to provide a scientific basis for standards that enable the digital transformation of composite product manufacturing.

1 Introduction

Products made of fibrous composite materials are everywhere, but a good theory for representing them in practice is notably absent. This has forced engineers to depend on drawings, cross-sectional views, notes, and tabular entries to define fibrous composite products and guide their manufacturing processes. Some solid and geometrical modeling tools have been improvised to aid and assist this cumbersome exercise, but these are viewed merely as workarounds in the absence of a good theory and computational tools that support the theory [1].

There are several reasons why it has been so hard to find a good theory in this field. Traditional metallic products can be defined by current computer-aided design (CAD) systems and manufactured by conventional processes; in fact, there are usually multiple ways to manufacture such traditional products. Therefore, such a product can be defined independent of the manufacturing process. But composite products are different because they are strongly dependent on the manufacturing processes used to produce them, and these manufacturing processes are subject to unceasing innovation and evolution. Since *the process defines the product* in these cases, traditional design theory and methodology (which hold that design can be decoupled from manufacturing) no longer apply. This is also the reason why traditional solid and geometrical modeling theories and methodologies implemented in current CAD systems are not sufficient to represent fibrous composite products. This problem is not restricted to composite products – there is a long list of other product categories for which current CAD systems do not provide adequate support [2].

Such deficiencies and drawbacks have not deterred engineers from using the current solid and geometrical modeling systems. They have augmented these systems with additional information, sometimes with ingenious informational artifacts, to carry out their mission. This has created a special breed of CAD systems that cater specifically to the composite product manufacturing domain. This is a bottom-up evolution, where pragmatic practical solutions are leading the development of engineering information systems and tools, without the benefit of a cohesive theory.

Such grass-roots developments have also resulted in major standardization efforts in ASME and ISO (International Organization for Standardization). Past and current editions of ASME Y14.37, ISO 10303-209, and ISO 10303-242 standards have codified the evolving industrial best practices in defining and modeling the information content of composite products [3-5]. These ASME and ISO standards are a combination of what the current solid and geometrical modeling systems can offer, and what additional information is required, to design and manufacture these composite products. What they lack is a comprehensive theory that explains, and expands upon, these sound industrial practices.

Hedberg Jr., Thomas; Barnard Feeney, Allison; Srinivasan, Vijay. "On Practice and Theory of Constructive Composite Geometry and Topology." Paper presented at ASME 2019 International Design Engineering Technical Conferences and Computers and Information in Engineering Conference, Anaheim, CA, US. August 18, 2019 - August 21, 2019.

In a mathematical sense, composite products are cell complexes with geometrical and topological structures [2]. This paper synthesizes a theory of constructive composite geometry and topology from the industrial best practices codified in the ASME and ISO standards. It offers a procedural representation from which relevant information can be extracted and other representations can be computed. It bears some resemblance to the theory of constructive solid geometry [6, 7], but there are some significant differences due to the rich internal fibrous structures and the flexibility of constituents in composite products.

This paper is envisioned as a first attempt in postulating a theory that is close to practice for fibrous composite products, thereby initiating further discussion to strengthen the theory while still retaining strong relevance to practice. The major scientific and technical contributions of this paper include (1) the introduction of the concept of constructive composite geometry, with a tree representation for it, (2) the capture of some of the critical constructive composite topology information in the form of an adjacency graph, and (3) the use of conformal mapping of oriented surfaces in the ply lay-up. These notions systematize what is already practiced in industry and partially codified in recent standards from ASME and ISO.

The paper is organized as follows. Section 2 describes the constructive nature of composite product definition codified in the ASME standards. Then Section 3 offers a constructive composite geometry representation in the form of a hierarchical tree. Additional information is captured in Section 4 for constructive composite topology in the form of an adjacency graph. Section 5 addresses the geometry and topology of fibers embedded the plies. Section 6 concludes the paper with a summary and some directions for further research and standardization.

2 Constructive Nature of Composite Product Definition

This paper focuses on fibrous composite products, which are also known as fiber-reinforced plastics (FRP). In these composite products, thin fibers (of circular cross-section) made up of materials such as carbon, glass, or aramid (e.g., Kevlar) are embedded in a plastic resin medium called a matrix. Both fibers and resins play important roles in composite products. Fibers are the load bearing members and are the major contributors to the strength and stiffness. The resins transfer loads among the fibers and they provide much needed protection to the fibers from ambient environment (e.g., resistance to corrosion); they are also responsible for the ductility and toughness of the composite product. Thermosetting resins, which include epoxy and polyester, are currently very popular even though they are not recyclable. Thermoplastic resins are recyclable, but such resins are still under development for large-scale industrial use.

An important discrete module of a composite product is a *ply*, which is usually an arrangement (in potentially intricate geometric patterns) of reinforcement fibers in a resin matrix. The ply is often treated as a fabric; in fact, the technology and terminology of manufacturing a ply is strongly influenced by the textile industry. Fibers can be woven in special patterns called 'preforms,' which can be impregnated in resins to produce 'prepregs' [8, 9]. The ASME standard defines a ply as 'one discrete piece of manufactured material (e.g., fabric, tape, adhesive film)' [3]. Two or more plies can be stacked up to form a *laminate* (see Fig. 4 for an illustration).

Another important discrete module in a composite product is a *core*, which is a light weight component sandwiched between plies. The primary role of a core is to increase the 'section modulus' of thin-walled structures without increasing their weight considerably. A core can have hollow interiors that may be filled with air or special gases.

Composite products are produced by stacking up (or, laying up) plies, cores, and other items in a specified sequence, and then subjecting them to a curing process [8, 9]. Curing is a chemical process that enables polymers in the resins contained in the plies to cross-link, which produces a harder and more homogenous matrix within which the fiber reinforcements are firmly embedded. This leads naturally to a procedural representation, where the process for constructing a geometric and information model for the product mimics the manufacturing process that produces it. This notion is retained strongly in the current industrial practice for defining and modeling composite products.

This contrasts with how the geometry of many conventional metallic products are defined, say in a CAD system, using a set of geometrical construction commands. Such commands are intended to be better suited for the ease of constructing the *nominal* three-dimensional (3D) solid and geometric model of a part, ostensibly with little concern to the way in which the part is manufactured, say using traditional machining processes. This approach is strongly encouraged by other popular and long-standing ASME and ISO standards [10, 11] that enforce the dogma that product geometry definition should not be mixed with manufacturing process specification. The manufacturing concerns are, of course, taken into account during tolerancing these parts to ensure their manufacturability. While this good intention of separating design from manufacturing permits multiple ways to produce the same product – thereby enabling optimization on other metrics such as cost, quality, and time – this philosophy does not seem to apply to composite products.

The constructive nature of composite product definition has long been seized upon by engineers who came up with drafting and modeling schemes, while augmenting them with tables and specialized symbols. Such engineering schemes were initially standardized by ISO in 2001 for information exchange and later by ASME in 2012 for drawing practices [12, 13]. These standards have been updated recently in 2019 [3-5].

The standardization of composite product definition by ASME is best illustrated with an example. Figure 1 shows the plan view of a composite part. Following the 'dash number' convention, this part is denoted as -101 and it is constructed by stacking up several plies and a core as shown in a cross-sectional view in Fig. 2. It is clear from these two illustrations that this composite part is actually a bonded assembly of several plies and a core. In fact, it is common to refer to such a part as a 'bond assembly,' sometimes abbreviated as 'BOND ASSY.'

10	P10	0°	10721
11	P11	45°	10721
12	P12	0°	10721

The plan and (cross-sectional) elevation views in Figs. 1 and 2 are augmented by an important informational artifact called a *ply table* (also known as a *laminate table*) such as the one shown in Table 1. While these plan and elevation views follow the traditional drawing conventions for all industrial parts, the ply table is a special information that is associated only with composite products. In addition to the 'ply level' and 'ply/item' columns, the ply table in Table 1 has an 'orientation' column to indicate the fiber orientations that provide the necessary direction-dependent anisotropic properties. The last column in Table 1 identifies the material code for each ply, which can link to a much richer set of information specific to that ply. It is often useful to provide a 3D exploded view of the part as shown in Fig. 3 to accompany a ply table and sectional views.

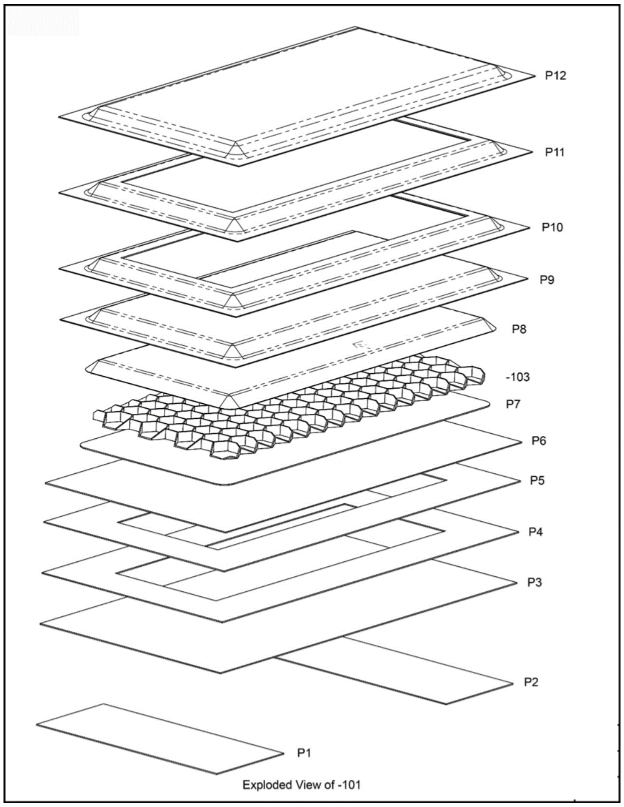

Fig. 3 A 3D exploded view of the composite part in Fig. 1 [3].

The figures and the ply table seen thus far provide a partial definition of a composite part in an *uncured* state. But this is not the final state of the product. Figure 4 explains how the ASME Y14.37 standard defines the uncured and cured states. In the uncured state on the left of Fig. 4, various plies are stacked up in a particular order to form a laminate. This laminate is then subjected to a curing process to produce the cured composite part on the right of Fig. 4. The ply interfaces disappear in this final product. It is interesting to note that much of the ASME and ISO standards are devoted to the definition and information modeling of the uncured state of the composite product and not to the 'net shape.' This important fact will be explored further in the rest of the paper.

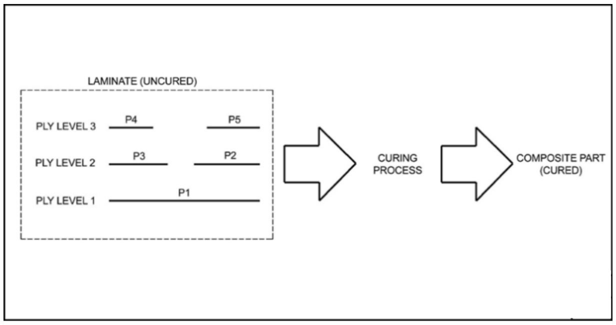

Fig. 4 Uncured and cured states in ASME standard [3].

The composites manufacturing process illustrated in these figures thus far may appear to be similar to semiconductor chip manufacturing. Both employ layered sequences of manufacturing processes, but there are important differences. One difference is that the semiconductor manufacturing uses subtractive processes (e.g., etching) as well as additive processes (e.g., sputtering). Another difference is that the composite manufacturing can produce complex 3D parts. Nevertheless, some of the ideas on geometrical and information modeling associated with semiconductor products may be useful for defining composite products.

While the logical design of a semiconductor chip can be carried out without invoking the manufacturing processes, the physical design of such a chip is strongly dictated by the sequence of process steps to which a semiconductor wafer is subjected. This notion will be carried further for composite products in rest of the paper. Section 3 will address the geometrical aspect, while Section 4 will consider the topological aspect of the constructive nature of composite product definition.

3 Constructive Composite Geometry

The example illustrated in Section 2 brings out some salient features of plies and ply tables in composite product definition. These include the following:

1. A ply is used both as a discrete physical artifact and as an information container. As a physical artifact, it contains literally the fibers and resins. As an information container it encapsulates complex information about the geometry, topology, and material of the fibers and resins in each instance of the ply. This seems to be the only practical way to handle the physical and information complexity of a composite product.

2. A ply table provides an ordered sequence (arranged from the top row to the bottom row) of the placement of the plies and cores. In a physical sense, this is part of the recipe for the manufacturing process that leads up to the uncured state of the product. In an informational context, this implies some geometrical and topological adjacency of not only the plies but also the fibers contained in them. Since the fibers remain firmly embedded in the hardened plastics after curing, this adjacency information of the plies is inherited by the fibers contained in the plies, both before and especially after curing. In other words, the ply table captures some crucial adjacency relationships among the fibers and these relationships remain invariant under the curing operation.

3. A ply table alone, of course, will not provide all the geometrical and topological information. The accompanying cross-sectional views (such as Fig. 2) and 3D exploded views (such as Fig. 3) supply much needed details. From a geometrical modeling perspective, it is interesting to note that a ply is depicted as a curve in a cross-sectional view in Fig. 2 and as a surface in a 3D exploded view in Fig. 3, even though a ply is a three-dimensional object with some definite thickness. This type of abstraction has a deeper implication than being just a convenient way for graphical presentation.

Further insights from the use of ply tables can be gained from examples shown in Figs. 5 and 6 taken from the ASME standard [3].

Fig. 5 A multi-stage bonded assembly [3].

Figure 5 shows a cross-sectional view and a set of ply tables for a multi-stage bonded assembly, which means that sub-assemblies such as '-3 BOND ASSY' and '-5 BOND ASSY' can be precured and then be bonded into the '-1 BOND ASSY.' It is interesting to observe that the ply table for '-1 BOND ASSY' contains links to other ply tables for '-3 BOND ASSY' and '-5 BOND ASSY,' thus suggesting a hierarchical tree structure for organizing this type of information. A similar example for a complex bonded assembly is shown in Fig. 6, where one ply table contains links to other ply tables.

In addition to the plies, other items such as '-7 CORE' in Fig. 5 and '-9 FILLER' in Fig. 6 can be included in a ply table. These cores and fillers can be modeled as 3D solids; even the precured subassemblies (such as '-3 BOND ASSY' and '-5 BOND ASSY' in Fig. 5; and '-3 BOND ASSY,' '-5 BOND ASSY,' and '-7 BOND ASSY' in Fig. 6) can be modeled as 3D solids. Representations of these solids then become both physical and information containers for other objects, just as the plies discussed earlier.

Fig. 6 A complex bonded assembly [3].

The notion of ply tables and their engineering use have by now been well established and deeply entrenched in composite manufacturing industry. In fact, this practice is so stable that all the earlier and current versions of the ASME and ISO standards have codified them and expanded them to cover other manufacturing processes such as braiding and pultrusion [8, 9]. So, it is reasonable to propose a constructive composite geometry (CCG) representation in the form of a hierarchical tree that is equivalent to a ply table.

Figure 7 shows a CCG tree for the '-101 BOND ASSEMBLY' associated with the ply table in Table 1 and the exploded view in Fig.3. The root node in the tree is the composite product denoted as -101 BOND ASSEMBLY. The leaf nodes are the plies, the core, and the tool. More information, such as 'orientation' and 'material' found in Table 1, can be associated with the leaf nodes as entities and attributes. The interior nodes in the CCG tree in Fig. 7 are denoted by the symbol ⊕ and it stands for an 'adjoin' operation.

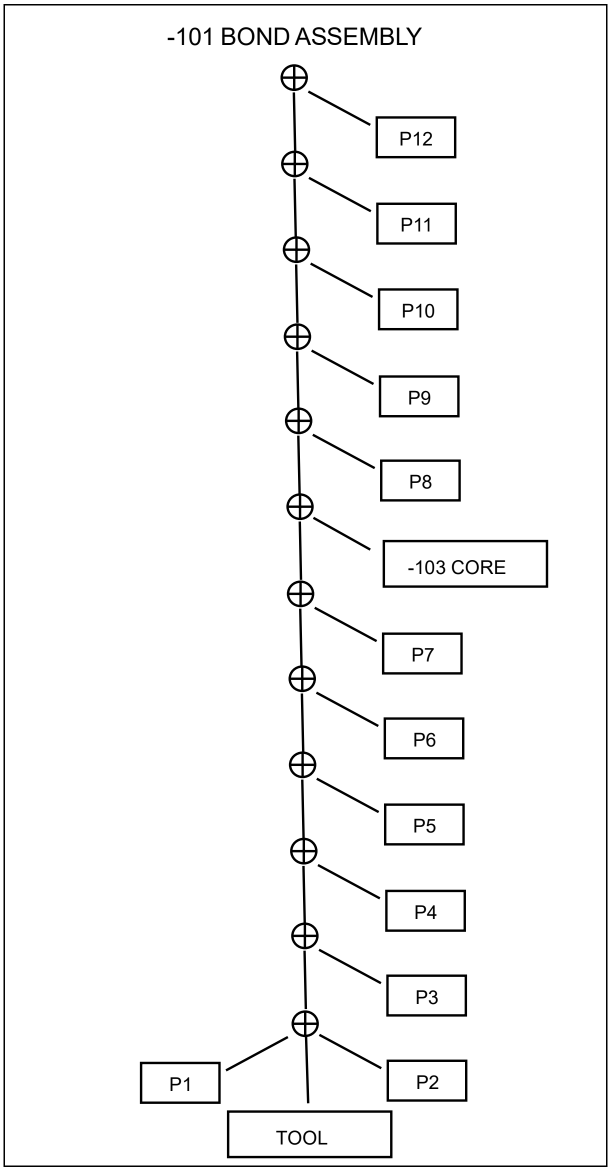

Fig. 7 A CCG tree for the -101 BOND ASSEMBLY in Table 1 and Fig. 2.

The adjoin operation, denoted by the symbol ⊕, is equivalent to a physical bonding (or gluing) of various plies and other items in the *uncured* state in a laminate (see Fig. 4). After curing, the thermosets or thermoplastics undergo chemical bonding, thereby rendering the adjoin operation as an approximation to a ‘set union’ operation among these plies in the *cured* state. Thus, the interpretation of the adjoin operation is state-dependent.

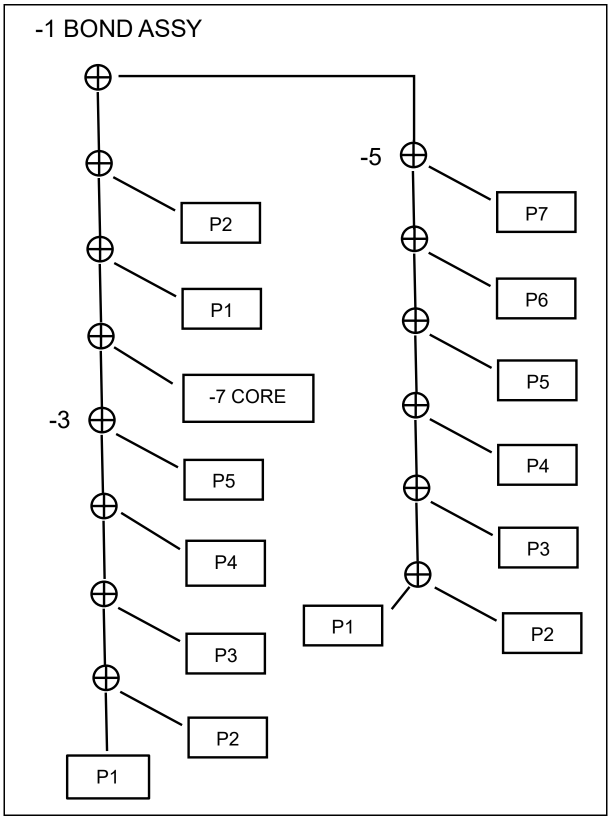

Fig. 8 A CCG tree for the -1 BOND ASSY in Fig. 5.

As a further example, Fig. 8 shows the CCG tree associated with the ply tables and figure in Fig. 5. At the root is the multi-stage bonded assembly denoted as ‘-1 BOND ASSY.’ Similarly, Fig. 9 shows the CCG tree associated with the ply tables and figures in Fig. 6, with the root node denoted as ‘-1 BOND ASSY.’ The hierarchical tree structures seen in Figs. 7, 8, and 9 are a direct consequence of the ply table structures standardized and shown in Table 1 and Figs. 5 and 6.

It is instructive to examine the three CCG trees in Figs. 7, 8, and 9 in some detail, along with their corresponding ply tables and figures.

1. *Tool*: Ply lay-up starts with a tool surface on a tool. The ‘tool side’ surface (often denoted as in Figs. 2 and 6) plays the role of a ‘datum feature’ in the composite product definition; a physical tool (with a surface on which the plies are laid) serves as the manufacturing/assembly fixture for the ply lay-up. Using this tool surface as a datum simulator, proper datums and datum systems can be established for the composite product definition [10, 11]. 3D modeling of the tool and the tool surface can be accomplished using currently available solid and geometrical modeling systems.

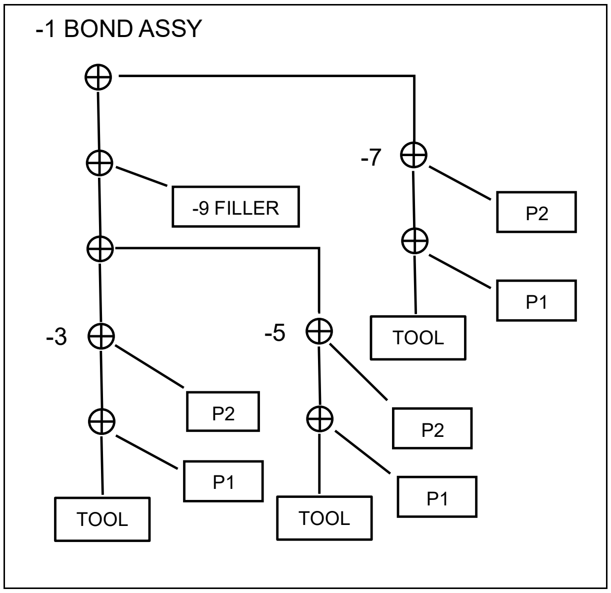

Fig. 9 A CCG tree for the -1 BOND ASSY in Fig. 6.

2. *Core/Filler*: Items such as core and filler can be modeled as 3D solids. Some of the cores, such as the one with honeycomb structure shown in the exploded view of Fig. 3, can have interior cavities that are filled with air or special gases. Figure 1 shows the ‘core ribbon direction’ for proper orientation of the core with respect to a datum reference frame, which can be established using the ‘tool side’ information mentioned earlier.

3. *Adjoin*: The adjoin operation, denoted by the symbol ⊕, is a binary operation like ‘addition’ and ‘union.’ It can be viewed as a simple gluing operation preserving a physical bonding in an uncured state; the interface between the adjoined objects are preserved in this state. In a cured state, the interfaces between the plies disappear due to chemical bonding and this is similar to the result of a ‘set union’ operation.

   The algebra of the adjoin operation requires some careful consideration. It is tempting to assign commutativity (that is, $P1 \oplus P2 = P2 \oplus P1$) and associativity (that is, $P1 \oplus (P2 \oplus P3) = (P1 \oplus P2) \oplus P3$) to this operation. But, it is not advisable to do so, due to the strong order dependency in the ply lay-up as described below.

4. *Ply*: As mentioned earlier, ASME defines a ply as ‘one discrete piece of manufactured material (e.g., fabric, tape,

Hedberg Jr., Thomas; Barnard Feeney, Allison; Srinivasan, Vijay. "On Practice and Theory of Constructive Composite Geometry and Topology." Paper presented at ASME 2019 International Design Engineering Technical Conferences and Computers and Information in Engineering Conference, Anaheim, CA, US. August 18, 2019 - August 21, 2019.

adhesive film)' [3]. The primary geometrical representation of a ply is that of a surface with certain thickness. Using the textile metaphor, a ply is like a cloth or a fabric. It can be viewed as a flat surface before a lay-up, and it can be draped as a curved surface on what has been already laid-up or on a tool surface.

The ply is flexible, and it can be tucked and squeezed to conform to the surface to which it is adjoined. The ply thickness may not remain constant during this lay-up operation; the main objective is to make the 'bottom side' of the ply stick to the surfaces on which it is laid without leaving any voids or holes. This poses some interesting challenges in modeling a ply as a 3D solid. This also contributes to the caution about commutativity and associativity of the adjoin operation raised earlier.

5. *Orientation*: Plies also encapsulate reinforcement fibers, both physically and informationally. This will be addressed later in Section 5 in some detail. An important information related to the fibers in a ply is their relative orientation with respect to an external reference frame, which can be established using datums mentioned earlier.

   The angles mentioned in the 'orientation' column of the ply tables seen thus far provide such information. Additionally, a local reference frame called a 'rosette' (as shown in the center of Fig. 1) can be affixed on a ply surface – sometimes in many places on a ply surface – to specify the orientation of the fibers within a ply. Figure 10 shows several examples of such ply orientation symbols associated with rosettes. An example of the use of a guide curve and rosettes is illustrated in Fig. 11. More rosette types and their usage can be found in the recent ASME standard [3]. A rosette is like a two-dimensional compass placed on an undulating terrain, indicating the local directions along which the fibers in a ply should be oriented.

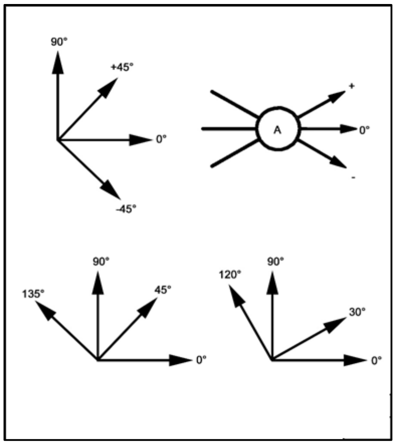

Fig. 10 Examples of ply orientation symbols [3].

6. *Material*: The identifier mentioned in the 'material' column of the ply tables provides the link to much richer information to various other material information about the plies, including critical information about the reinforcement fibers and resins.

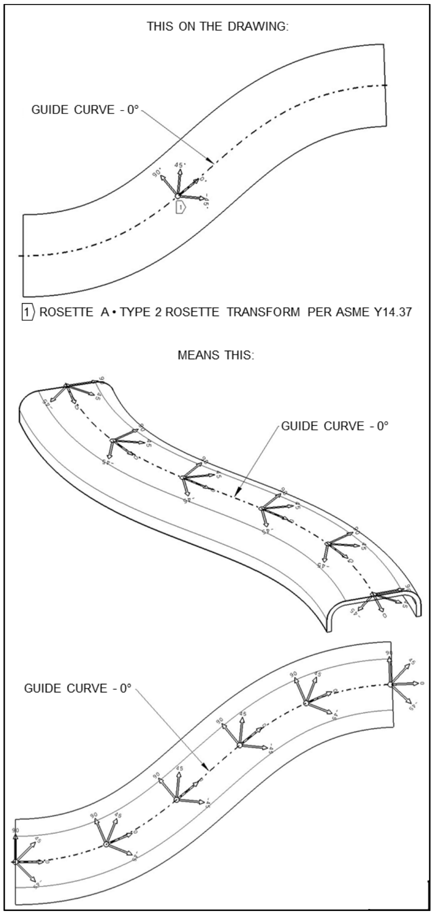

Fig. 11 An example of using a particular type of rosette [3].

The CCG tree is similar to the more familiar constructive solid geometry (CSG) tree [6, 7]. Both are procedural representations from which other representations can be derived. For example, a boundary representation (also known as B-rep) of a solid can be derived from its CSG representation to facilitate several important applications. Following this line of thinking, one may expect that an explicit cell-complex representation of a composite product may be derived from its CCG representation. It turns out that this requires a careful consideration of the topology of the composite products, which will be addressed next.

4 Constructive Composite Topology

The concept of topology captures the notion of adjacency of geometrical objects without paying too much attention to the underlying geometrical details. This does not mean that the geometrical details do not matter; the adjacency of 3D cells in a composite product critically depends on how various plies and other items are positioned in an assembly. Topology, represented as an adjacency graph, turns out to be one of the most robust properties that should be captured in a composite product definition and controlled in its manufacturing.

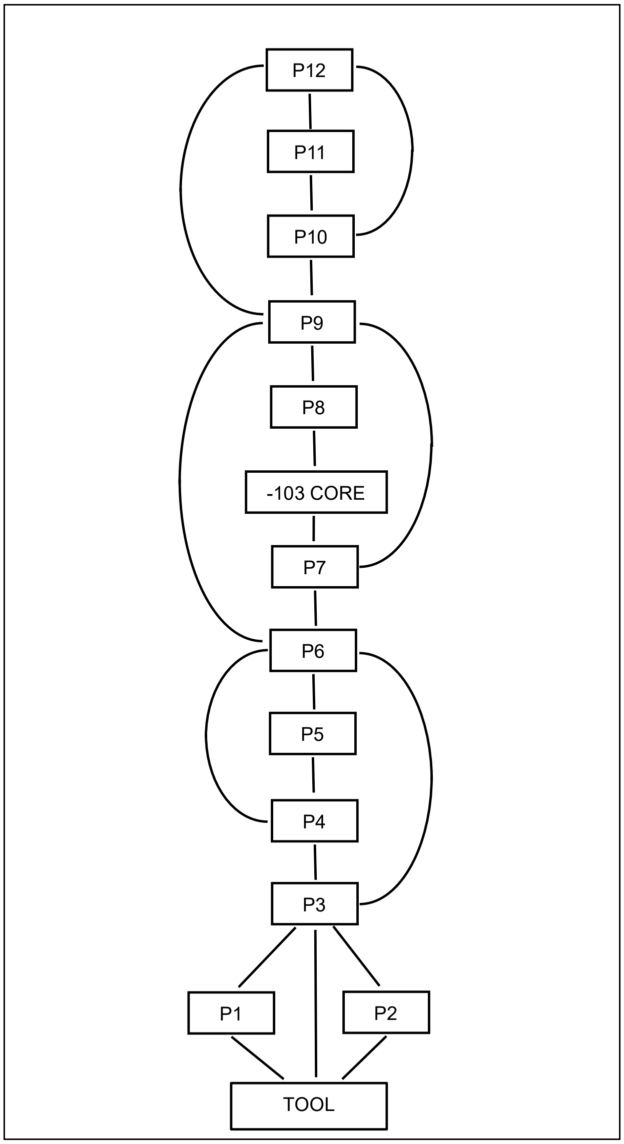

Fig. 12 A CCT graph for the -101 BOND ASSEMBLY in Table 1 and Figs. 2 and 7.

To establish the adjacency of 3D objects in a composite product, consider the plies, cores, and fillers as 3D solids. Figure 12 shows an adjacency graph of the constructive composite topology (CCT) for the -101 BOND ASSEMBLY in Table 1 and Figs. 2 and 7. A similar CCT graph for the -1 BOND ASSY seen earlier in Figs. 5 and 8 is shown in Fig. 13. Also, the CCT graph for the -1 BOND ASSY encountered earlier in Figs. 6 and 9 is shown in Fig. 14. In all these three CCT graphs, the nodes are the plies, cores, fillers, tools, and precured subassemblies; these are displayed as rectangular boxes. The arcs represent the fact that the solids in the nodes joined by each arc have a finite surface area of contact in the uncured state of the bonded assembly.

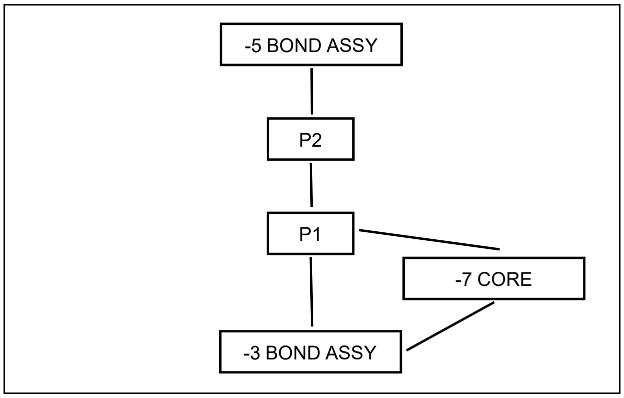

Fig. 13 A CCT graph for the -1 BOND ASSY in Figs. 5 and 8.

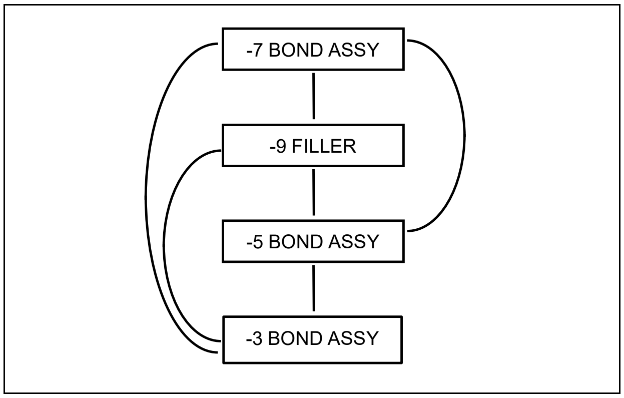

Fig. 14 A CCT graph for the -1 BOND ASSY in Figs. 6 and 9.

Figure 15 illustrates the cell structure and the adjacency relationship using an example previously encountered in Figs. 5, 8, and 13. The cross-sectional view in Fig. 15 captures only a small portion of the bonded assembly, and the dimensions are exaggerated for clarity. The core and the plies in this example are bonded to the objects on which they are laid. It is important that no 'air bubble' or 'air hole' is introduced in the lay-up process or

Hedberg Jr., Thomas; Barnard Feeney, Allison; Srinivasan, Vijay. "On Practice and Theory of Constructive Composite Geometry and Topology." Paper presented at ASME 2019 International Design Engineering Technical Conferences and Computers and Information in Engineering Conference, Anaheim, CA, US. August 18, 2019 - August 21, 2019.

in the 3D model creation. This poses a challenging problem when approximations to the 3D models, such as tessellated polyhedra, are used for 3D representations of various constituents in a bonded assembly.

Each of the four objects in Fig. 15 is considered as a 3D cell. If any two of these 3D cells have a contact over a surface area, then they are joined by an arc in the CCT graph shown in Fig. 13. This illustrates the concept of adjacency used in all the three CCT graphs shown in Figs. 12, 13, and 14.

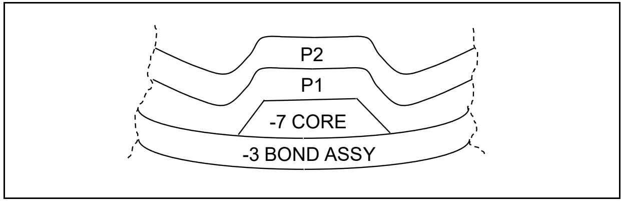

Fig. 15 Cross-section of a portion of an approximate 3D model of the cell-complex of the '-1 BOND ASSY' in Figs. 5 and 8. Drawing is not to scale.

As a further illustration of the CCT graph, consider the example shown in Figs. 1, 2, and 3. Figure 16 shows the cell structure and the adjacency relationship using a cross-sectional view of an approximate 3D model. Such topological information is represented only in a CCT graph; it is not available explicitly either in an exploded view such as Fig. 3 or in a ply table such as Table 1.

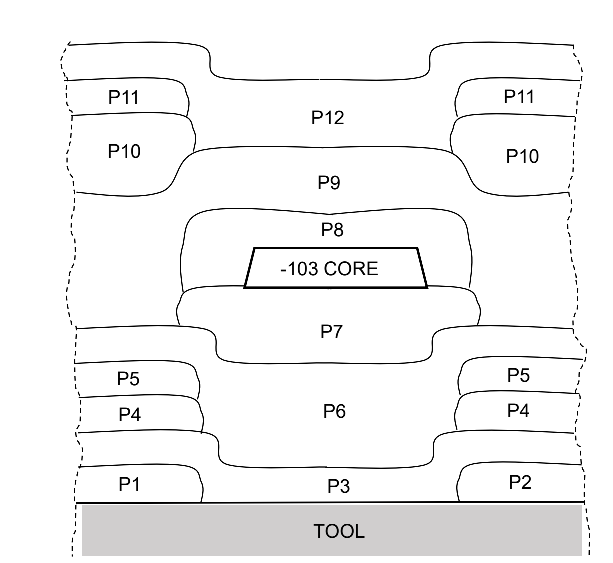

Fig. 16 Cross-section of a portion of an approximate 3D model of the cell-complex of the '-101 BOND ASSEMBLY' in Figs. 1, 2, and 3. Drawing is not to scale.

It is also clear from Figs. 15 and 16 that 'ply thickness' is not a simple number after the ply is stacked up in a laminate in an uncured state. These plies are indeed pliable, and they undergo a homeomorphic transformation as they go from the state of a flat fabric into a stacked-up ply in a laminate in an uncured state. Again, it is important to avoid any air pockets or air holes (neither 'through holes' nor 'blind holes') during the stack-up process.

With these examples as preliminaries, the following observations can be made about the structure and property of the CCT graph.

1. *The CCG tree provides a useful input to build the CCT graph*. The adjoin operation in the CCG tree suggests an adjacency relationship between its operands. CCT graph contains these relationships, but it also captures more adjacency relationships.

2. *The CCT graph is a subgraph of the dual graph of the cell complex*. Algebraic topology of a cell complex, as applied to a composite product, consists of a hierarchy of 3-cells (solids) bounded by 2-cells (surfaces) bounded by 1-cells (edges) bounded by 0-cells (vertices) [14]. A dual graph of this cell complex will include cells of all these dimensions; but the CCT graph captures only the 0 and 1 dimensional subsets of this dual graph.

3. *The plies undergo a homeomorphic transformation in the lay-up process*. The plies start out as flat fabrics. As a ply is draped in the lay-up process by tucking, stretching, and squeezing, it undergoes a homeomorphic transformation, which is a basic notion in topology [14]. Under such a homeomorphic transformation, neighboring points of a ply remain as neighbors. This is an important property that is observed during the lay-up process to ensure the integrity of the reinforcement fibers (e.g., no tearing) contained in the plies. It is also an important property that can be used in 3D modeling of the laid-up plies in an uncured state.

   Such homeomorphic transformations are shown, albeit with some exaggeration, in Figs. 15 and 16. The ply thickness can undergo changes under this transformation. But it can be argued that the volume of the ply remains the same, obeying the conservation of mass (before curing). Thus, the most robust statement that can be made is that the plies undergo a volume-preserving homeomorphic transformation during the lay-up process.

4. *The CCG tree and CCT graph serve as important primary elements of the procedural representation*. The robustness of CCG trees and CCT graphs has been well established in the industrial practice though decades of use in the form of ply tables and accompanying figures. Taking them as important primary representations, explicit 3D representations may be derived as needed for the uncured laminates and cured bonded assemblies. This is similar to the derivation of a B-rep from a CSG representation of a

solid, where the CSG is the primary (procedural) representation and B-rep is the derived (explicit) representation [6, 7]. Specific composite manufacturing properties, such as volume-preserving homeomorphic transformations mentioned above, may be utilized for constructing the 3D representations of such cells.

5 Geometry and Topology of Reinforcement Fibers

Plies contain reinforcement fibers that contribute much of the strength and stiffness to the composite products. These fibers are combined using textile technologies, such as weaving, stitching, seaming, and braiding, to form various patterns in a fabric. Such fabrics can be created as ‘preforms’ as shown in Fig. 17, where each colored strip contains many fibers. These preforms can also be impregnated in resins to create plies as ‘prepregs’ that can be handled as cloths, as shown in Fig. 18.

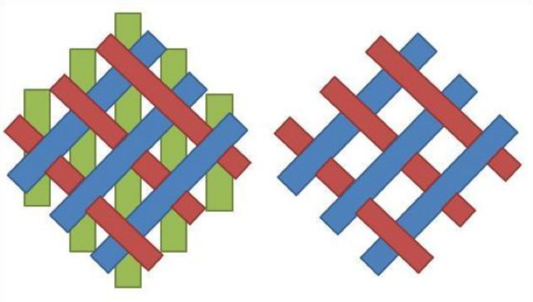

Fig. 17 Examples of preforms in creating plies [15].

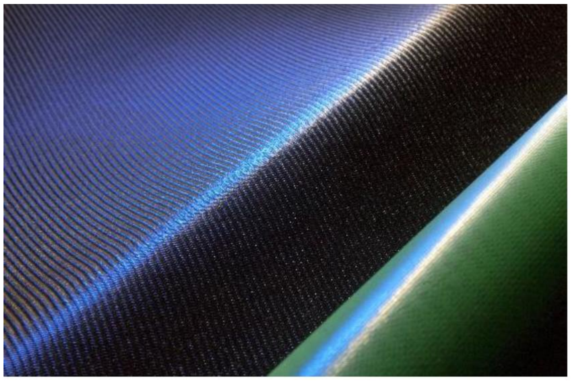

Fig. 18 Example of prepregs in creating plies [16].

The ASME and ISO standards do not address the details of the fiber arrangements in plies. Instead, they refer to other standards such as the ASTM standard on stiches and seams [17]. The ‘material’ attribute in the ply table provides links to such fiber arrangement details within each ply.

The geometry and topology of the fiber arrangements in a ply can benefit from research literature on textiles [18]. When a ply is draped as a cloth to form a laminate, the local orientations of the fibers receive a great deal of attention in practice, as illustrated in Fig. 11 using rosettes. From such standardized practices, a theory for the geometry and topology of bundles of reinforcement fibers can be derived using the following two important invariance properties:

1. *Conformal mapping to preserve local fiber orientations*. When a flat fabric containing reinforcement fibers is draped onto a curved surface, as shown in Fig. 11 for example, the local orientations of fibers are preserved within each ply. This practice can be directly related to the theory of conformal mapping of oriented surfaces, which preserves the angles and shapes of infinitesimally small figures but not necessarily their sizes or curvatures [19]. In fact, the standardized definitions of rosettes [3] and their usage in practice can be formalized mathematically as conformal mapping of oriented surfaces. Such mappings occur in the lay-up of each ply to form a laminate before the curing operation. These fiber orientations are also expected to be preserved in the cured state of the composite product, within some orientation angle tolerance.

   In a typical conformal mapping of oriented surfaces, the ‘domain’ surface is parameterized using (u, v) coordinates, and it is mapped to a ‘range’ surface that is parameterized using (u', v') coordinates. It is then customary to talk about u-curves being mapped to u'-curves, and v-curves being mapped to v'-curves. In the context of manufacturing of composite products, these u-curves, u'-curves, v-curves, and v'-curves take on a physical meaning. These curves are the representations of the fibers in a semi-discrete form. An interesting constraint that arises in such conformal mapping is that the fiber lengths are preserved in the lay-up process.

2. *Preservation of fiber adjacency between layers*. As noted in Fig. 4, the cured composite part does not preserve the interfaces between the plies. However, the adjacency relationships among the plies and other items established in the CCT graph (such as Figs. 12, 13, and 14) are inherited by the bundles of fibers contained in these plies. This provides two important types of information about the bundles of fibers in a cured composite product: (1) Each bundle of fiber is given an identifier that is inherited from the ply within which it is impregnated; (2) A partial spatial ordering of these bundles of fibers in the cured composite product can be derived from the CCT graph. Such information is important for inspection (e.g., nondestructive testing) and structural analysis purposes. For example, a cluster analysis of fibers in a 3D computed tomography image of a cured composite product may benefit greatly from a prior knowledge of the adjacency of bundles of the fibers.

6 Summary and Directions for Future Research

This paper took some initial steps towards a theory of constructive composite geometry and topology. This theory is synthesized from industrial best practices codified in recent ASME and ISO standards [3, 4]. It is also motivated by the need for better scientific tools to explore new frontiers in modeling material structures that are produced by modern manufacturing technologies [2]. The major features of this theory are:

1. A CCG tree, which maintains a one-to-one mapping with the ply/laminate table standardized by ASME and ISO. An 'adjoin' operation in the CCG tree defines the bonding (both physical and chemical) between various plies and other items in the assembly.

2. A CCT graph, which captures the adjacency relationship among plies and other items in an uncured state of a laminate, and this adjacency relationship is inherited by the bundles of fibers in the cured composite product.

3. A conformal mapping between a flat ply surface and a draped ply surface in a laminate; this mapping preserves the local orientations of fibers (in terms of angle between fibers) as standardized by ASME and ISO using rosettes and other orientation specifications.

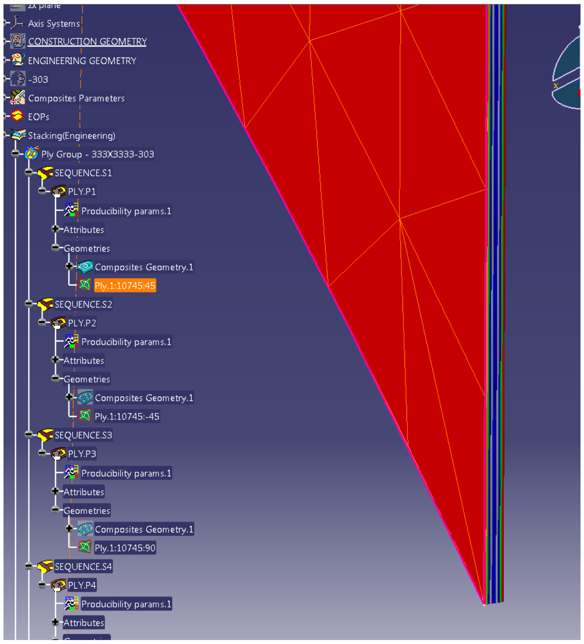

Fig. 19 Example of a composite part used for testing standardized 3D model data exchange [20].

Some of these theoretical abstractions have been implemented already in practice. In major CAD systems that support composite products, a 'model tree' is a prominent visual component of the user interface; this can be easily related to the CCG tree. Figure 19 shows a screen shot of a composite part used for testing standardized 3D model exchange [20]. It clearly shows a tree-like representation for the ply stack-up under the 'Stacking (Engineering)' node in the model tree displayed on the left.

While these are encouraging signs, more research and standardization need to be undertaken along the following lines:

- The CCG tree and CCT graph can be extended to cover more composite manufacturing technologies such as infusion, pultrusion, and braiding. Recent ASME and ISO standards have already taken initial steps in this direction [3, 4].

- 3D modeling of uncured and cured states of composite products can be improved considerably, with proper attention to the conformal mapping of ply surfaces and the homeomorphic transformation of ply (and other) solid cells, as described in the body of the paper.

- Better harmonization of ASME and ISO standards is needed so that the composite product definition practices and 3D models for information exchange are properly aligned.

***Abstract*— The Third Generation Partnership Project (3GPP) defines various pre-configured channel parameters for the Long-Term Evolution (LTE) Device-to-Device (D2D) communications with Physical Sidelink (SL) Channels. In this paper, we investigate the impacts of channel parameter settings on the performance of content deliveries for Public Safety Network (PSN) applications in Out-of-Coverage (OOC) scenario. We first measure the reliability of the SL channels under various sets of channel parameters using Monte Carlo simulations. Then, for a given PSN application, the acquired reliability results are utilized to help determining the amount of delay that is to be introduced to the system, such that the throughput requirement for the application is assured during the transmissions. To the best of our knowledge, this is the first LTE D2D work that focuses on OOC mission-critical communications performance in group traffic settings. Our results are valuable to both network operators, for using them as references in selecting a best set of channel parameters, and to future studies on more complex transmission patterns and network scenarios using D2D communications in PSNs.**

I. Introduction

A. Background

During disasters, network infrastructures become susceptible to damages, and sometimes the entire network connection could be cut out [1]. To resolve this challenge we investigate the mission-critical communication (MCC) performances of the LTE Device-to-Device (D2D) communication protocol, ProSe (Proximity Services), when operating in Out-of-Coverage (OOC) environment under communication Mode 2.

Mode 2 communications in ProSe utilize the LTE Uplink resources to form Sidelink (SL) communication channels known as the ***P**hysical **S**idelink **C**ontrol **Ch**annel* (PSCCH) and the ***P**hysical **S**idelink **S**hared **Ch**annel* (PSSCH) that allow User Equipment (UEs) to establish direct communications, broadcasting in nature, without any backhauling. Due to this reason, it is considered as a prominent technology for group voice/data deliveries in OOC scenarios, both in the current LTE PSN settings and for ubiquitous applications in the future Fifth Generation New Radio (5G NR) settings.

However, since in OOC scenario there is no centralized coordination of the UEs, individual UEs allocate their own resources in the SL Resource Pool (RP) autonomously. This competitiveness among devices can cause severe packet losses. In this work, we adopt the packet loss models proposed in [2], [3], where packet loss is caused by Collision and Half-Duplex Effect (HDE). Later, we review the packet loss model and how to detect packet loss in the channels in Section III.

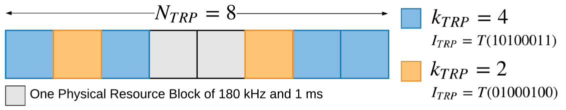

Fig. 1. **Time Resource Pattern (TRP)**: I_{TRP} is the index of the TRP mask which is a binary bit map of length N_{TRP}; when a mask bit is 1 then that bit is to be used for transmitting one data TB in the PSSCH; k_{TRP} is the number of subframes a UE can allocate its TBs within one N_{TRP} length, hence representing the number of 1's in a TRP mask. We fix $N_{TRP} = 8$.

In addition, due to its broadcasting nature, D2D communication does not have acknowledgment. To mitigate potential packet losses, two methods are specified by 3GPP [4]: $i)$ by transmitting duplicate copies of the Transport Blocks (TBs); specifically, two copies for the Sidelink Control Information (SCI) TBs, and four copies for the associated data message TBs. As well as, $ii)$ by limiting, k_{TRP}, the number of subframes each UE can allocate in every $N_{TRP} = 8$ subframes in the PSSCH, where TRP stands for Time Resource Pattern. The concept of TRP is illustrated in Fig. 1 with more details.

B. Problem Description

To test the performance of the proposed D2D solution in mission-critical settings, we considered an OOC group communication scenario with Mode 2 communications among N_u Half-Duplex UEs held by First Responders (FRs), all within each others' proximity. Now assume the group leader, denoted by UE-1, has an MCC message that must be disseminated to ALL the other $(N_u - 1)$ UEs in the group.

§ First, we examine the successful transmission probabilities of the SL channels by defining the **PSCCH Reliability** $\mathbb{P}\{\mathcal{S}_C\}$ and the **PSSCH Reliability** $\mathbb{P}\{\mathcal{S}_D\}$ as the probabilities of the following two events, respectively:

• $\mathcal{S}_C$: **successful reception of leader's SCI TB(s)**, "the event where all the other $(N_u - 1)$ UEs would receive at least one copy of UE-1's non-collided SCI TB in the PSCCH of a single independent SL period."

• $\mathcal{S}_D$: **successful reception of leader's data TB(s)**, "the event where all the other $(N_u - 1)$ UEs would receive at least one copy of UE-1's non-collided data TB in the PSSCH of a single independent SL period where event $\mathcal{S}_C$ took place."

Feng, Siyuan; Choi, Hyong-Ah; Griffith, David W.; Rouil, Richard A. "On Selecting Channel Parameters for Public Safety Network Applications in LTE Direct." Paper presented at IEEE Consumer Communications & Networking Conference (CCNC), Las Vegas, NV. January 10, 2020 - January 13, 2020.

§ Secondly, we consider a PSN application with a certain throughput requirement of $\mathcal{Q}$ bits/sec that is to be fulfilled, i.e., the Guaranteed Bit Rate (GBR) of that application. We are interested in the question that: while guaranteeing event $\mathcal{S}_D$ in the proximity, what is the best channel configuration that is to be used by the system such that the UE-1 reaches $\mathcal{Q}$ in the transmissions? We compare the efficiencies among each set of channel parameters through the notion of **Amount of Delay** that is introduced to the system during the transmissions.

We propose to examine the above metrics within the domain defined by the pre-configured SL channel parameters [5] presented in Table I. This is because, in consideration of FR UEs' precious yet limited battery life, it is reasonable to argue that the FR UEs should be set up before being deployed to a disaster site. Even if the settings are to be adjusted on-the-fly, it would still be more power efficient to switch among these pre-configurations. We discuss these pre-configured channel parameters and their impacts in later sections.

To the best of our knowledge, this is the first LTE D2D communications work that focuses on OOC MCC performance in group traffic settings, where the channel parameters are meaningful from 3GPP standard perspective; and could have practical impacts on promoting further research and development of the ProSe in public safety domains.

The rest of the paper is organized as follow. In Section II, we briefly review related work. Then, in Section III and IV, we present our main results on the two identified problems and the methodologies on acquiring these results. Lastly, we conclude our paper and briefly talk about future work in Section V.

II. Related Work

In [2], [3], Griffith et al. analytically modeled the channel reliability problem for PSNs and conducted extensive validations through simulating the SL channels. However, their work did not consider the throughput factor of the UEs; hence has yet to address the impacts of channel reliability onto the higher layers. Also, in their simulations, unlike ours, the channel parameters were rather artificial.

In [6], Cipriano and Panaitopol did investigate the throughput factor; however their work did not focus on the mission-critical aspect. More specifically, both their criteria for a successful transmission and throughput were aggregated over all the UEs. However, we consider the delivery of the leader's message of utmost importance. Also, best-effort throughput is not the most proper metric for limited PSNs, since the extra throughput would be "wasted" after the GBR is met.

To the best of our knowledge, most existing literature discuss performances utilizing the aggregated throughput notion. Hence, by considering the MCC Quality-of-Service perspective, our work is rather novel; and our results will be more prospective and beneficial to the public safety community.

III. Channel Reliability

A. Packet Loss in SL Channels

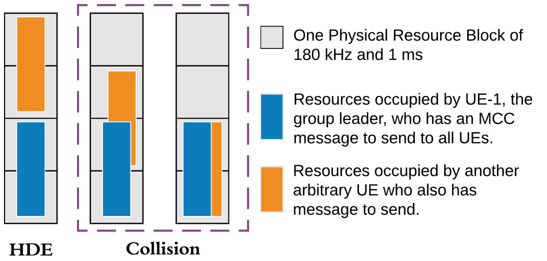
Now, we briefly review the two factors causing packet losses in SL channels; the general idea is being illustrated in Fig. 2. Then we discuss the steps on how to detect packet losses in the PSCCH and PSSCH.

First of all, since the UEs being considered are using Half-Duplex transmissions, i.e., if a UE is transmitting at one subframe, it won't be able receive at that subframe. Thus, in this case, as shown in the left-most of Fig. 2, the UE with its TB labeled with orange will not be able to hear the leader's transmission at that subframe, and vice versa. However, all the other UEs who are not transmitting at that subframe will be able to hear both.

Secondly, if two UEs' allocated TBs reside in the same subframe and occupy the same set of resources, then a "hard" collision happens to these two set of TBs. In this case, unlike in HDE, not only the two UEs will not be able to hear each other, but also, since these transmitted signals would add up with each other, none of the other UEs who can hear the TBs can differentiate nor successfully decode them. Thus, these two TBs and the encoded bits are to be completely discarded.

There also exists the "soft" collision scenario, where two TBs are partially overlapped. However, since all UEs are within each others' proximity, considering the worst case that the interference would still be too much for anyone to separate the two signals. Hence, these two TBs are still to be discarded. More delicate decisions could be done in the future for this part, such that when the signal-to-interference ratio is high enough, the collided TB(s) could be somewhat recovered.

Also note that, without the instructions encoded in the SCI, UEs will not be able to monitor the correct Physical Resource Block (PRB) spectrum that contains the associated data. Hence, a successful reception of the SCI is the premise of a successful reception of the data.



One Physical Resource Block of 180 kHz and 1 ms
Resources occupied by UE-1, the group leader, who has an MCC message to send to all UEs.
Resources occupied by another arbitrary UE who also has message to send.
HDE
Collision

Fig. 2. **Packet Loss Model**: from left to right, each sub-figures showcases the Half-Duplex Effect, the "Soft" Collision, and the "Hard" Collision; where each TB occupies 2 PRBs.

§ Now, for event $\mathcal{S}_C$, in order to detect packet loss in the PSCCH based on our model, we employ the following steps:

1) Since a collision in the PSCCH only happens when two UEs choose the exact same random number n_{PSCCH}, to check for collisions, we simply compare UE-1's random numbers with those of the other UEs. If any UE chooses the same random number as UE-1 does, then, by our assumption, this whole SL period is going to be discarded.

2) Then to check for full HDE, we first compute the SCI allocation subframe numbers (b_1, b_2) from n_{PSCCH} [4] for each UE; and check if there is any UE who has the exact

same subframe pair as UE-1 does; i.e., if any UE will miss both SCI TBs of UE-1.

§ Now, given event $\mathcal{S}_C$ took place in an SL period, for event $\mathcal{S}_D$ in that period, to detect packet loss in the PSSCH, we employ the following steps:

3) First we perform a quick pre-check for full HDE by inspecting if any UE chooses the same I_{TRP} as UE-1 does; i.e., if any UE will miss all four data TBs of UE-1.

4) Then to check for collisions for UE-1, we do the following: for an non-leader UE, at subframes where it shares allocations with UE-1, we check the overlapping situation their TBs in the frequency-domain; if at a subframe these two TBs are colliding, then for UE-1, its TB at this subframe is going to be discarded. We perform this for all non-leader UEs, and check if all of UE-1's TBs are collided.

5) Lastly, for UE-1's remaining non-collided TBs, we iteratively check for HDE by comparing the TRP masks again.

B. PSSCH Reference Measurement Settings

From the packet loss model, it can be seen that given a fixed channel bandwidth and some number of simultaneous transmitters N_u, in the time-domain, the likelihood of HDEs taking places is affected by the lengths of the channels and how the TBs spread out in time within the corresponding channels; while in the frequency-domain, the likelihood of collisions taking places is affected by the allocation size of the TBs.

For SCI messages, 3GPP specifies all the TBs are to occupy only one PRB [4, Table A.6.4-1]; and the spread between the two TBs in time is deterministic. Hence $\mathbb{P}\{\mathcal{S}_C\}$ is only affected by N_u and the length of the PSCCH, L_{PSCCH}.

On the other hand, for data TBs, the *Fixed Reference Measurement Channel for PSSCH* [5, Subclause A.6.5], shown in Table I, defines five different TB schemes with varying Allocated RBs amounts and Modulation of Coding Scheme (MCS) Indices pairs for 10 MHz bandwidth channels. Hence, $\mathbb{P}\{\mathcal{S}_D\}$ is affected by not only N_u, the length of the PSSCH, and $\mathbb{P}\{\mathcal{S}_C\}$, but also the CD (which is an indexing prefix, not an acronym) setting used, as well as k_{TRP}, which stochastically determines how the four data TBs spread in time.

TABLE I
PSSCH REFERENCE MEASUREMENT CHANNEL

Ref. Channel	Allocated RBs	TB Size	MCS Index
$CD.1$	10	872	5
$CD.2$	10	2536	14
$CD.4$	50	12960	14
$CD.5$	2	328	10
$CD.7$	50	25456	23

C. SL Channel Resource Pool Settings

Before the evaluation on channel reliability, we configure our channel RP accordingly. We assume all the 50 PRBs are utilized for SL during public safety events. Also, in the evaluation, we assume all UEs are having good enough signal strengths for demodulating data TBs with varying CD settings; hence we categorize the references into three classes based on the allocation sizes, namely, $CD.5$, $CD.1/2$, and $CD.4/7$. Other RP-related settings are configured as follow:

1. Length of the PSCCH, L_{PSCCH}, is set to 24 subframes per period; based on the result in [2, Fig. 10], such that when $N_u \leq 15$, $\mathbb{P}\{\mathcal{S}_C\}$ is at least the target reliability of 95 %.

2. k_{TRP} is set to either 2 or 4 subframes per TRP mask length (8 subframes). This is because when $k_{TRP} = 1$, too few masks are available, hence the chance of getting HDE is going to be higher; whereas when $k_{TRP} = 8$, HDE will always happen when there are more than 1 transmitters [3].

3. SL Period Length, L_{Period}, is chosen from the values in $\{40, 80, 160, 320\}$ subframes per SL period [7], and is derived from the combined lengths of the PSCCH and PSSCH. Since this factor only affects throughput, for the channel reliability part, we simply simulate under the 40 subframes setting; i.e., there are 16 subframes in the PSSCH, which fits in exactly two sets of TRP masks. This is important since if $k_{TRP} = 2$, two sets of TRP masks are required in order complete one transmission of the four copies of the data TB. Whereas, if $k_{TRP} = 4$, two non-duplicate transmissions can be made.

Later, when throughput is involved, the period length matters in the same way that it determines how many TRP masks there are within one SL period; hence affects the number of non-duplicate transmissions that can be done per period.

D. Evaluation on Channel Reliability

Since currently there is no D2D-enabled chipset publicly available, conducting hardware tests is not an option. Hence, given RP settings, and varying UE and channel parameter settings, we evaluate the channel reliability by conducting Monte Carlo simulations, as follow: $i)$ at each SL period, UEs' SCI TBs and data TBs are generated and allocated in corresponding channels based on the SL UE procedures; and then $ii)$ using the packet loss detection schemes described above, we observe whether events $\mathcal{S}_C$ and $\mathcal{S}_D$ take place at that period. Overall, for each set of channel parameter settings, we check $\mathbb{P}\{\mathcal{S}_D\}$ out of 20 000 (sufficiently large) independent successful $\mathcal{S}_C$ events. In the experiment, all the UEs are transmitting with the same set of parameters. The reliability results over all the possible channel parameter setting combinations are shown in Fig. 3.

In Fig. 3 on the left, we observe that, for a given N_u, the $\mathbb{P}\{\mathcal{S}_C\}$ is not affected by simulation variables. We also note that the PSCCH reliability of at least 95 % with the given RP structure is consistent with the results in [2]. On the right, when $N_u > 2$, different parameter pairs result in drastically varying PSSCH reliability results. As we can observe from the results, by choosing different CD and k_{TRP} pairs, there is a trade-off between having a higher throughput and having a higher reliability. We will address this trade-off in the next section.

Here, we only present the reliability results obtained from one of many runs of our Monte Carlo simulations. The differences among the results of the runs, for the same settings, are no more than 0.5 %. Hence, the results are representative.

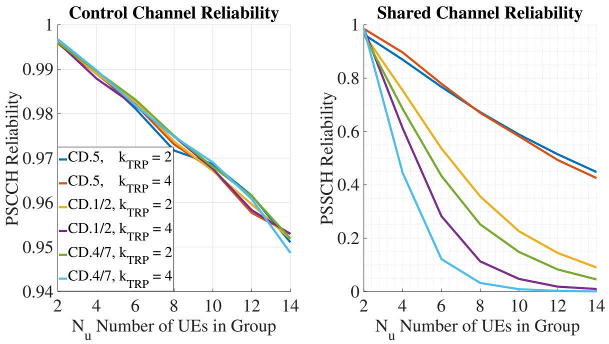


Fig. 3. Simulated results of **PSCCH Reliability** $\mathbb{P}\{\mathcal{S}_C\}$ (left) and **PSSCH Reliability** $\mathbb{P}\{\mathcal{S}_D\}$ (right) for different chosen CD Reference Measurements and k_{TRP} combinations under various N_u values.

IV. Throughput Planning and Delay

In this section, we incorporate the channel reliability results acquired above with the notion of PSN application GBR $\mathcal{Q}$ and try to derive the amount of delay metric. In order to do so, we propose a duplicative transmission scheme that assures the success of group deliveries of each second-worth data; and based on the amount of duplications needed for each SL period under different channel parameter settings, we calculate the amount of delay.

In our experiments, the PSN application GBR values are originally conducted by the Minnesota Department of Public Safety [8] and later modified by the Communications Technology Laboratory (CTL) at the National Institute of Standards and Technology (NIST) with additional network-layer overhead added. Since the reference channel parameters act between the network-layer and the transport-layer, the GBRs we utilize are compatible with the cross-layer settings.

A. Data Broadcasting and Throughput

We observe that, in order for UE-1 to successfully broadcast its application content in the SL channel and attain a throughput at least the amount $\mathcal{Q}$, it needs to transmit in multiple periods within a one second window. The number of transmissions, given an SL RP, then depends on $i)$ the period length L_{Period} and $ii)$ the k_{TRP} setting of the UEs, as explain in the following.

$i)$ For example, if the SL period length is 40 ms, then there are going to be $\lfloor 1000/40 \rfloor = 25$ full SL periods that can be utilized for transmissions; comparing with if the SL period length is 80 ms, then there are fewer, 12, full periods that can be utilized. However, when using a longer period, the data rate (not the actual throughput) is going to increase. When the period length is 80 ms, besides the 24 subframes of control region, the remaining 56 subframes can accommodate 6 TRP masks per period; comparing with only 2 per period in the 40 ms period length case. Later, we denote the number of full periods per second as ρ, and number of TRP masks within one period as γ.

$ii)$ Meanwhile, given the same RP, if $k_{TRP} = 2$, then within each TRP mask, only 1 transmission can be done, since in this case only half of the 4 copies are going to be allocated within each of 8-subframe set; comparing with when $k_{TRP} = 4$, within each period, 2 transmissions can be done, where the second transmission has the exact same allocation as the first one; i.e., the PSSCH reliability stays the same. However, this does not necessarily mean the throughput is increased when using the tighter mask, since as we can see from the reliability results, in most cases, the reliability is significantly lower when $k_{TRP} = 4$ comparing to that when $k_{TRP} = 2$ under the same N_u and CD settings. Thus when $k_{TRP} = 4$, it is more likely to have packet loss taking places, which will jeopardize the whole transmission. Thus, by having a longer period, the penalty for packet loss is going to be higher than that of having a shorter period.

Hence, both factors play important roles in attaining a desired throughput for UE-1, along with the actual allocation choices, i.e., the CD options for PSSCH reference measures.

B. Performance Evaluations

Now we begin to discuss the throughput planning part of our study, where given a fixed number of N_u FR UEs, a PSN application with GBR $\mathcal{Q}$, we want to check if it would be possible for UE-1 to achieve latency-free transmissions, and if not, what is the amount of delay that should be expected?

We introduce the notion of *overall transmission successful probability*, $\mathcal{P}$, as the transmission successful probability over i contiguous periods within each independent second; and if the single period channel reliability is p, then we have $\mathcal{P} = p^i$. We define the target probability as $\hat{p}$; hence as long as $\mathcal{P}$ reaches the target threshold, the second-wise transmission is considered to be successful.

Next, we investigate how the factors mentioned above, i.e., L_{Period}, k_{TRP}, and the selected CD Reference Measurement affect the transmission performance, measured through the delay amount δ. In reality, this evaluation is conducted before the deployment taking place, such that the preferable parameter setups can be implemented for the channel and UEs beforehand; and also after the deployment a UE can switch to a different CD setup that is more appropriate for its own demand based on the obtained results.

We demonstrate the process on how to obtain the amount of delay for an application under various channel and UE settings, by giving a walk-through for the "Next Generation 911 (NG911) Video Medium Resolution" streaming application, with $\mathcal{Q} = 274,562$ bits/sec, when $L_{Period} = 40$ ms, as follow. The formal algorithm description for obtaining the delay amount δ is given by **Algorithm 1**.

1. We first assume all ρ periods within a second are to be used for transmission, to get the minimum throughput that must be met for each transmission and use it to decide what are the choices among the CD settings that are valid for our current parameter settings, by averaging $\mathcal{Q}$ over the total number of transmissions within one second. In the example,

Algorithm 1 Amount of Transmission Delay per Second

```
Input: GBR of Application $Q$, Period Length $L_{Period}$, UEs' $k_{TRP}$,
    Threshold for Overall Transmission Successful Probability $\hat{p}$;

```

there are $\rho = 25$ full periods. If $k_{TRP} = 2$, the number of 16-subframe pairs is $\gamma = \lfloor (40-24)/16 \rfloor = 1$; and if $k_{TRP} = 4$, the number of 8-subframe sets is 2. Then, the total number of transmissions would equal to $(25 \times 1 \times k_{TRP}/2)$.

If $k_{TRP} = 2$, then each period can only allocates one transmission; hence, if all the 25 periods are being used for the transmission, each period must attain a TB of size $\omega = \lceil \mathcal{Q}/25 \rceil = 10983$ bits/allocation, which maps to the $CD.4$ Reference Measurement. Then, if we divide the GBR by the product of the TB size of $CD.4$ and the number of transmissions per period, we would find that if $CD.4$ is used as the allocation scheme, then $\eta = 22$ full periods are actually going to be needed. Here, we assume when all the periods are transmitting, the choice is $CD.4$. If we plan to use $CD.7$ which has a larger TB size, even fewer periods, $\eta = 11$ are going to be needed. Let us denote when $k_{TRP} = 2$ and using $CD.4$ as **Case a)**, and when $k_{TRP} = 2$ and using $CD.7$ as **Case b)**.

If $k_{TRP} = 4$, which doubles the throughput in each period, then the minimum required TB size would be about halved, $\omega = 5492$ bits/allocation, and this again maps to the $CD.4$ Reference Measurement. Similarly, we can choose a higher TB size. If we choose to transmit with $CD.4$, then $\eta = 11$ periods are needed; if $CD.7$ is chosen, then $\eta = 6$. We denote when $k_{TRP} = 4$ and using $CD.4$ as **Case c)**, and when $k_{TRP} = 4$ and using $CD.7$ as **Case d)**.

2. Now, given number of UEs in the group, say, $N_u = 2$, we want to compute $\mathcal{P}$ as p^{η}, i.e., using only η periods.

Hence, for **Case a)**, where $p = 96.41$ %, $p^{11} = 44.74$ %, which is going to be significantly lower than $\hat{p}$, the threshold for having a successful transmission over one second. Similarly, for **Case b)** and **Case c)**, after the exponentiation, we have $0.9641^{11} = 66.89$ % and $0.9861^{11} = 85.75$ %, respectively, and both fall short to meet the goal $\hat{p}$.

However, for **Case d)**, since it requires much less transmission periods, the overall probability, $0.9861^{6} = 91.94$ %, meets the goal, and, as a result would cause no delay at all.

3. For the former three cases, in order to mitigate this exponentially add-up attenuation effect, for each of the periods, we propose that more than one copies are to be transmitted. When the modulated information in a period is transmitted for τ times, call it **trials**, the probability that at least one copy is successfully transmitted is calculated as $(1-(1-p)^{\tau})$.

For **Case a)**, if $\tau = 2$, then the successful probability over a second is $(1-(1-p)^{\tau})^{11} = 97.20$ %, and thus the success of transmissions is going to be assured. This is very similar to the idea of transmitting multiple copies within a period, but now the duplication is regarding the periods instead of the allocations within the periods. For the other cases, $\tau = 2$ as well.

4. However, as we just discussed, by transmitting extra copies of the periods, the delivery for the content within each second is going to be delayed.

In both **Case b)** and **Case c)**, since all the 11 periods are going to be used for transmissions, and each periods are going through 2 **trials** to assure the success of transmission, in total $11 \times 2 = 22$ periods are going to be transmitted, which still falls into the one second (25 periods) range; and hence also would not cause any delay. On the other hand, for **Case a)**, 44 periods are needed, where 25 of them fall within the one second range, and the other 19 are going to be counted as the delay portion; hence, for the content of the first second, the delay is going to be $\delta = 19 \times 40 = 760$ ms.

Hence, delay-wise, we can see **Case a)** would be the least favorable scheme among the four to choose for this application, under currently tested settings. For **Case d)**, it can also transmit multiple copies to further improve its $\mathcal{P}$.

In general, by adjusting the three parameters, which results in different η and τ values, will change the amount of delay. Hence, for various PSN applications with different GBR values, for various N_u values, and among all the valid combinations of the three parameters, we conduct extensive experiments to collect the resulting delay amount δ using our proposed **Algorithm 1**. Our experiments generate sets of tables on the δ values with completeness; hence network operator can then set up the SL channel and the D2D UEs according to these pre-computed δ values so that the delay budget is met. The results can also be used to draft new latency budget policies, since none of the existing ones were made for OOC scenario in particular.

Due to space limitation, we only present part of our experimental results, as shown in Fig. 4 for the "NG911 Video MQ" application which has a relatively high GBR value; and in Fig. 5 for the "Phone Voice" application who has the intrinsic highest priority in communication, with a moderate GBR of 30,440 bits/sec. and for both applications we focus on $N_u = 4$, where zero delay is achievable. When N_u becomes larger, it is most likely that at least some degrees of delay is to be introduced, and network operators can evaluate which schemes are better under circumstances by considering the trade-offs.

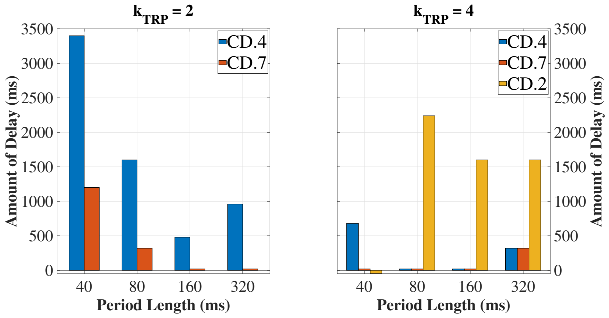

Fig. 4. Amount of delay for “NG911 Video MQ” application with $\mathcal{Q} = 274,562$ bits/second, for $N_u = 4$; within each group of bars, from left to right, each bar represents $CD.4$, $CD.7$ and $CD.2$ (if exists), respectively.

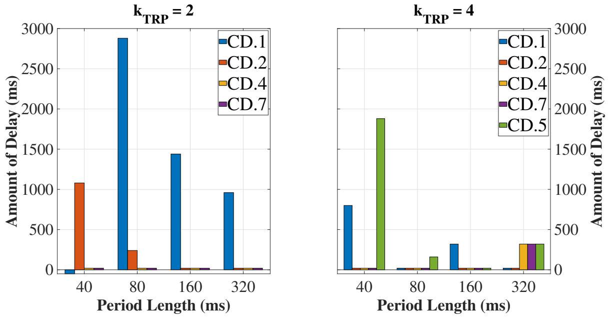

Fig. 5. Amount of delay for “Phone Voice” application with $\mathcal{Q} = 30,440$ bits/second, for $N_u = 4$; within each group of bars, from left to right, each bar represents $CD.1, 2, 4, 7$, and $CD.5$ (if exists), respectively.

In both Fig. 4 and Fig. 5, we use bars with very small heights to represent that there are no delays for the communications under certain parameter settings. Also, the yellow and blue bars with negative values indicate invalid data, since those settings will not be able to achieve $\mathcal{Q}$ at $L_{Period} = 40$ ms.

When comparing the two figures, we can see that when $\mathcal{Q}$ becomes smaller, more reference measurements with smaller TB sizes become valid for transmission. However, it is obvious that, in most cases, although channel parameters with smaller TB sizes have much higher channel reliability, they do **NOT** produce smaller delay values, due to the exponentially add-up attenuation on the reliability. Two exceptions being that, in Fig. 5 when $L_{Period} = 160$ and 320, settings with smaller TB sizes would actually produce smaller amount of delays. On the other hand, channel parameters with larger TB sizes usually require receiving UEs to have better channel qualities in order to actually demodulate the data TBs, which obviously is not always achievable in real-life situations. Thus, it is up to network operators to balance the trade-off accordingly.

V. Conclusion and Future Work

In this work, we thoroughly investigate the channel parameters that will affect the channel reliability, and consequently, the amount of delay introduced during communication, with varying FR group sizes and GBRs of PSN applications. We introduce an approach to assure the successful delivery of content under a rigorous packet loss model, and derive the amount of delay introduced by applying this approach under all the possible parameter combinations.

It can be seen from the amount of delay results that, although in general, settings that carry out larger TB sizes per allocation, despite of having much lower channel reliability, would produce smaller amount of delays; exceptions do exist, and hence the problem is indeed worth studying. Thus, our results have the potential to benefit network operators and researchers in the future operations and studies on SL channels.

As we all know, standards are evolving as technologies develop. Therefore, some of the parameters we investigate in this work may be extended and end up having more values to be utilized to increase the channel reliability, UE throughput, and thus reduce the amount of delay being introduced. We plan to generalize the domains of certain parameters, which will likely make it impossible to construct a table that contains all the parameter information. We will investigate the development of an algorithm that would yield an optimal setting without having to generate the complete table.

Furthermore, there are plentiful of topics that can be expanded into and studied based on our work. For example: **Role-based D2D UEs** where UEs may choose different parameters based on their demand and behavior/roles; and, **Multi-hop D2D Communication** where messages being passed through link paths between base station and remote UEs via multiple D2D-enabled relay UEs.

***Abstract*—Public safety incidents typically involve significant amount of group traffic. This paper initializes our study in exploring the potential spectrum savings and improvement in first responders experience by using Multicast Broadcast Single Frequency Network (MBSFN) to serve group traffic among first responders. Towards this goal, this paper proposes a comprehensive methodology that closely follows The 3rd Generation Partnership Project (3GPP) specifications and considers unicast multiple-input multiple-output (MIMO) and MBSFN without MIMO. High fidelity Block Error Rate (BLER) curves for both MBSFN and unicast are generated, and Signal-to-noise ratio (SNR) points to switch Channel Quality Indicators (CQIs) are extracted and analyzed. Several simulation scenarios have been designed and the empirical results are analyzed.**

***Index Terms*—BLER curves, CQI, LTE, MBSFN, MIMO, public safety broadband network, unicast.**

I. Introduction

In 2012, the Congress passed the Middle Class Tax Relief and Job Creation Act of 2012 [1]. The act calls for the establishment of a national public safety broadband network to expand high-speed wireless broadband and to improve communications interoperability among first responders. Meanwhile, the Long Term Evolution (LTE) networks have been deployed for several years throughout the nation to serve millions of commercial users, and point-to-point unicast transmission is the typical mechanism deployed.

Compared with commercial traffic, public safety incidents typically involve significant amount of group traffic among first responders [2]. Using traditional point-to-point unicast communication to serve this traffic requires to transmit the same content multiple times over the air interface. On the contrary, if multicast transmission is used, the content needs to be transmitted only once over the air interface. This potential saving on the precious spectrum and improvement in first responders' user experience trigger the exploration of using multicast to serve group traffic among first responders. Towards this goal, this paper considers the public safety broadband network that is currently built upon LTE technologies using Band 14 (B14) 10 MHz bandwidth Frequency Division Duplex (FDD), with focus on downlink and Multimedia Broadcast Multicast Service Single Frequency Network (MBSFN) [3].

MBSFN has been studied in the literature from various perspectives. In [4], four adaptive Modulation and Coding Scheme (MCS) selection algorithms have been proposed. Except the bottom-up algorithm which selects the minimum MCS for all user equipments (UEs) in MBSFN, the others cannot guarantee all UEs to successfully decode the data. Also this work directly uses unicast Block Error Rate (BLER) curves for MBSFN. In [5], MBSFN and Single Cell Point To Multipoint (SC-PTM) are evaluated together with the unicast transmission. However, an important feature, multiple-input multiple-output (MIMO), is not considered in unicast. In [6], an optimal UE grouping algorithms in MBSFN is proposed. Since the minimum MCS is selected for all UEs in MBSFN, UE grouping with separate assigned resource may improve the overall performance. There the UE is associated with the same MCS in unicast and multicast modes. As we will see later, it is not always the case. The performance of Multimedia Broadcast Multicast Services (MBMS) and unicast when transmitting video is compared in [7]. The authors use average MCS of all UEs for the expected performance calculation. The comparison is also based on the same MCSs for unicast and multicast.

Our ultimate goal is to quantify network and user performance improvements if MBSFN and unicast communications are adapted based on specific network deployments and device distributions. Our system model and simulation closely follow the 3rd Generation Partnership Project (3GPP) standard with MIMO features included for unicast transmission but not MBSFN [3] [8]. Signal-to-interference-plus-noise ratio (SINR) values in unicast and MBSFN are calculated separately based on their unique models, thus we do not simply use MCS in unicast settings for the MBSFN. In addition, by considering comprehensive physical (PHY) and medium access control (MAC) layers, link level simulations were conducted and traceable high fidelity BLER vs Signal-to-Noise Ratio (SNR) vs Channel Quality Indicator (CQI) curves were generated and analyzed. To our knowledge, this modeling with the above features together for system level performance analysis is the first of its kind.

The rest of this paper is organized as follows. Section II reviews MBSFN and unicast as defined in 3GPP. Section III outlines our methodology and describes our link level simulation design in detail. Simulation results and analysis are presented and summarized in Section IV. Finally, Section V summarizes the paper and outlines steps for future research.

II. Review of unicast and MBSFN in 3GPP

With focus on major factors that have direct impacts on performance comparison and simulation design, this section

Liu, Chunmei; Shen, Chen; Chuang, Jack; Rouil, Richard A.; Choi, Hyeong-Ah. "Throughput Analysis between Unicast and MBSFN from Link Level to System Level." Paper presented at 2019 IEEE 90th Vehicular Technology Conference: VTC2019-Fall, Honolulu, HI, US. September 23, 2019 - September 25, 2019.

reviews MBSFN as specified by 3GPP, and highlights differences between unicast and MBSFN.

In MBSFN, MBMS data is transmitted from multiple cells to the destination UE. All cells involved are tightly synchronized and transmit the same content over the same subcarriers, and all transmissions received by the UE differ only in arrival times, amplitudes, and phases. Given the redundant transmissions via multiple eNodeBs, the SINR is improved, with the greatest improvement being seen at the cell edge.

Fig. 1 illustrates a typical MBSFN subframe as specified in 3GPP [9], with one subframe lasting one Transmission Time Interval (TTI) in time domain. The non-MBSFN region is for controls and signals, and the MBSFN region is where MBMS data is transmitted. In the MBSFN region, in addition to MBMS data, MBSFN reference signals (RSs) are used by the UEs for channel estimation. Note that there is a gap between the two regions [9].

MBSFN reference symbols

Fig. 1: MBSFN Subframe Structure

As a comparison, Fig. 2 illustrates a typical unicast subframe. The figure shows the configuration with normal cyclic prefix (CP) and 2 symbols for control region, which are typical LTE network settings. The cell-specific reference signals (CRSs) shown are with one antenna port. Subframe structure with other configurations can be found in [9].

By comparing Fig. 1 and Fig. 2, it can be seen that MBSFN RSs have tighter spacing than unicast CRSs, which leads to higher overhead and less resource elements (REs) available for user data transmissions. In addition, MBSFN subframes and non-MBSFN subframes are interleaved in time. Moreover, while normal CP is used in typical LTE networks for unicast, extended CP is used for MBSFN to facilitate transmissions from multiple cells to arrive at the UE within CP. This reduces the number of OFDM symbols available for user data from 12 for unicast to 10 for MBSFN, as shown in Fig. 1 and Fig. 2. Furthermore, since subframe 0, 4, 5, and 9 in each radio frame carries signals that are essential for network operations in their data region [9], these four subframes are reserved for unicast transmission and cannot be configured as MBSFN subframes.

Control resource elements

Fig. 2: Unicast Subframe Structure - One Antenna Port

3GPP also specifies that a single transport block (TB) is used per subframe for MBSFN, and that TB uses all the MBSFN resources in that subframe [3]. Specific to the public safety broadband network on B14 with 10 MHz spectrum, this corresponds to 50 resource blocks (RBs). Whereas in unicast, RBs in one subframe are typically divided into multiple sets, with each set assigned to a different user.

For unicast, MIMO has been one major technology adopted by LTE and provides significant improvements in performance and spectral efficiency. Up to release 15, 3GPP defines 10 transmission modes that are intended to fully utilize MIMO under different situations [8]. Up to two codewords can be used for a single UE. Contrarily, in MBSFN, due to its multicast nature, 3GPP specifies no transmit diversity scheme, and MBSFN is mapped on a single layer spatial multiplexing. That is, MBSFN cannot take advantage of MIMO gains.

In addition, hybrid automatic repeat request (HARQ) is a key component that ensures reliability and performance for unicast. In MBSFN, 3GPP specifies that a single transmission is used, and there is no Radio link control (RLC) retransmissions and no HARQ. Hence in order to deliver acceptable service to upper layers, lower target BLER for single transmission is typically used for MBSFN. Lost MBMS packets for certain UEs are typically recovered by retransmissions from the application layer via unicast.

III. Methodology

This section outlines the overall design for performance comparison between unicast and MBSFN, then describes the link level simulation design in detail.

A. System Model

Fig. 3 illustrates our system design. After setting up the scenario to be simulated, both unicast and MBSFN are run, and the resulting performance is recorded and compared. For both unicast and MBSFN, without loss of generality, perfect channel knowledge and zero feedback delay are assumed.

Liu, Chunmei; Shen, Chen; Chuang, Jack; Rouil, Richard A.; Choi, Hyeong-Ah. "Throughput Analysis between Unicast and MBSFN from Link Level to System Level." Paper presented at 2019 IEEE 90th Vehicular Technology Conference: VTC2019-Fall, Honolulu, HI, US. September 23, 2019 - September 25, 2019.

The control signaling is not modelled. For MBSFN, the unicast traffic used for application layer retransmissions are not modelled.

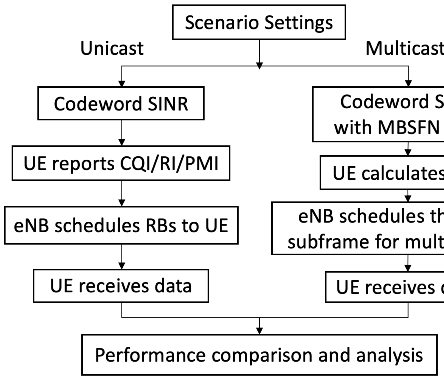

Fig. 3: Overall Design

For both unicast and MBSFN, due to its reputation of accurately predicting BLER [10]–[12], Mutual Information based Exponential SNR Mapping (MIESM) is applied to map the post-equalization SINR to Additive white Gaussian noise (AWGN) equivalent effective SNR. The general equation of the SINR to SNR mapping is as below:

$$\beta_m = f_m^{-1}\Big(\frac{1}{N_{RE}}\sum_{c=1}^{N_{RE}} f_m(\beta^c)\Big) \tag{1}$$

where β_m is the AWGN equivalent SNR for modulation m, $f_m(.)$ is the Bit Interleaved Coded Modulation (BICM) capacity of modulation alphabet m that is associated with the MCS m, β^c is the post equalization SINR for RE c, and N_{RE} is the total number of REs utilized for the transmission. In our simulation, to save simulation time, the averaging is from half RB to codeword [8].

By using Eq. (1), we can translate any channel-interference scenario to an equivalent AWGN channel, and the sample based simulation is required only once when acquiring BLER vs SNR vs CQI curves, which will be described in detail in Section III-B.

For unicast, the overall channel consists of the precomputed pathloss, shadowing, and microscale fading. The post-equalization SINR is calculated using zero forcing equalizer. Then the MIESM maps the time-frequency selective channel experienced over a number of REs and over spatial streams when spatial multiplexing is employed, to an AWGN channel that achieves the same average spectral efficiency in terms of the BICM capacity. Next, based on the AWGN BLER curves from link level simulation, each UE estimates the achievable throughput for all possible number of layers, and selects the optimal Rank Indicator (RI). Afterwards, each UE reports the selected CQI, RI, and Precoding Matrix Indicator (PMI) to the eNodeB. With the above reports from the UEs, the eNodeB schedules its RBs based on the configured scheduler, where proportional fairness scheduler is selected for our study. Finally, with the BLER curves, post-equalization SINR, and the assigned MCS from the eNodeB, each UE records successful packets and sends NACK for unsuccessful packets.

For MBSFN, the channel model used is the same as the unicast one. While calculating the post-equalization SINR, we use run time precoding and Zero-Forcing equalizer, with the modelled constructive signals from eNodeBs in the MBSFN area. The detailed modeling will be explained in [13]. The resulting post equalization SINR for RE c, β^c, can be calculated as in Eq. (2) and (3), where I_M represents the inter-symbol interference from cells that participate MBSFN transmission.

$$\beta^c = \frac{1}{\sum_{i=1}^{N_M}(1-w_i)P_i^c\|F^cH^{ic}\underline{1}_{nTx}\|^2 + I_M + \|F^c\|^2 N_0} \tag{2}$$

$$I_M = \sum_{i=N_M+1}^{N} P_i^c\|F^cH^{ic}W^{ic}\|^2 \tag{3}$$

where N is the total number of cells, and the first N_M cells are those that participate in MBSFN transmission, and cell $N_{M+1}, ..., N$ are cells that do not participate in MBSFN transmission. w_i is the weighting function for cell i as defined in [14]. $P_i^c, i = 1, ..., N$ is the signal power from cell i at RE c after taking into account path loss and shadowing but without microscale fading. $H^{ic}, i = 1, ...N$ is the channel matrix from cell i to the UE at RE c. W^{ic} is the precoding matrix used by cell $i, i = N_M + 1, ..., N$. F^c is the zero-forcing equalizer. N_0 is the thermal noise. $\underline{1}_{nTx}$ is (nTx)x1 column vector with all elements being 1.

The MIESM approach is then applied to map the post equalization SINR to AWGN equivalent SNR, and each UE calculates it CQI with the MBSFN BLER curve from link level simulation (Section III-B) and reports it back to the eNodeB. The MBSFN eNodeBs select the MCS based on the minimum CQI among all MBSFN UEs and assign the whole subframe for multicast data. At last, UEs receive the data and calculate their throughput.

B. Link Level Simulation Design

As mentioned in Section III-A, the objectives of the link level simulation are to generate BLER curves for each CQI under AWGN channel, for both unicast and MBSFN, and to retrieve CQI switching points associated with target BLERs. For this purpose, Vienna link level simulator [10][1] is selected as the base platform. The simulator is designed for unicast. Its PHY layer architecture is consistent with the typical LTE physical layer procedure and that defined in 3GPP [9]. After evaluation, our simulation reused the simulator for unicast with little modifications on settings. For MBSFN, the simulator is extended to support MBSFN.

Specifically, the link simulated for both unicast and multicast is one point-to-point link between one eNB and one

[1] Any mention of commercial products in the paper is for information only; it does not imply recommendation or endorsement by NIST.

UE, with public safety band downlink center frequency of 763 MHz and 10 MHz bandwidth. CQI indices are the ones based on QPSK, 16QAM, and 64QAM, as shown in Table 7.2.3-1 in [8]. AWGN channel is chosen as mentioned in Section III-A. At the UE side, perfect channel knowledge is assumed and zero-forcing equalizer is employed. At the eNB side, transport block size (TBS) is calculated based on MCS order, coding rate, and RBs allocated as in Table 7.2.3-1 in [8]. In addition, in case of large TBS, TB segmentation and de-segmentation are performed to fit the maximum code block size defined per 3GPP [15]. Moreover, since the BLER curve is to be used in later system level simulation (Section III-A), there is no HARQ retransmission in link level simulation.

For unicast, normal CP is selected, and number of OFDM symbols for control region is set to be 2, both of which are typical LTE network deployment settings (Fig 2). Since the focus is on user data transmissions, control region is not simulated. However, since primary and secondary synchronization signal (PSS and SSS) fall into data region and occupy resource elements (REs), they are both simulated (Section II). Regarding CRSs, different RS sets map to different antenna ports [9]. To reduce the number of BLER curves used in later system level simulations and without loss of generality, RSs mapping to one antenna port is selected for this study (Fig. 2).

Per 3GPP standards, for unicast, when UE reports CQI, transport block error probability should not exceed 0.1 [8]. Hence the target BLER for CQI switching is selected to be 0.1. Also note that since PSS and SSS fall into data region in subframe 0 and 5 but not in other subframes [8], the 10 subframes within one radio frame are no longer identical in the sample space. However, within one subframe, the number of REs occupied by primary and secondary synchronization signals is small compared with total number of REs, and their impacts on BLER is hence insignificant. Therefore, to simplify the design, all subframes are treated equally in BLER calculation. 5000 subframes are simulated to provide enough confidence level.

For MBSFN, extended CP is selected as specified by 3GPP [9]. Similar to unicast simulation design, since the focus is on user data transmissions, non-MBSFN region is not simulated (Fig. 1). As mentioned in Section II, subframe 0, 4, 5 and 9 cannot be used for MBSFN. Hence they do not contribute to BLER for MBSFN and therefore are not simulated. Different from unicast, there is no need to simulate PSS and SSS. This is because they fall into subframe #0 and #5, both of which can not be used as an MBSFN subframe.

Since in MBSFN there are no HARQ retransmissions and no RLC retransmissions, lower target BLER is expected and selected to be 0.01. In addition, MBSFN subframes are identical in sample space, and 5000 subframes are simulated to provide enough confidence level.

One challenge in MBSFN simulation design is the location of MBSFN RSs. As shown in Fig. 1, MBSFN RS distribution is not the same across two slots. However, Vienna link level simulator is structured in the way that a transmit signal is mapped on REs based on symmetric slots. One major function of RSs is to support channel estimation. Since our simulation converts SINR in multipath channel to equivalent SNR and perfect channel knowledge is assumed, the locations of the RSs are not expected to change the BLER results. Based on this analysis, one design to simulate the MBSFN RSs is to simulate them by their total number instead of actual locations in subframes. We tested this design by comparing BLER curves of 16 RSs, one with uniformly distributed 16 RSs across the subframe, and the other with concentrating the 16 RSs in two OFDM symbols. The resulting BLER curves show no observable significant differences.

Based on the former analysis and verification, MBSFN RSs are simulated with focus on their total number and by putting 9 RSs at subcarrier 2 to 10 for symbol 3, and another 9 RSs at subcarrier 2 to 10 for symbol 9. Moreover, because of the assumption of perfect channel knowledge, the sequences used by MBSFN RSs would not change the simulation results. Hence, to save the effort in generating MBSFN RS sequence, the reference signal sequences Vienna generated for unicast are reused.

IV. Simulation results

Based on the simulation design described in Section III, link level simulations have been implemented and performed for the public safety band. The obtained BLER curves are shown in Fig. 4 and Fig. 5 for unicast and MBSFN, respectively. The curves in Fig. 4 and Fig. 5 successfully support our initial projection that there would be no significant difference between MBSFN and unicast BLER curves over SNR in AWGN channel, despite that the MBSFN BLER curves shift a little bit to the left. The CQI is the major parameter which will impact BLER in AWGN.

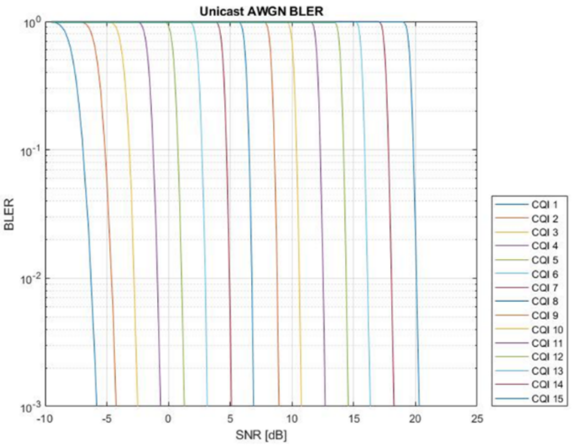

Fig. 4: Unicast BLER for AWGN B14 700 MHz Downlink

Given a target BLER of 0.1 for unicast and 0.01 for MBSFN, we also extracted CQI switching points and listed them in Table I. For comparison purposes, switching points for target BLER of 0.01 for unicast and 0.1 for MBSFN are also listed. We discovered that for the same target BLER, for

Liu, Chunmei; Shen, Chen; Chuang, Jack; Rouil, Richard A.; Choi, Hyeong-Ah. "Throughput Analysis between Unicast and MBSFN from Link Level to System Level." Paper presented at 2019 IEEE 90th Vehicular Technology Conference: VTC2019-Fall, Honolulu, HI, US. September 23, 2019 - September 25, 2019.

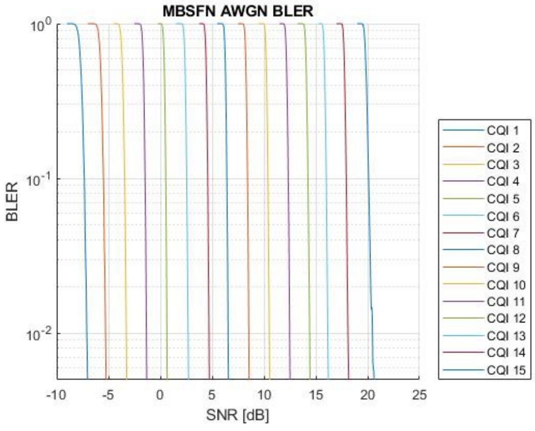

Fig. 5: MBSFN BLER for AWGN B14 700 MHz Downlink

low CQIs, MBSFN requires less SNR than unicast, while for high CQIs, unicast requires less SNR. We also discovered that with different target values, the switching points do not differ significantly.

Note that similar BLER curves and CQI switching points do not imply that the unicast and MBSFN will perform similarly in actual networks. Due to different system architecture, in actual networks when unicast or MBSFN is applied, the first responders could experience different combined SINR before the equalizer even in the same multipath scenario (for example after MBSFN gain especially at cell edge). After the SINR to SNR translation, the AWGN equivalent SNR is different. This could lead to different CQI reports for MBSFN and unicast to meet BLER requirement, and hence different performance first responders would experience. This projection is verified by the system level simulation results described below.

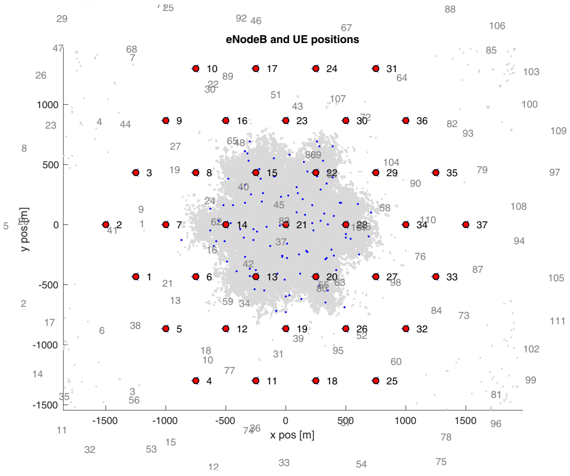

Fig. 6: Network Layout

The network layout used in the system level simulation is shown in Fig. 6. The network is the typical tri-sectored site hexagonal grid with 37 sites and 111 cells in total. First responders are uniformly located in the shaded center 7 sites 21 cells, with 5 first responders per cell unless mentioned otherwise. The outer two rings of 30 sites are included to simulate interference. Inter-site distance is set to be 500 meters. The eNB transmission power is set as 40 W, and the antenna height and the receiver height are 32 m and 1.5 m, respectively. The number of eNB transmit antennas is 8, and the number of UE receiver antennas is 4. Urban macro channel model is used [16]. For unicast, transmission mode 9 [8] is employed, which allows spatial multiplexing to take advantage of MIMO gains. For MBSFN, the MBSFN area is the center 7 sites where first responders are located.

Fig. 7 shows the cumulative distribution function (CDF) of the average AWGN equivalent effective SNR over time experienced by codewords for unicast and MBSFN. Note that in unicast when more than 1 layer is applied (MIMO), the number of codewords could be 2. In this case, the effective SNR of each codeword contributes to one sample in generating the CDF. This figure shows that MBSFN has significant higher effective SNR than unicast. This improvement comes from several factors. The first is that in unicast the cells in the center 7 sites generate interference to each other, while in MBSFN they do not. The second is the MBSFN gain due to transmissions from multiple cells. The third is that in unicast when there are two codewords, the signal power is distributed to two codewords instead of one, which lower the SNR of each codeword.

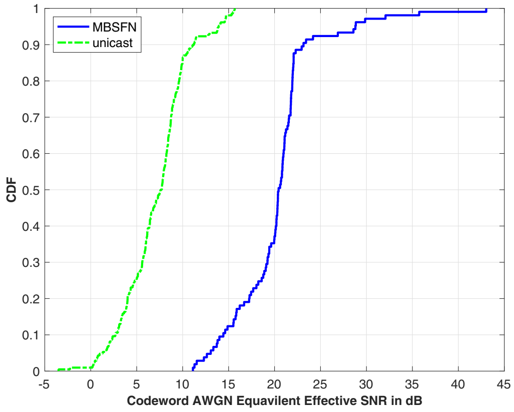

Fig. 7: CDF of AWGN Equivalent Effective SNR

Fig. 8 shows comparison of reported CQI between MBSFN and unicast from 10 randomly selected UEs in TTI 23. Note that for unicast, some UEs report 2 CQIs and some report 1. This is because with MIMO when there are two codewords, each codeword is associated with one CQI. It can be observed that in the selected case, MBSFN has higher CQI than unicast, which is consistent with Fig. 7. Contrary to the assumption in some literature which assume that MBSFN MCS is the

TABLE I: CQI switching points at target BLER 0.1 and 0.01, SNR in dB

minimum of unicast MCSs of all UEs, the lowest MBSFN CQI is not necessarily the lowest unicast CQI.

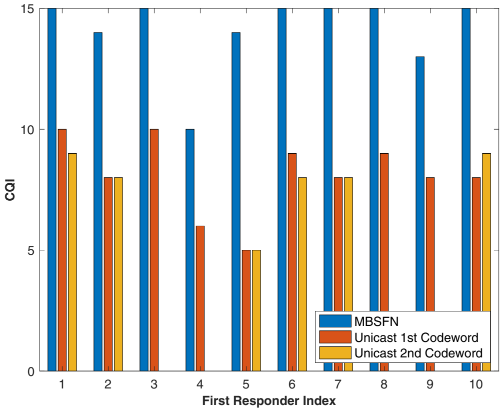

Fig. 8: Comparison between MBSFN CQI and Unicast CQI

The CDF of first responder throughput is shown in Fig. 9, for both unicast and MBSFN. Note that different from Fig. 7, in unicast when spatial multiplexing is triggered and 2 codewords are used for the UE, both codewords contribute to this UE's throughput and together generate one sample in throughput CDF. Meanwhile, in MBSFN 6 out of 10 subframes are used, which is the maximum specified by the standard. It can be observed that the MBSFN CDF is close to a vertical line. This is because of the low target BLER of 0.01, and the fact that all UEs are receiving the same content at the same time, using the same MCS and RBs. Hence all first responders experience similar throughput. In this specific case, MBSFN shows higher throughput. MBSFN also has higher average throughput of 9.76 Mb/s than unicast 6.02 Mb/s, which is not shown in the figure. With increasing number of first responders, this throughput gap will be bigger.

To show the impact of selecting the lowest MCS in MBSFN, the potential throughput UEs would achieve per their individual CQI reporting is plotted in red. This potential throughput is much higher than the actual throughput, and its lowest value is the same as the actual MBSFN throughput. The potential MBSFN throughput is also much higher than the unicast throughput. One reason is the higher effective SNR as shown in Fig. 7. Another reason is that MBSFN uses all RBs for its transmission and that applies to all UEs, while in unicast the RBs are shared by the UEs. That is, the resource used by each UE is much more in MBSFN than that in unicast. However, given the lowest MCS selection in MBSFN, the actual throughput experienced by first responders is much lower than the potential MBSFN throughput.

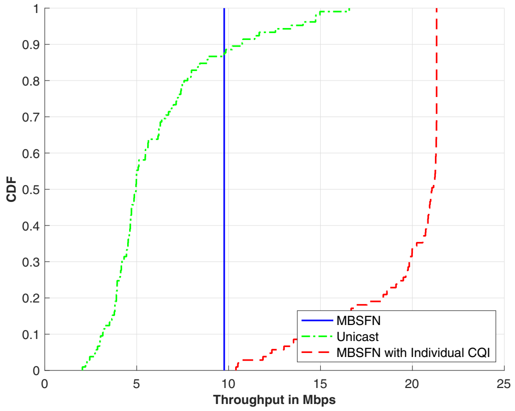

Fig. 9: Throughput CDF for Unicast and MBSFN

Fig. 10 shows the histogram of CQIs for MBSFN reported from all UEs in one TTI. In this case, although majority of the UEs reported the highest possible CQI of 15, there are UEs that reported CQI of 10. These UEs lowered the MCS used by MBSFN, and hence the MBSFN throughput.

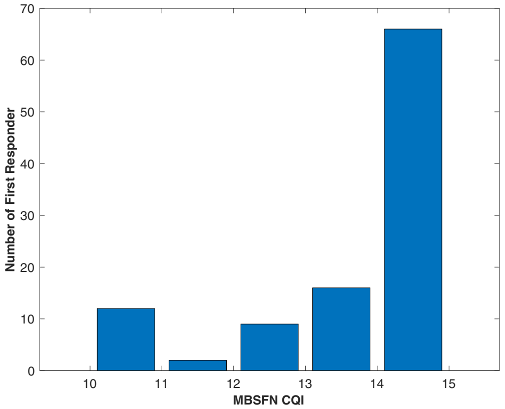

Fig. 10: MBSFN CQI Histogram in TTI 23

Fig. 11 further shows how minimum CQI in MBSFN varies in time. It can be observed that in most time, the minimum

MBSFN CQIs remain stable. The more first responders per sector, the lower the minimum CQI is.

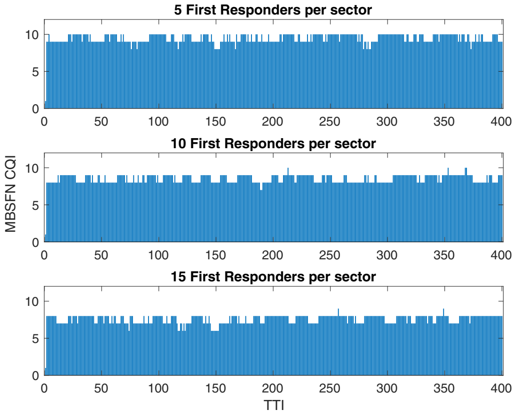

Fig. 11: MBSFN Minimum CQI with Time

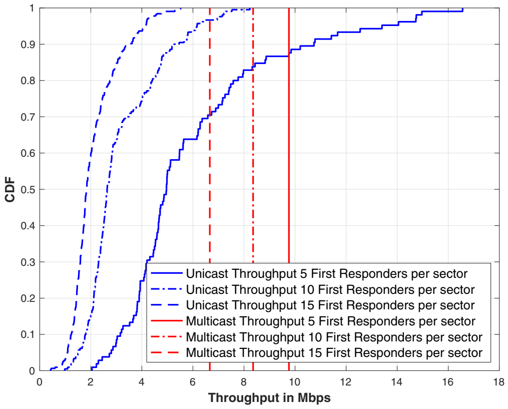

Fig. 12: Throughput CDF with 5, 10, and 15 First Responders per Sector

Finally, Fig. 12 shows first responders' throughput CDF when there are 5, 10, and 15 first responders per sector, respectively. It can be observed that the first responders' throughput in unicast decreases significantly as first responders' density increases, while in MBSFN it is less sensitive. The relatively lower throughput in MBSFN with more first responders is due to the slightly lower MBSFN CQI, as shown in Fig. 11. Also note that in the cases shown, MBSFN throughput is higher than majority of unicast throughput. In case of 15 first responders per sector, the MBSFN throughput is even higher than the highest throughput in unicast. This is consistent with our analysis in Fig. 7.

V. Conclusion

In this paper we generated high fidelity BLER curves for both MBSFN and unicast, and extracted and analyzed SNR points to switch CQIs. The BLER curves and CQI switching points were then fed into our comprehensive system level simulations, which considers unicast with MIMO and MBSFN without MIMO as well as all 3GPP PHY and MAC features. The resulting SINR, throughput, and CQI for both unicast and multicast were also analyzed.

While throughput is one major metric for performance, another perspective of group traffic is that the content is available to first responders simultaneously. Our next step is to introduce other metrics in addition to throughput, and to use the results in this paper to further investigate the trade offs between unicast and multicast. We will also optimize LTE system to meet first responder needs and to ensure quality service for everyone.

***Abstract*—In many public safety scenarios, Device-to-Device (D2D) communication should be capable of handling out-of-coverage situations, ensuring that D2D devices can communicate directly without the aid of network infrastructure. While a number of resource allocation schemes for D2D communication in Long-Term Evolution (LTE) have been proposed, the majority consider only in-coverage scenarios that rely on a centralized controller to coordinate among D2D devices, and are unable to handle out-of-coverage communication. To address this issue, in this paper we investigate a set of distributed resource allocation schemes for out-of-coverage D2D group communication. To be specific, we first provide guidelines concerning how to allocate D2D resources based on Modulation and Coding Scheme (MCS), Physical Resource Block (PRB) size, and Time Resource Pattern (TRP) to meet the QoS requirements of applications. We then design three distributed resource allocation schemes that select PRBs in the resource pool and/or adjust the transmitting power based on the level of available information about the network environment. The first scheme, called the basic random allocation scheme, allows the transmitting User Equipment (UE) to randomly select resource blocks from the resource pool and transmit data at maximum power. The second scheme, which enhances the basic random scheme and is denoted as the Received Signal Strength (RSS)-based random allocation scheme, leverages RSS to reduce the power consumption of the transmitting UEs and interference to other groups. The third scheme proposed, designated the interference-aware allocation scheme, allows the transmitting UE to explore the interference experienced by receiving UEs within its D2D group and select resource blocks that interfere with the smallest number of UEs within the group. In doing so, the communication interference among transmitting UEs can be reduced, resulting in a higher probability of system coverage compared with the two random allocation schemes. To evaluate the designed distributed resource allocation schemes, we conduct extensive performance evaluation, validating their effectiveness in a variety of deployment scenarios.**

***Keywords*—D2D Communication, Out-of-Coverage, Distributed Resource Allocation.**

I. Introduction

To carry out public safety response and disaster recovery, emergency response communication is critical [1], [2], [3], [4], [5], [6]. When a large disaster occurs, network infrastructure will likely be overloaded, if not damaged and unavailable. To maintain continuous communications among first responders and victims, technologies to enable direct communication are paramount. Device-to-Device (D2D) communication, as one of several viable technologies to enable direct communication, is considered as a critically important technology in public safety research and development. With D2D, first responders and victims can directly communicate, enabling the sharing and collection of information, and providing situation awareness of public safety events. In these public safety scenarios, D2D communication needs to operate under out-of-coverage conditions, in which D2D devices need to communicate directly without the aid of network infrastructures [7], [8].

To carry out resource allocation in LTE-based D2D out-of-coverage situations, the following challenges need to be addressed. First, communication cannot rely on centralized controllers (base stations, etc.) to conduct resource allocation for D2D UEs. While a number of resource allocation schemes have been proposed, most consider only in-coverage D2D scenarios, where centralized controllers are required to coordinate resources. Additionally, these schemes often assume that complete knowledge of the Channel State Information (CSI) of communication and interference channels are available. Nonetheless, such an assumption is not applicable to the out-of-coverage D2D scenarios investigated in this paper. Second, in D2D group communication, as no physical layer feedback exists, little information regarding CSI is available. Thus, how to leverage the available information to improve system performance becomes a challenging issue. Third, UEs (including both transmitters and receivers) have less computation capabilities and are more sensitive to power consumption than larger and more heavily equipped base stations. Thus, existing complex resource allocation schemes become infeasible on UEs due to the limited computing and energy resources. Thus, the design of lightweight and distributed resource allocation schemes is essential to enable out-of-coverage D2D communications.

To address the issues presented thus far, in this paper we make the following concrete contributions.

- **Problem Formalization.** We formalize the resource allocation problem for out-of-coverage D2D communication in LTE-based networks. As the problem is a multi-dimensional issue, we consider several key factors together, including Modulation and Coding Scheme (MCS), Physical Resource Block (PRB) size, Time Resource Pattern (TRP) and transmitting power, to satisfy the quality of service (QoS) requirements for public safety applications. Once we complete the selection of these key factors, other important decisions include which PRBs in the pre-allocated resource pool should be used and what is the transmitting power level that should be utilized to transmit the signal so that the overall system coverage

Wang, Jian; Rouil, Richard A.; Cintron, Fernando. "Distributed Resource Allocation Schemes for Out-of-Coverage D2D Communications."
Paper presented at 2019 IEEE Global Communications Conference (GLOBECOM), Waikoloa, HI, US. December 09, 2019 - December 13, 2019.

probability can be maximized.

- **Distributed Resource Allocation Schemes.** Based on the formalized problem, we design three distributed resource allocation schemes. Particularly, we first design a basic random allocation scheme, which allows the transmitting UE to randomly select resource blocks from the pre-configured resource pool. This scheme does not assume that the transmitting UE has any knowledge of the network. We then propose the Received Signal Strength (RSS)-based random resource allocation scheme that leverages the available information of the network so that the overall system performance can be improved. The RSS-based random scheme aims to reduce the power consumption of the transmitting UE by leveraging the D2D discovery service and identify the maximum path loss in the D2D group. Finally, we design the interference-aware allocation scheme, which allocates resources by avoiding interference of transmitting UEs. With this scheme, the transmitting UE collects information pertaining to the interference experienced by the receiving UEs in its group, and further selects resource blocks that are used by the least number of UEs. By doing this, the communication interference among transmitting UEs can be reduced so that the system coverage probability can be improved.
- **Extensive Evaluation.** We conduct extensive performance evaluation to show the effectiveness of our proposed schemes in allocating communication resources in out-of-coverage D2D communications with respect to system coverage probability, which is defined as the probability of average received Signal-to-Interference-plus-Noise Ratio (SINR) being larger than the minimum threshold required to successfully decode the information. We also measure the power consumption reduction of the RSS-based random scheme and investigate the tradeoffs of power savings and system coverage probability. Our findings show that the basic random scheme works effectively when the region is not dense (i.e., only a few communication groups exist in the region and the receivers in a group are closely located around the transmitter). When the geographic sizes of groups is small, power control could be used to reduce UE transmission losses with a marginal sacrifice in the coverage performance. When the region becomes more dense, the performance of the two random resource selection schemes deteriorate. Furthermore, the interference-aware scheme can significantly improve the coverage by mitigating interference among groups.

The remainder of this paper is organized as follows: In Section II, we provide a literature review of research relevant to our study. In Section III, we introduce the system model. In Section IV, we introduce the problem formalization, design rationale, and our designed distributed schemes in detail. In Section V, we present the performance evaluation results. Finally, we conclude the paper in Section VI.

II. Related Work

In this section, we review research works relevant to our study. D2D communication is essential for supporting public safety applications, as it enables continuous communication when network infrastructure is either damaged or overloaded [3]. D2D communication has the potential to not only improve communication resilience, but also improve spectrum efficiency, system throughput, energy efficiency, and system delay performance [9], [5], [6].

Generally speaking, D2D communication can be categorized as either in-coverage or out-of-coverage [9], [5], [6]. Particularly, in-coverage D2D means that D2D UEs are within the coverage range of network infrastructure, while out-coverage D2D means that D2D UEs are not in the coverage range of network infrastructure. When UEs are in-coverage, they may share the same radio resources with cellular services (underlay) [10], or use their dedicated resource pool for communication (overlay) [11]. For in-network D2D, traffic can either directly flow between two UEs or flow through the base station. In underlay cases, one challenge is how to minimize the impact of D2D on cellular networks and improve spectrum efficiency, while in overlay cases, challenges include how to choose proper resource pools for D2D so that resource use can be maximized. For out-of-coverage D2D, the primary challenge is how to effectively manage communication resources without the aid of base stations as centralized controllers or coordinators.

There is a body of research on D2D resource management, most of which are concerned with in-coverage D2D [5], [6], [9]. These existing D2D resource management efforts address coverage issues by designing a variety of resource allocation schemes to optimize certain performance metrics, including maximizing system throughput [12], [13], minimizing link outage probability [14], and maximizing overall energy efficiency [15], among others. The optimization objectives are also subject to a number of constraints, including transmission power, minimum QoS requirements, and physical resources, among others. D2D resource allocation also needs to consider a number of other factors, such as user traffic scheduling (i.e., how often the data will be transmitted), MCS selection, the size of physical resource blocks, transmission power, and mode selection to determine whether to utilize D2D or cellular communication modes (again, only for in-network scenarios). All of these factors are interconnected and jointly affect system performance. Thus, to simplify the problem, existing solutions often optimize one or several parameters of the entire parameter set. Commonly used techniques include integer/linear programming, convex optimization, mixed integer nonlinear programming, game theory approaches, and heuristic algorithm design, among others.

Most existing D2D research has focused on in-network underlay scenarios, ranging from the simple setup of one cellular UE and one D2D pair [10], to multiple D2D pairs and multiple cellular UEs [16], [17]. One focus is interference management, which includes issues such as how to minimize the impact of D2D communication on existing cellular services and how to manage cellular-to-D2D interference [16], [11]. For example, Su *et al.* [16] focused on D2D underlay in-band communication, studying how to control the interference from D2D UEs to the primary cellular UE by designing proper resource allocation and mode selection strategies. To solve the problem, a particle-swam optimization (PSO-MSRA)-based scheme was designed to maximize system throughput while guaranteeing the minimal rate requirement for all D2D users. Ye *et al.* adopted a game theory-based scheme and formulated the resource allocation in D2D underlay into a two-stage optimization problem [17]. While the proposed scheme might not find the optimum solution, it allows resources to be allocated in a distributed fashion. Notice that most of existing efforts on in-network are on underlay D2D, and perfect CSI is commonly assumed. There are some existing efforts on in-network overlay D2D as well. For instance, Lee *et al.* [11] studied D2D overlay resource allocation using graph-coloring to maximize the sum rate of D2D links. As a centralized solution, in their scheme, the eNodeB collects a list of high-interfering D2Ds and allocates resource to D2D transmitters.

As our work targets public safety scenarios, communication, and especially group communication, among public safety personnel need be maintained in the event of large-scale emergencies and disasters. Our research focuses on out-of-coverage D2D group communications, which have not been well explored. In our study, we take into account key factors that can be leveraged by a D2D UE locally, and design our solution to be practical, such that it could be implemented within the existing 3GPP framework with no or only slight modifications. We design three distributed schemes to conduct resource allocation for D2D communication to accommodate the special challenges associated with out-of-coverage communications.

III. System Model

In this section, we introduce the system model. In our study, we consider D2D group communication scenarios, in which a number of D2D nodes (i.e., UEs) that belong to different function groups are deployed in a geographical location and perform public safety missions. Within a group, there is one transmitter UE and multiple receiver UEs. The communications between transmitter UE and receiver UEs are performed directly through D2D communication links. Since UEs are not covered by network infrastructure, such as cellular networks, each UE has a pre-configured resource pool with K units in order to perform D2D communications in out-of-coverage scenarios. Without loss of the generality, we assume all UEs are configured with the same resource pool settings.

Figure 1 illustrates the network model, in which the deployment area is a circular area A with radius R. Within A, there are M groups uniformly randomly deployed, denoted as $G_1, G_2, \ldots, G_M$. Within a group G_i ($i \in [1, M]$), there is an active transmitter UE TXi and all other UEs within the same group are uniformly randomly located in a circular region that is centered on the transmitter UE_i with radius r.

Channel gain between transmitter TX_i ($i \in [1, M]$) and receiver UE_j is denoted as g_{ij}. When we compute the channel gain, path loss, large-scale shadowing, and small-scale fading are considered [18]. We also assume that the channel is a slow changing and semi-static. If we can collect coarse channel state information (e.g., CSI) using upper layer signaling (e.g., D2D discovery messages), such information could be used to guide resource allocation.

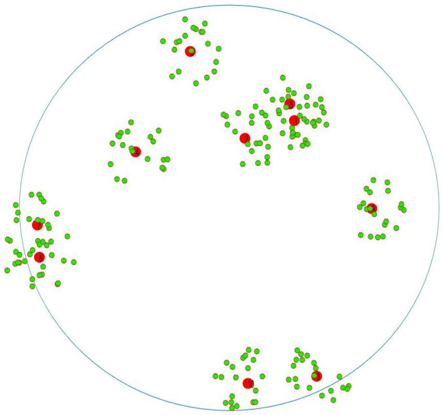

Fig. 1: Network Model

For transmitter TX_i (the transmitter in group i), we denote its transmission power as P_i. We assume all the transmitting groups are running the same application, such as mission critical voice. Resource allocation decisions include the selection of MCS, PRB size, TRP, transmission power, and PRB locations in the resource pool. We first allocate D2D resources by selecting MCS, PRB size, and TRP to meet QoS requirements of the application, such as requirements for throughput and delay. Based on the allocation scheme that we choose, we then divide the resource pool into a number of channels. Each channel occupies the same number of resources and a transmitter is using one channel.

Given M transmitters and K channels for D2D communication, we define the resource usage matrix U as

$$U_{M\times K} = \begin{bmatrix} 1 & 0 & 0 & \ldots & 0 \\ 0 & 1 & 0 & \ldots & 0 \\ \vdots & & \vdots & & \\ 0 & 0 & 0 & \ldots & 1 \end{bmatrix}$$

where $U_{i,j} =$

$$\begin{cases} 1, & \text{if TX } i \text{ uses channel } j \\ 0, & \text{if otherwise} \end{cases} \tag{1}$$

In our study, we consider an outdoor environment and adopt the 3GPP outdoor-to-outdoor (O2O) path loss model [19]. The line-of-sight (LOS) path loss PL_{LOS} and non-line-of-sight (NLOS) path loss PL_{NLOS} are defined as

$$\begin{aligned} PL_{LOS} = {} & 40\log_{10}(d) + 7.56 - 17.3\log_{10}(h_{BS}^{'}) \\ & - 17.3\log_{10}(h_{MS}^{'}) + 2.7\log_{10}(f_c) \\ & + 20\log_{10}(f_C/f_{REF}), \end{aligned} \tag{2}$$

$$\begin{aligned} PL_{NLOS} = {} & (44.9 - 6.55\log_{10}(h_{BS}))\log_{10}(d) + \\ & 5.83\log_{10}(h_{BS}) + 16.33 + 26.16\log_{10}(f_C) - 5. \end{aligned} \tag{3}$$

Here, d is the distance between transmitter and receiver, and $h_{BS}^{'}$ and $h_{MS}^{'}$ are the effective heights for transmitter and receiver in meters, respectively, both of which are set to 0.8 m.

Also, f_c is the carrier frequency, set to 700 MHz, and the reference frequency f_{REF} is 2 GHz. For large-scale shadowing, log-normal shadowing with 7 dB standard deviation is used. For small-scale fading, Rayleigh fading is adopted. The probability of LOS is a function of distance following $P_{LOS} = min(18/d, 1)(1 - exp(-d/36)) + exp(-d/36)$.

IV. Proposed Schemes

In this section, we introduce our schemes in detail. Particularly, we first introduce coverage probability, which is used to evaluate our schemes, and present the optimization of coverage probability to motivate the design of distributed resource allocation. We then outline the problem definition and introduce the design rationale. Finally, we present our proposed schemes to allocate communication resources for out-of-coverage D2D.

A. Coverage Probability

In this study, we use coverage probability as the primary evaluation metric. Generally speaking, coverage probability is defined as the probability that the average received SINR is above the minimum threshold required to successfully decode the transmitted message. The coverage probability of a single transmitter and receiver link is a function of distance, and its expression is [18]

$$\frac{1}{\sqrt{\pi}\Gamma(m)}\int_{-\infty}^{+\infty}\exp(-x^2)\Gamma(m, \frac{m\gamma}{10^{\frac{\sqrt{2}\sigma_s x+\mu}{10}}})\, dx. \tag{4}$$

Here, $x = \frac{10log_{10}w-\mu}{\sqrt{2}\sigma}$ and $w = 10^{(\frac{\sqrt{2}\sigma_s x+\mu}{10})}$, σ_s is the standard deviation of the Log-normal shadowing, and μ is the received power after considering the path loss in dBm. $\Gamma(m)$ is the $\Gamma(.)$ function with an input of m, where $m = 1$ for Rayleigh fading. Also, γ is the decoding threshold that is dependent on the thermal noise, receiver noise figure, and SNR decoding threshold.

Considering interferences, the SINR of UEj in group i using channel k, denoted as $SINR_{j,k}$, can be computed as

$$SINR_{j,k} = \frac{P_{i,k}g_{i,j}}{\sum_{l=1,l\neq i}^{M} U_{l,k}P_{l,k}g_{l,j} + N}, \tag{5}$$

where $P_{i,k}$ is the transmitted power of transmitter UE i using channel k, $g_{i,j}$ is the channel gain between transmitter UE TX_i and receiver UE UE_j, M is the size of transmitter UEs, $U_{l,k}$ is the element of matrix defined in Equation (1), and N is the noise floor on the receiver, which includes thermal noise and noise introduced by the device. Notice that the channel gain includes the path loss, shadowing, and small scale fading.

For a given deployment (fixed transmitter and receiver locations), the path loss and shadowing for each link are fixed, we first compute the UE's average coverage probability over small-scale fading. For UE_j using channel k, its SINR can be written as

$$SINR_{j,k} = \gamma = \frac{g_0\omega_0}{\sum_{l=1,l\neq i}^{M} U_{l,k}g_l\omega_l + N}, \tag{6}$$

where ω_0 and ω_l are the local mean powers of the desired signal S_0 and interference signal S_l, i.e., the received powers after considering path loss and shadowing, which are fixed for a deployment. Also, g_0 and g_l are the power gain of the Rayleigh fading.

We define the coverage probability of UE_i as

$$\begin{aligned} P(\gamma \geq \beta|\omega) &= P(\frac{g_0\omega_0}{N + \sum_{l=1,l\neq i}^{M} U_{l,k}g_l\omega_l} \geq \beta|\omega), \\ &= P(\beta^{-1}g_0\omega_0 - \sum_{l=1,l\neq i}^{M} U_{l,k}g_l\omega_l \geq N|\omega), \\ &= P(S \geq \sum_{l=1,l\neq i}^{M} U_{l,k}g_l\omega_l + N|\omega). \end{aligned} \tag{7}$$

Here, β is the SNR threshold for successfully decoding the information from noisy communication channels in a given probability. Since g_0 and g_l are the power gains of the Rayleigh fading, the probability density function (PDF) of $S = \beta^{-1}g_0\omega_0$ is $f_S(s) = \frac{\beta}{\omega_0}\exp(\frac{-\beta s}{\omega_0})$ and let $y_l = U_{l,k}g_l\omega_l$, Equation (7) can be rewritten as:

$$\begin{aligned} P(\gamma \geq \beta|\omega) &= \int \cdots \int_Y \int_{N+\sum_{l=1,l\neq i}^{M} y_l}^{\infty} f_S(s)f_Y(y_1, \ldots, y_M)\, dsdY \\ &= \exp(-\beta_0 N)\int \cdots \int_Y exp(-\beta_0 \sum_{l=1,l\neq i}^{M} y_l) \\ &\quad f_Y(y_1, \ldots, y_M)\, dY \end{aligned} \tag{8}$$

Here, $\beta_0 = \frac{\beta}{\omega_0}$.

Since the UEs are deployed independently, y_i is an independent and identically distributed (i.i.d) random variable. Thus, we have

$$P(\gamma \geq \beta|\omega) = exp(-\beta_0 N)\prod_{l=1,l\neq i}^{M}\int_0^{\infty} exp(-\beta_0 y_l)f_Y(y_l)dy_l. \tag{9}$$

If the transmitter picks a channel randomly from a pre-allocated pool, we have PDF of $y_l = U_{l,k}g_l w_l$ as,

$$f_Y(y_l) = (1 - p_i)\delta(y_l) + p_i * \frac{1}{\omega_l}\exp(-\frac{y_l}{\omega_l}), \tag{10}$$

where $p_i = \frac{1}{N_{ch}}$ and N_{ch} is the total channel numbers.

After plugging in Equation (10), we have

$$\begin{aligned} P(\gamma \geq \beta|\omega) &= exp(-\beta_0 N)\prod_{l=1,l\neq i}^{M}\int_0^{\infty} exp(-\beta_0 y_l)((1 - \frac{1}{N_{ch}})\delta(y_l) \\ &\quad + \frac{1}{N_{ch}}\omega_l exp(-\frac{y_l}{\omega_l}))dy_l, \\ &= exp(-\beta_0 N)\prod_{l=1,l\neq i}^{M}\frac{1 + \beta_0\omega_l(1 - \frac{1}{N_{ch}})}{1 + \beta_0\omega_l}. \end{aligned} \tag{11}$$

Once we have the coverage probability for each UE with Equation (11), we can obtain the average UE's coverage probability in a fixed deployment. We then simulate the coverage probability over different deployments to obtain the average coverage probability for given system configurations, which vary by region size, number of groups, group region size, and others.

In a multi-group environment, we can choose matrix U such that the UE's average coverage probability can be maximized, i.e.

$$\begin{aligned} \max_{R} \sum_{i,k} P(S_{i,k} \geq t^{-1} + \sum_{l=1,l\neq i}^{M} U_{l,k} g_l w_l | w) \\ s.t. \sum_{j} U_{i,j} = 1,\ P_i \leq P_{max} \end{aligned} \tag{12}$$

Since the objective function is not a closed formula, directly finding for U matrix is very challenging. In addition, in out-of-coverage scenarios, without physical layer feedback and centralized control, it is difficult to collect sufficient information necessary to obtain the settings to maximize the average coverage probability. Thus, this motivates us to design distributed resource allocation schemes that are feasible in out-of-coverage D2D communications. In our study, we design an interference-aware scheduling scheme to select matrix U. Using the random channel selection scheme as a baseline, we investigate whether the coverage performance can be improved by selecting channels based on detected interference information. Once we have the channel allocation matrix U designed, the average coverage probability of UE i for a fixed deployment can be evaluated as:

$$\begin{aligned} P(\gamma_i \geq \beta|\omega) &= P(S \geq \sum_{l=1,l\neq i}^{M} U_{l,k} t_l + \tau^{-1}|\omega) \\ &= \int_T \cdots \int \int_{\tau^{-1}+\sum_{l=1,l\neq i}^{M} U_{l,k} t_l}^{\infty} f_S(s) \\ & f_T(t_1, \ldots, t_M)\, ds dT, \\ &= \exp(-\beta_0 N) \int_T \cdots \int exp(-\beta_0 \sum_{l=1}^{M} U_{l,k} t_l) \\ & f_T(t_1) \ldots f_T(t_M)\, dT, \\ &= \exp(-\beta_0 N) \prod_{l=1,l\neq i,U_{l,k}=1}^{M} \frac{1}{1+\beta_0 \omega_l}. \end{aligned} \tag{13}$$

Here, $f_T(t_l = g_l \omega_l) = \frac{1}{\omega_l} \exp(\frac{-t_l}{\omega_l})$.

Using Equations (11) and (13), we average out the small-scale fading, which can significantly reduce simulation time. To validate these two equations, we ran Monto Carlo simulations to simulate small-scale fading, and the comparison can be seen in Figure 2 and Figure 3. From both figures, we observe that the full-scale Monto Carlo simulations match well with the analytical results provided by Equations (10) and (13).

B. *Design Rationale*

Recall that, unlike in-coverage communication, in the out-of-coverage case, there is no base station acting as a central controller to allocate resources for each UE, and UEs need to schedule their resources autonomously. Thus, the problem we seek to address is, in the group communication scenario as described in Section III, how can transmitter UEs select resources with consideration for MCS, PRB size, and TRP to satisfy the QoS requirements of D2D communication, and how can UEs select transmitting power and the location of PRBs in the resource pool to improve system coverage probability. Notice that our focus is to improve the coverage probability so that the reliability requirements of public safety applications can be fulfilled. Other objectives (power consumption, system throughput, etc.) can be considered and extended in future extensions to this study.

According to the definition of coverage probability, UE j has coverage if $SINR_j > \beta$. Here, β is the SNR threshold in dB for UEj in order to achieve 10^{-2} Block Error Rate (BLER) after 4^{th} D2D transmissions. Notice that β is MCS dependent.

Depending on the availability of information on the deployment environment, we propose the following resource allocation schemes:

- *Basic Random Allocation Scheme*. In this scheme, each UE randomly selects resources from the resource pool in a uniform fashion based solely on its throughput requirement, without leveraging any knowledge, such as CSI. In this scheme, we do not conduct power control, such that the UE uses the maximum transmission power to send messages (what we consider the default configuration).
- *Received Signal Strength (RSS)-Based Random Allocation Scheme.* In this scheme, we intend to reduce UE power consumption by leveraging the D2D discovery service to identify the maximum path loss in the D2D group. Based on the maximum path loss in a group, the transmission power can be adjusted in the transmitting UEs, leading to reduction in power consumption, and potentially reduced interference with neighboring groups. Notice that UEs still randomly select the resources from the resource pool in a uniform fashion.
- *Interference-Aware Allocation Scheme.* In this scheme, the transmitter UE collects information on the interference experienced by the receiver UEs in its group, and selects the channels that can be detected by the least number of UEs in its group. By doing this, the communication interference among UEs can be reduced, such that the overall system coverage probability can be improved.

In the following, we describe our designed resource allocation schemes in detail.

C. *Basic Random Allocation Scheme*

In the basic random allocation scheme, to satisfy the throughput requirements of UEs, we need to select the proper combination of MCS, PRB size, and TRP. Notice that the resource pool size and transmission period length are pre-configured for all UEs to communicate outside cellular coverage. To illustrate this resource allocation scheme, we give an example. To support AMR-WB (Adaptive Multi-Rate - Wideband Speech Codec) voice applications, a throughput of 12.65 kbits/s is required, which means 253 bits for every 20 ms. After adding 3 bytes of RoHC (Robust Header Compression), LLC (Logical Link Control), and MAC (Media Access Control) headers, a transport block with a minimum size of 300 bits is required. If the period length is 40 ms, and 8

4	5	-7.5	6.99	-0.51
0	12	-11	10.79	-0.21
5	4	-6.6	6.02	-0.58

TABLE I: D values for different MCS and PRB combinations

subframes within the period are used for transmission, considering 4 retransmissions, a new transport block is transmitted every 20 ms.

Once the number of subframes to be transmitted in a transmission period is determined, we need to determine the transport block size to meet the QoS requirement (i.e., the amount of data to be transmitted in a subframe) of UEs. To satisfy the designated transport block size, we have several MCS and PRB size combinations. The problem is how to select the desired MCS and PRB pair among these combinations. As shown in our prior study [18], to successfully decode a transmitted message through a D2D link, a higher MCS value requires a higher SNR threshold. In contrast, if we choose a low MCS, we will use more PRBs, and noise floor will rise for the channel. The received signal strength should be greater than the receiver sensitivity to decode the signal successfully, and thus the maximum path loss that we can tolerate to achieve reliable communication is $P_{TX} - N - NF - SNR_{th}$ [18]. Here, N is the thermal noise floor and depends on the channel bandwidth, NF is the device noise figure, and SNR_{th} is the SNR to achieve 1 % BLER after the 4^{th} transmission.

Thus, with fixed transmitting power and noise figure, maximizing the path loss is equivalent to minimizing the sum of N and SNR_{th}. To maximize the propagation distance (i.e., maximizing the path loss that the receiver can tolerate), we consider the following objective: for each MCS and PRB size combination, we compute the utility function D_{max} as follows:

$$D_{max} = 10 \log_{10} PRB + SNR_{th}. \tag{14}$$

We then pick the MCS and PRB size combination so that the smallest D value can be realized. We thus search through the MCS and PRB combinations that meet the throughput requirements. Table I illustrates some examples of D values. From the table, we can see that, by choosing the minimum D value, MCS 5 and PRB size 4 will be selected.

The average coverage probability of a link between one transmitter and one receiver for Rayleigh fading channel is computed by leveraging our prior work [18], and the results are shown in Figure 4. In the figure, we show the coverage probability for 5 different PRB and MCS combinations. Among these combinations, as a combination of MCS 16 and PRB 1 leads to the highest D value, the worst performance is achieved, while as a combination of MCS 10 and PRB 2 leads to the lowest D value, the best performance is achieved. A combination of MCS 5 and PRB 4 leads to the second best, resulting in the performance being close to the best. For the single D2D link, by picking the MCS and PRB combination with the lowest D value, we can maximize its coverage probability.

Notice that the aforementioned result is only for D2D links without interference from other transmitters. If each D2D transmitter uses this strategy, in a multi-group environment, it may not achieve the overall best system performance with respect to coverage probability. The resource allocation scheme using the smaller PRB can cause less interference to neighboring groups, which could outperform the best pair (e.g., MCS 5, PRB 4) with the increase of D2D groups in the region. Thus, depending on how dense the area is (i.e., the number of D2D groups packed in this area), a UE needs to give weight to a particular PRB size in order to achieve better system performance. With the pre-knowledge of the number of D2D groups in the deployed area, the UE can select the MCS and PRB pair accordingly so that the overall system performance can be improved. Algorithm 1 shows the procedure for selecting the MCS and PRB combination with the smallest D value in order to maximize coverage probability. As Algorithm 1 computes the MCS and PRB pair with the smallest D value by enumerating all combinations, its complexity is $O(n_{MCS} * n_{PRB})$, where n_{MCS} is the total number of MCSs and n_{PRB} is the total number of PRBs.

Algorithm 1: Algorithm for Selecting MCS and PRB Combination

```
Input: Throughput requirement and TRP settings

  smallest $D$ value
```

In the following, we introduce two other schemes that leverage available network information to improve the system performance.

D. RSS-based Random Scheme

We now introduce the RSS-based random resource allocation scheme, which adopts power control to reduce the energy consumption of the transmitter UEs and potentially reduces interference to neighboring groups. In the RSS-based random scheme, we leverage the D2D discovery service. There are two discovery modes: (i) *Model* A, and (ii) *Model* B. In Model A, the UE sends a discovery message autonomously, while in Model B, the UE is polled by neighboring nodes and sends the discovery response. Through Model B, the transmitter UE can send inquiries to its D2D group. Based on the SD-RSRP (Sidelink Discovery Reference Single Received Power) of the discovery response message, the path loss of UEs in the group can be estimated. Notice that RSRP is the average power received on the resource elements that carry the Demodulation Reference Signal (DMRS) of a decoded PSDCH (Physical Sidelink Discovery CHannel) signal. From the SD-RSRP and UE's transmitter power, the time averaged channel loss from the receiving UE in the group to the transmitter UE can be estimated. As D2D uses the LTE uplink spectrum for communication, D2D channels in both directions are reciprocal. Thus, we can estimate the channel loss from the transmitter UE to the receiver UE based on channel reciprocity.

Once the maximum channel loss in a group is available, the transmitter UE can use the same MCS and PRB as identified using the basic random allocation scheme, but instead of always transmitting using the maximum power, it may transmit with a reduced transmission power using the channel loss information. We assume network deployment is not fast-changing, and thus the CSI collected in the discovery process can be used to assist communication.

Power control can be conducted either open-loop or closed-loop. The open-loop control is to set the transmission power based on path loss and shadowing information, while the closed-loop control is used more often to accommodate the fast-fading effect. By controlling the transmitting power, UEs can not only save energy and improve battery life, but also reduce interference with other transmitting UEs in neighboring groups while preserving QoS of the UEs. Since D2D group communications do not have physical layer feedback and only coarse channel state information is available, we can only estimate path loss and shadowing effects from the discovery message from its group UEs, and the channel information is used to set transmitting power.

In this scheme, we introduce the compensation factor (CF), which denotes how much compensation we want for the channel loss (including both path loss and shadowing). The transmitted power after power control is

$$P_{tx} = \min((1-CF)P_{max} + CF \times PL_{max} + \text{noise floor}, P_{max}), \quad (15)$$

where the PL_{max} is the maximum channel loss of the radio link between transmitter UE and its group UEs. When CF is 1, P_{tx} is the minimum transmitting power to bring the received average power just above the noise floor. With the growth of CF, we can increase the transmitting power to have more margin and account for small-scale fading and the interference from other groups. Protocol 1 shows the detailed procedure for conducting power control.

Protocol 1 RSS-based Random Scheme

Inputs: Preselected MCS and PRB, and CF value
Output: UE transmitting power
Protocol:

1) Transmit UE sends discovery request using maximum power
2) UEs send back discovery responses after decoding the request using the maximum power
3) Transmit UE calculates the maximum channel loss experienced by its group and sets its transmit power using Equation (15)

Protocol 2 Interference Aware-Based Scheme

Inputs: Preselected MCS and PRB, and resource pool (channels)
Output: Which PRBs to select in the resource pool
Protocol:

1) Each UE monitors the channel that it can detect, and builds a list of channel with RSS greater than -105 dBm
2) Transmit UE sends discovery request using maximum power
3) UEs send back discovery responses with the channel list using the maximum power after decoding the request
4) Transmit UE sorts the interference channels by interference level, i.e. the number of group UEs that can detect this channel
5) Compute the channel that has the lowest level of interference

E. *Interference-Aware Allocation Scheme*

The resource allocation of the two aforementioned schemes are based on the random selection strategy, meaning that the transmitter UE randomly selects the PRB location uniformly from the resource pool. Notice that, in our study, we assume all transmitting UEs use just one channel, and each channel contains the same number of resource blocks. Thus, the problem becomes how to pick the channel for transmitter UEs. If a transmitter UE selects a channel randomly without knowledge of its environment, it may not achieve desirable system performance.

To consider interference, the transmitter UE first collects information about the interference experienced by the receiver UEs within its D2D group. This can be carried out by sending a discovery query message to nearby UEs. The UEs within the same group, after receiving the message, then piggy back the channels that it can detect (i.e., average RSS is above -105 dBm) using the discovery response message. When the information is collected, the transmitting UE will rank each channel by the number of group UEs that can detect that channel (i.e., the number of group members that are interfered by that channel). The channel detected by the least number of transmitters will be selected by the transmitter UE. If there are multiple channels that could satisfy the requirements, we will select the channel that has been used most recently. If no such information available, we will randomly pick one from the multiple channels. For example, if two transmitters can be detected by the same receiver, these two transmitters become interferers to each other, and we should try to put these two on different channels so that interference between them can be avoided. Thus, if a transmitter's total number of interference channels is less than the size of the channel pool, the transmitter can use one of the unused channels to transmit. If the transmitter is located within a much more dense area, and all the channels have been used by all neighbor transmitters, the channel detected by the minimum number of UEs in its group will be picked. Protocol 2 shows the detailed procedure for conducting the channel selection with the least interference.

V. Performance Evaluation

In this section, we present our performance evaluation. In particular, we first introduce the evaluation methodology and provide evaluation results.

A. *Methodology*

To evaluate the performance of the D2D group communication system, we consider coverage probability, defined in Section IV, as the key metric. To evaluate the power saving performance, we measure the power saved in the transmitting UE as the ratio of the power usage from all transmitter UEs transmitting at maximum power to the power usage when the power control scheme is in place, the results of which are presented in units of dB.

To simulate a group communication scenario, a number of UE groups are deployed in a circular region with radius 3000 m. Within each group, 20 receiver UEs are deployed within a small circle around the transmitter UE. We evaluate the performance by varying the number of groups in the region in order to simulate a region with different levels of density. We also evaluate the impact of group size on performance by varying the closeness of the receivers to the transmitters. We assume all the transmitter UEs have full buffers so that the transmission is continuous. For fixed locations of transmitters and receivers, we generate log-normal random variables to simulate the shadowing effect of the channel between each transmitter and receiver pair. With the deployment and shadowing information, we can compute the area mean power of a receiver and use Equations (10) and (13) in Section IV-A to compute the average coverage probability of a deployment, and we can simulate hundreds of deployments to obtain average performance.

B. *Results*

1) Basic Random Allocation Scheme: Figure 5 illustrates the coverage probability vs. the number of D2D groups in a range of [1, 10]. Figure 6 illustrates the coverage probability vs. the number D2D groups in a range of [10, 100]. From both figures, we can make the following observations. First, when the number of groups increases, the coverage probability reduces due to the increase in interference. When UEs in a group are geographically close to each other (i.e., r is 300 m), receiving UEs have higher desired signal power and experience less interference from other transmitter groups, such that the average coverage probability is better than for UEs in more dispersed groups (i.e., r is 500 m). For just a single D2D group, the combination of MCS 5 and PRB 4 achieves the best coverage with a small margin over MCS 10 and RPB 2 (due to the smallest D value). With the increase in number of D2D groups, MCS 10 and PRB 2 soon outperform MCS 5 and PRB 4.

Additionally, with PRB 12, since it uses MCS 0, which requires the lowest SNR to decode the signal, when there is only 1 group, it performs better than MCS 16 and PRB 1. However, when the number of UE groups in a region reaches a certain level, the interference becomes a problem. When this

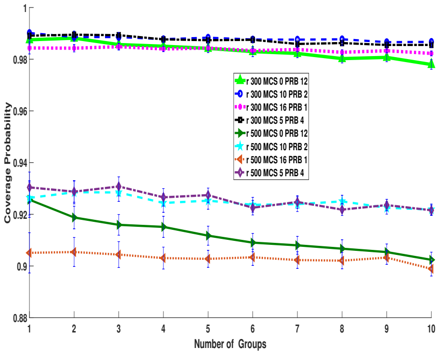

Fig. 5: Basic Random Scheme (R = 3000 m, r = 100 m, 500 m, Group=[1,10])

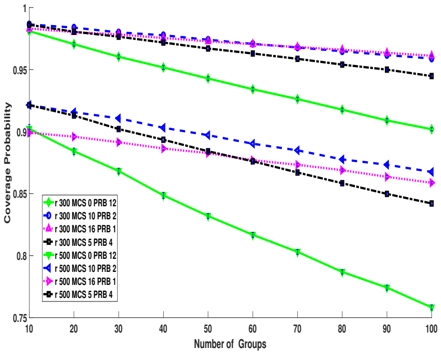

Fig. 6: Basic Random Scheme (R = 3000 m, r =300 m, 500 m, Group=[10,100])

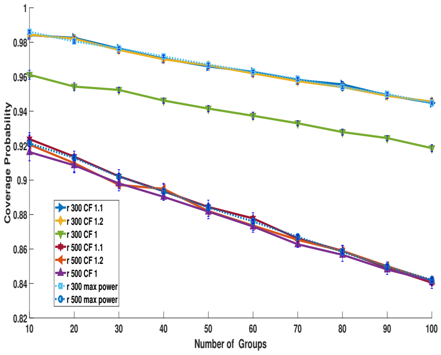

Fig. 7: Coverage Probability of RSS-based Random Scheme (MCS=10, PRB=2)

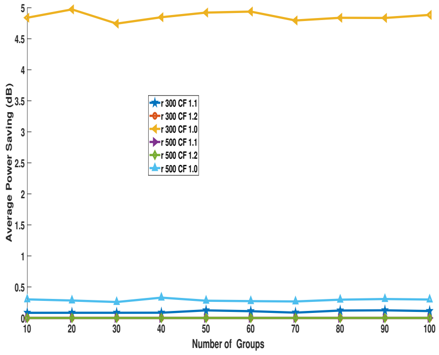

Fig. 8: Power Saving of RSS-Based Random Scheme (MCS = 10, PRB = 2)

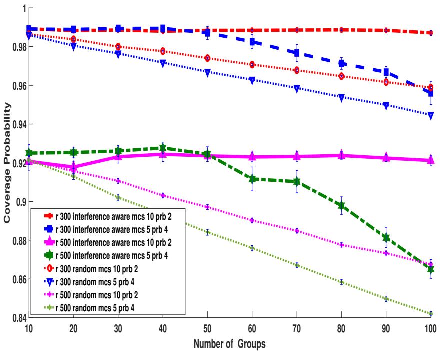

Fig. 9: Coverage Probability of Interference Aware Allocation Scheme (R = 3000 m, r = 300 m, 500 m)

occurs, MCS 12 starts having better coverage probability than MCS 0. This is because, with the fixed resource block size, more channels can be divided for PRB 12 than for PRB 1, leading to a lower chance of collision in the frequency domain. In general, when the system is dense, or more transmitters are deployed in a given region, the resource allocation schemes that using less resources have a performance advantage. Notice that, in the basic random scheme, we do not take into account the interference from different groups. This is the decision made by the transmitter UE itself. If each D2D UE uses this scheme, it may not achieve the overall best average coverage probability. Thus, depending on how dense the area is (i.e., how many D2D groups are packed into the deployment area), the UE more heavily weights a smaller PRB size in order to achieve better coverage.

2) RSS-Based Random Allocation Scheme: Figure 7 illustrates the average coverage probability vs. the number of groups (which varies from 10 to 100), where power control is used with different values of CF. Notice that, when CF is 1, we have enough transmitting power to compensate for the average channel loss due to path loss and shadowing. When CF is greater than 1, we overcompensate for the average channel loss to accommodate for the small-scale fading and the interference from other transmitters. Figure 8 illustrates the average power savings in transmitter UEs as the number of groups varies from 10 to 100, and the system implements the RSS-based random scheme. For both figures, the PRB size is set to 2 and the MCS is fixed at 10.

From these two figures, we can observe that, when r is small (r is 300 m) and CF is 1, UEs can save around 5 dB in transmitting power on average, with about a 2 % drop in the coverage probability. However, when r becomes large (r is 500 m), to compensate for the largest channel loss in a D2D group, the transmitting power is close to the maximum transmitting power and the power savings become insignificant (around 0.3 dB). As a consequence, the coverage probability is comparable to that of the maximum transmitting power. When CF is 1.1 or 1.2, there is almost no power savings, meaning that the transmitting UEs are approximately using the maximum transmitting power. Based on our evaluation results, we confirm that there are tradeoffs between coverage probability and power saving improvements, meaning that greater power savings results in a sacrifice in the form of lower coverage probability.

3) Interference-Aware Allocation Scheme: Figure 9 shows the average coverage probability for two different UE groups with receive UE deployment distances of r=300 m and r = 500 m. We also demonstrate the performance of two MCS configurations (i.e., MCS 10 and MCS 5). We can observe that, when the UEs are closer together, the coverage performance is good, even with a random channel selection. When MCS is 10, since it uses less PRBs, radio resources can be divided into more channels. With the interference-aware scheme, when there are up to 100 groups in the circular region of radius of 3000 m, the interference can be mitigated well and the average coverage probability remains flat. However, when MCS is 5, since it uses double the size of PRB compared to MCS 10, the number of channel divisions that it can allocate is only half. Thus, we can observe that the coverage probability for MCS 5 starts dropping when the number of groups reaches approximately 50, since there are not enough channels to avoid interference. Thus, using neighboring D2D group information, we confirm that coverage probability can be significantly improved, especially when region is dense, assuming appropriate channel selection.

VI. Final Remarks

In this paper, we have addressed the resource allocation issue of out-of-coverage D2D scenarios for public safety communications and investigated three distributed resource allocation schemes. To be specific, we first showed how UEs could schedule resources based on the throughput requirements of applications and maximize transmission coverage. We then investigated how to select the physical block size in the resource pool once the decision is made on MCS and PRB size. To do so, we proposed three distributed resource allocation schemes. In the basic random allocation scheme, no D2D deployment information is relied upon to select resources. In the RSS-based random allocation scheme, power control is used to reduce the energy consumption of the transmitting UEs. In addition to the random allocation schemes, we propose an inference-aware scheme that allows transmitter UEs to collect interference information from nearby D2D groups. By using such information, the interference among UEs can be reduced, leading to performance improvement. We conducted an extensive performance evaluation to validate the effectiveness of our proposed schemes. Our findings show that the basic random allocation scheme works effectively when the region is not dense, the power control scheme is capable of reducing UE transmission power with only a small sacrifice in coverage performance when receiver UEs belong to a group are deployed close to the transmitter, and the interference-aware scheme can significantly improve coverage by mitigating interference among groups.

Abstract— **Multipath is one of the limiting factors for an accurate outdoor and indoor localization. We proposed an approach that uses a multipath mitigation derived from the undesired frequency-to-amplitude conversion of a frequency modulated (FM) signal experiencing multipath.**

Keywords*— *fading; frequency modulation; indoor location; multipath

I. Introduction

Multipath propagation is one of the limiting factors for an accurate outdoor and indoor localization [1, 2]. It introduces multipath fading due to the interference of the direct line-of-sight (LOS) signal with reflected signals from objects such as buildings, ground, trees, and other obstacles. The destructive interference of LOS and the reflected signals can create frequency dependent spectral nulls. Indoors, multipath fading occurs frequently and makes it quite difficult to accurately estimate the direct path length. Different multipath compensation schemes have been proposed and implemented over the years to tackle the effect of multipath propagation for accurate location [3, 4]. In this paper, we describe a method of multipath correction that uses correlation between frequency modulation (FM) and amplitude modulation (AM) signals due to frequency-to-amplitude conversion of a FM signal experiencing multipath. The simulation result of the proposed multipath mitigation method is presented.

II. Methods/Results

The proposed approach of multipath mitigation utilizes the undesired frequency-to-amplitude conversion of a frequency modulated (FM) signal experiencing multipath. The basic concept is to measure correlation between the demodulated FM and AM of the received signal under multipath environment and create a control signal for feed-forward correction. One advantage of measuring AM is its simplicity, it requires an AM detector which is a simpler, smaller, and less expensive device.

The block diagram of the scheme used for reducing multipath effects on FM signals is shown in Fig. 1. We implemented this configuration in a LabVIEW simulation. First, the TX signal was generated by frequency modulating a carrier with white Gaussian noise. A model for a simple multipath channel was created by adding a single delayed, attenuated version of the TX signal to itself.

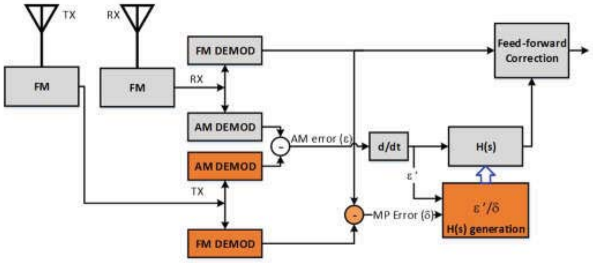

Fig. 1. Block diagram of the FM-AM correlation measurement and compensation technique. The orange blocks are required only for H(s) generation. H(s) is the control transfer function that maps amplitude fluctuations to multipath (MP) error. In case of two-way ranging known modulation symbols can be used for H(s) generation.

Sending the TX signal through this multipath channel generates the received signal RX. The received signal is simultaneously FM and AM demodulated. In addition, the TX signal is also FM and AM demodulated at the transmitter end. The instantaneous multipath error, $\delta(t)$ is determined by subtracting the received FM demodulated signal from the transmitted FM demodulated signal. Similarly, the AM error, $\varepsilon(t)$ is obtained by subtracting the received and transmitted AM demodulated signals. The cross-power spectral density (CPSD) which is a measure of correlation between two time- series, is calculated between $\delta(t)$ and $\varepsilon(t)$ and is given by

$$S_{\delta\varepsilon}\left(f\right)=\frac{2}{T}\left\langle\Delta\left(f\right)\mathrm{A}^{*}\left(f\right)\right\rangle_{m}, \qquad (1)$$

where, $\Delta(f)$ and $\mathrm{A}(f)$ are the Fourier transforms of $\delta(t)$ and $\varepsilon(t)$ respectively, T is the measurement time normalizing the power spectral density (PSD) to 1 Hz, “*” indicates the complex conjugate, and $\langle\ \rangle_m$ denotes an ensemble of m averages. The simulation results in decibels (dB) of $S_{\delta\varepsilon}$ along with S_δ (= PSD of $\delta(t)$) and S_ε (= PSD of $\varepsilon(t)$) are shown in Fig. 2. The degree of correlation between S_δ and S_ε can be described by a correlation function, ρ [5]

$$\rho=\frac{S_{\delta\varepsilon}}{\sqrt{S_{\delta}S_{\varepsilon}}}, \qquad (2)$$

Hati, Archita; Nelson, Craig. "Multipath Mitigation from FM-AM Correlation." Paper presented at 2019 IEEE IFCS-EFTF, Orlando, FL, US. April 14, 2019 - April 18, 2019.

where $\sqrt{S_\delta S_\varepsilon}$ is the geometric mean of S_φ and S_α. The values of ρ range from 0 to 1 and $\rho = 1$ represents 100 % correlation. Fig. 2 shows that the cross-spectrum is almost the expected geometric mean between 10 kHz and 1 MHz offset frequencies indicating almost a 100 % correlation. Further, it can be seen from Fig. 2 that the slope of S_ε is f^0 and S_δ is f^2, so if we generate a control signal utilizing S_ε that is of same magnitude, the same noise slope, and opposite phase as the S_δ , then this control signal can be used in a feedforward approach to reduce the error due to multipath.

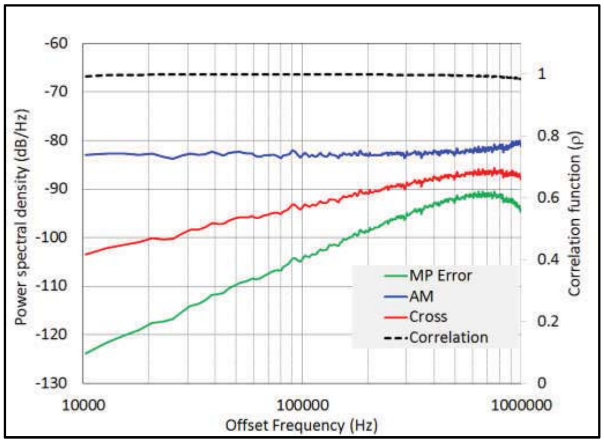

Fig. 2. Plot of the power spectral density $S_{\delta\varepsilon}$ (cross) along with S_δ (multipath error) and S_ε (AM) (left axis). The plot shows almost 100 % correlation (ρ = 1) as shown on the right axis. For this simulation, a 100 MHz carrier frequency modulated with white noise (standard deviation = 0.1, noise bandwidth = 1.0 MHz, modulation index = 0.3) and multipath delay, τ = 13 ns was used. MP – Multipath.

To simplify the control transfer function, H(s), the slopes between S_δ and S_ε can easily be matched by taking the time derivative of $\varepsilon(t)$ to produce $\varepsilon'(t) = d\varepsilon(t)/dt$. This is shown in Fig. 3 (a) indicating that S_δ, $S_{\varepsilon'}$ and $S_{\delta\varepsilon'}$ all now have the same slope. Here, $S_{\varepsilon'}$ is the PSD of $\varepsilon'(t)$ and $S_{\delta\varepsilon'}$ is the CPSD between $\delta(t)$ and $\varepsilon'(t)$. H(s), which maps amplitude fluctuations to multipath error is generated with the LabVIEW frequency response function (FRF). For calculating H(s), $\varepsilon'(t)$ is used as the stimulus signal and $\delta(t)$ as the response signal. Once the transfer function is created, $\varepsilon'(t)$ is filtered with the transfer function and applied to the FM demodulated signal in a feedforward fashion. The PSD of the multipath error $\delta(t)$ is measured with and without the control signal and is shown in Fig. 3 (b). An improvement of greater than 20 dB over two decades of offset frequencies can be seen. However, this scheme works for a fixed multipath condition and requires re-calculation of the transfer function when multipath environment changes (i.e. the antennas positions move). This problem can possibly be addressed with an adaptive control system. Also, in case of two-way ranging conditions a known modulation symbols can be used for H(s) generation.

III. Conclusions

We proposed a new multipath mitigation technique suitable for narrowband systems. It relies on FM-AM correlation when the FM signal experiences multipath, we reported more than 20 dB reduction of multipath distortion.

Best in Class: Leveraging Robot Performance Standards in Academic Competitions to Encourage Development and Dissemination

Raymond K Sheh[1,2] and Adam S Jacoff[2]

ABSTRACT

Standard test methods and academic competitions share much in common. We detail how we use standard test methods to promote education, research, development, and dissemination among the academic community. Since 2014, we have used competitions and open source robot designs to focus students, and particularly high school students, on the challenges of emergency response and public safety robotics. Our two main initiatives are the Rapidly Manufactured Robot Challenge (RMRC), which forms part of the RoboCup Rescue Robot League (RRL), and the Open Academic Robot Kit (OARKit). The RRL and RMRC leverage Standard Test Methods for Response Robots, developed under ASTM International Subcommittee E54.09 on Homeland Security Applications: Response Robots. The standards developed under ASTM E54.09 are significantly supported by the pre-normative research collaboration between the US Department of Homeland Security (DHS) and the US National Institute of Standards and Technology (NIST). These standard test methods are an effective way of communicating the challenges of the domain and focusing research and development on open problems. By measuring the performance of prototypical implementations in a consistent, comparable manner, standard test methods also allow students to compare performance with each other, as well as with commercial, deployed robots. The OARKit aims to capitalize on the ease of comparison and collaboration that comes with the use of standard

Paper presented at ASTM STP1614 on Symposium on Homeland Security and Public Safety: Research, Applications and Standards, San Diego, CA, US. June 28, 2018 - June 29, 2018.

test methods by lowering the resource and expertise barriers for entry into response robotics research. This family of robot designs form ideal starting points for new and existing teams to enter the RMRC. Teams build these robots by following basic instructions and then improve them in their area of expertise. The results are then rigorously measured in the competition and disseminated to other teams. Thus the community of teams share each other's developments and push the state-of-the-art forward.

Robot Competitions, Response Robotics, Education

Introduction

Standard test methods share many similar characteristics with competitions, particularly competitions that focus on individuals or teams achieving a score that is then compared with others. In both standard test methods and competitions, performance is measured in a way that is intended to be fair, repeatable, reproducible, and significant in some way.

The RoboCup Rescue Robot League (RRL) has been running since 2000. This research competition, originally for university research students, aims to foster the development of technologies to address gaps in the deployed capabilities of response robots[3], such as those deployed for addressing natural disasters, explosive ordnance disposal, or nuclear incident response. This competition forms an integral part of the development process for the Standard Test Methods for Response Robots, developed under ASTM International Subcommittee E54.09 on Homeland Security Applications: Response Robots. The RRL is an incubator for conceiving,

[3] Certain commercial products are identified in this paper to foster understanding. Such identification does not imply recommendation or endorsement by the National Institute of Standards and Technology, nor does it imply that the products identified are necessarily the best available for the purpose.

developing, refining, and validating new test methods, in the presence of prototypical robots that embody new capabilities and ideas. It also disseminates the test methods among the academic and developer communities and provides an opportunity to perform repeatability and reproducibility testing.

The RRL Rapidly Manufactured Robot Challenge (RMRC) is a research competition aimed at high school and early undergraduate students. It also leverages these test methods to expose these younger students to open research challenges in the field of response robotics. Since 2014, we have been developing the RMRC alongside the Open Academic Robot Kit (OARKit), an initiative that aims to bring interesting research-level robots into high school and undergraduate classrooms. It lowers the barrier of entry in terms of cost and resources by leveraging open source principles and low cost, rapid manufacturing and prototyping equipment such as 3D printers and laser cutters. In this paper, we present the history, motivation, and latest developments of these two initiatives and their close relationship to the ASTM E54.09 standard test method development efforts.

Robotics competitions bring significant benefits to younger students and research communities alike. For example, they provide inspiration to students, both by way of the application as well as through observing their peers from the other side of town or the other side of the world. They are a conduit for disseminating information about the challenges and best-in-class solutions to those challenges. They guide the thinking of students towards gaps in current capabilities and provide a way to measure their progress towards addressing them. They also bring to the attention of industry and government the capabilities being developed in classrooms and institutions that may otherwise not be apparent, and present them in a way that is directly comparable to the deployed state-of-the-science.

Standard test methods can play an important role in amplifying these benefits by ensuring that the challenges that guide and inspire the students direct them towards measurable deficiencies in the current state-of-the-art. The Standard Test Methods for Response Robots are designed to be elemental, abstracted tasks that are directly relevant to the real world tasks that response robots must perform in applications such as search and rescue, explosive ordnance disposal, hazardous and nuclear waste cleanup, disaster survey, military reconnaissance, and the like.

They do not replace testing of robots in operational scenarios; rather they provide an indication of the strengths and weaknesses of the robotic system and are a filter to determine which systems are ready for operational testing. To use a sporting analogy, they are like the basic tests of running, jumping, catching, throwing, and so-on that a coach might use to determine how their team is performing and where individual players may need to improve. These tests would also be used by the coach to filter new players before they play their first test game.

THE HISTORY OF ROBOCUP

Since 1997, the RoboCup Federation has been holding robotics competitions. These first focused on the Artificial Intelligence (AI) research community. In the 20 years since, it has branched out across both the wide array of robotics-related topics as well as the various age groups, from junior school students through to early career researchers.

The objective of RoboCup is that “By the middle of the 21st century, a team of fully autonomous humanoid robot soccer players shall win a soccer game, complying with the official rules of Fédération Internationale de Football Association (FIFA, the world soccer governing organization), against the winner of the most recent World Cup.” [1]. Conceived as a “Grand Challenge”, RoboCup is a vehicle to promote robotics and AI research. It is also a type of “standard problem” that can be replicated around the world, with rules that are familiar to many around the world and are well-documented and understood.

The RoboCup Rescue Robot League

In 2000-2001, the RoboCup Rescue Robot League was introduced. This competition, first piloted at the Association for the Advancement of Artificial Intelligence (AAAI) 1999-2000 conferences, brought the challenge of the Urban Search and Rescue task to university students, who were tasked with building a robot that could survey a disaster site, find victims, determine their condition, and build maps of the environment [2]. In these early years, the arena consisted of various random items of furniture, debris, and other household items, arranged into three regions that represented different mobility challenges [3] [4].

The competition was run in three rounds. First, a preliminary round is run with all teams being given multiple opportunities to search and survey the arena. The arena was often split in half, allowing two teams to run at the same time before switching sides. Teams scored points by finding mannequin body parts as simulated "victims", and other objects of interest, overcoming debris and other obstacles strewn around the arena. The points were added up and a clear break in the scores was sought that separated out the top 5-10 teams, thus avoiding the situation where a team "just" missed out. These teams progressed to the finals. Teams were given the whole arena to search and survey, with the team that found the most victims and brought back the most information was declared the winner.

During these two rounds, teams were prevented from observing the arena until after their runs, thus the competition was truly a search task. While realistic, this competition was less reliable as a standard test due to the highly random nature of the behavior of the robots, as well as the element of luck involved in searching the arena.

A third round, called Best-in-Class, allowed teams that specialized in particular aspects of the competition to demonstrate their capabilities, even if they did not have the broad base of expertise that would allow them to win the overall competition. Initially, Best-in-Class awards were given for Mobility and Autonomy. These focused on the robot's ability to traverse terrain and to navigate autonomously, respectively. In later years, this was joined by Manipulation, which focused on robots with the ability to manipulate objects.

Starting in 2005, in conjunction with the launching of the ASTM standardization effort supported by DHS, prototypical standard test method elements began being introduced into the arena. This started with the Random Stepfields [5] shown in Figure 1, a repeatable, reproducible analog for unstructured terrain. The random mannequin body parts that were the simulated "victims" in previous years were also replaced by standard artefacts, designed to test the abilities of the robots' various sensors, such as thermal and visible light cameras, microphones, carbon dioxide sensors, and so-on. In subsequent years, the arena shifted to being based on standard test method apparatuses, primarily for terrain traversal such as crossing ramps, symmetric stepfields, and stairs. Thus, as teams ran their robots through the arena, they were also, in effect, performing informal tests within the standard test methods.

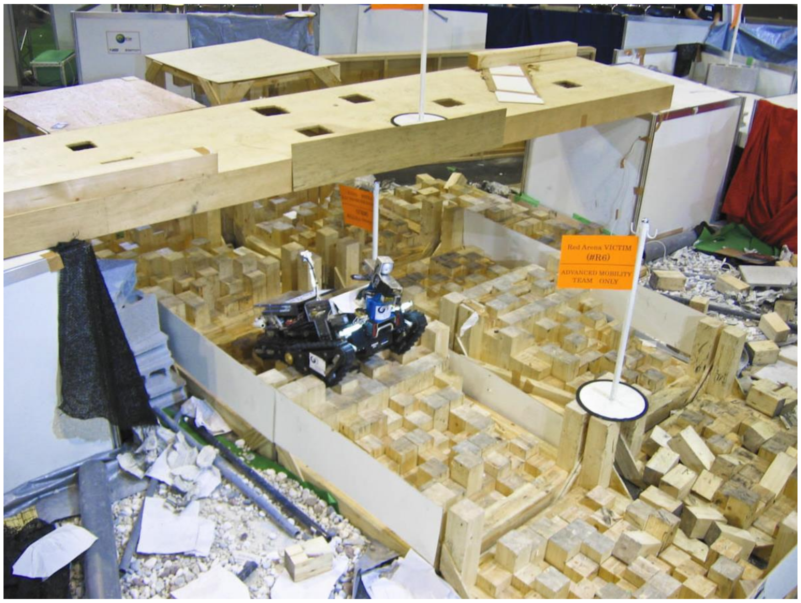

Figure 1: The Random Stepfields at the RoboCup Rescue Robot League 2005.

To further reduce the element of chance in the competition, in the late 2000's the secrecy component of the competition was also dropped, with team members being allowed to enter the arena prior to the run and verify that it had been re-set correctly after the previous team's run. This had the effect of switching the competition from a search task to one of focusing on the test methods integrated into the arena. The more test methods teams could overcome, the more "victim" sensor test boards they could reach and thus more points they could obtain. At the same time, the Best-in-Class competitions were introduced as separate rounds within the standard test method apparatuses. Most obvious of these was the Best-in-Class Mobility competition, which was a direct application of ASTM E2828-11 Standard Test Method for Evaluating Emergency Response Robot Capabilities: Mobility: Confined Area Terrains: Symmetric Stepfields [6].

Around 2015, the competition progressed further towards standardization. Instead of running one or a small number of standard test method rounds as a Best-in-Class round, the preliminary rounds were replaced by standard test method runs within separate lanes. The goal became that of statistically significant testing in the preliminary rounds with as many teams as possible running tests in parallel. The scores for each test were normalized according to the best performing team in that test and then combined to determine which teams progressed to the final rounds.

Outreach Activities

The RoboCup Rescue Robot League goes beyond just a competition. The overall goal of the League is to advance the state-of-the-science in response robotics, in part by fostering the sharing of capabilities between teams. The competition itself goes some way towards this by allowing teams to observe each other's capabilities, as tested in comparable test methods. However, it can be quite difficult for teams to share information during competition, if only because time and development effort pressures mean that many teams, especially those who are performing particularly well, would rather focus on their next competition run.

As a result, the RoboCup Rescue Robot League also hosts regular teaching camps [7] or summer schools. The League community is also active in academic conferences, particularly the RoboCup Symposium and the International Symposium on Safety, Security and Rescue Robotics (SSRR), run by the Institute of Electrical and Electronic Engineers (IEEE) Robotics and Automation Society (RAS). These venues provide a more relaxed environment in which those who developed the Best-in-Class capabilities of the previous competition can present their work.

The teaching camps in particular are structured to be highly practical. Usually half of the time is set aside for traditional lectures and presentations, while half of the time is spent in multi-tracked practical sessions where smaller groups are led in the implementation, or re-implementation, of a capability that they can then take and build upon or use as a point of comparison. This provides opportunities for other teams to bring their own robots and learn, in a hands-on fashion, how to implement these capabilities. Examples of capabilities that have been spread through the league through these events include various 2D and 3D Simultaneous Localization and Mapping (SLAM) implementations [8], inverse kinematics, aerial robots, and user interfaces.

These events also form a valuable opportunity to form collaborations with stakeholders outside of traditional university academia. The teaching camps and summer schools are usually hosted at a site where responders train and always have a contingent of responders in attendance, such as firefighters and police officers. These personnel attend alongside the students, with the goal of sharing their knowledge of the application, grounding the students' understanding of where their technologies may be useful, as well as to learn about new capabilities that may be of use to them but may not be well known outside the laboratory. Other academic sectors have also attended these events to learn about potential opportunities to expand their activities. Indeed, the RMRC was launched at the 2014 Safety, Security and Rescue Robotics Summer School and Workshop [9], which was jointly hosted by the Perth Artifactory makerspace and Curtin University. For the first time, a contingent of high school teachers joined the event and formed the core teams that participated in the pilot competitions in the following years.

Finally, these events provide an opportunity to analyze the outcomes of the prototypical test methods, experiment with them in a more informal setting, and document them in preparation for potential standardization. They also provide an avenue to disseminate in more detail the test methods among the broader academic community.

COMPETITION TRADE-OFFS

In discussing robot and AI competitions and their ability to advance research goals, we find it useful to consider competitions according to two different trade-offs. The first is the task, be it abstract or real-world application based. The second is expected novelty, be it known or research.

Competition Task Trade-Off

An example of an abstract task is robotic chess. This is a game, developed for a particular purpose. On the one hand, while the research challenges are still very real and applicable, the game is heavily abstracted from open real-world challenges. On the other hand, the problem is also very well defined with a well understood set of semantics, problem definition, and evaluation metric.

In contrast, a real-world application based task might be the US Defense Advanced Research Projects Agency (DARPA) Urban Challenge [10] which involves autonomous robotic vehicles driving through an urban area, complete with other autonomous and human-operated vehicles. The top performers in such a competition have produced a working solution that solves an open real-world application problem. Of course there is usually still significant work to be done to make their entry viable in the real world from safety, economic, production, and regulatory perspectives (among others). However, administering and competing in such competitions tend to be very resource intensive. This limits both the ability to run such competitions as well as the ability of teams to compete.

All competitions trade off between these two characteristics depending on their goals, a compromise that is generally mutually exclusive. Our goal with the RRL and RMRC is to balance being abstract enough to make it easy to administer and compete in these competitions, while also being close enough to the application that they can foster and evaluate the development of technologies that are applicable to real-world problems in the short to medium term.

We leverage the Standard Test Methods for Response Robots as a way to achieve a balance between these two characteristics. Test methods, by their nature, must be both abstract enough to be reproducible and repeatable, scientifically rigorous, and economically viable to reproduce and disseminate, and yet the resulting metrics must clearly be an accurate reflection of a real-world need. By building a competition based around standard test methods, we take advantage of all of the development effort, industry and end-user consultations, and international experience behind these test methods; resources that are generally unavailable to most competitions.

Competition Novelty Trade-Off

Competitions also vary in terms of the novelty of the challenges and expected solutions. On the one hand are competitions where the underlying problems are relatively well understood. Teams are differentiated by how well they can answer this problem, which may still require some degree of novelty, but in general what is required of teams is well understood. Examples include track racing or flat-floor mazes. Such competitions encourage refinement and optimization of solutions.

On the other hand are competitions that pose problems for which there is no known satisfactory solution. Such competitions encourage a much wider variation in solutions, but these solutions also tend to be less well optimized and more experimental. The RoboCup Rescue Robot League is an example of an application that tends towards this end of the spectrum.

RELATED WORK

Research competitions and open source hardware initiatives have been gaining significant traction over the last decade as their value to both teaching and research have become recognized. In this section we will discuss some related competitions and initiatives.

Related Competitions

Robotics competitions have been a feature of high schools for many decades as teachers have leveraged their ability to consolidate the many aspects of what is now called STEAM – Science, Technology, Engineering, Art, and Mathematics – into an event that inspires creativity and problem solving. As a result there is currently a plethora of different competitions, many of which are surveyed in [11].

RoboCup itself is a family of competitions for participants from 14 years old (some regional competitions have lower limits) up to early career researchers (and beyond). In the Junior category, which allows students up to 19 years old, there are three main competitions: OnStage (performance), Soccer, and Rescue. There are also additional challenges such as the CoSpace challenge [12] as well as the RMRC itself. Apart from the RMRC, these competitions are based on games and abstract tasks.

Beyond RoboCup, perhaps one of the best known families of robotics competitions in the present day are the "For Inspiration and Recognition of Science and Technology", or FIRST, Robotics Competitions [13]. Catering to students from kindergarten through high school, the various competitions that make up FIRST aim to not only inspire students to partake in the study of science and technology, but to also teach students about other life skills such as "self-confidence, communication, and leadership".

To this end, RoboCup Junior and FIRST quite deliberately pick somewhat abstract games, made up of combinations of tasks such as moving balls into goals, navigating mazes, pushing levers, and delivering objects on a flat playing field. The point of the competition isn't the solution to the problem itself, but rather the journey that students take in solving the problem. Competitions such as RoboCup Junior OnStage also focus on artistic aspects, particularly as it relates to performance art. CoSpace augments the real robotics competition with a parallel virtual robotics environment to enable more advanced programming and algorithm development. FIRST augments these problem solving tasks with those that encourage teamwork, professionalism, and community service, such as having to form ad-hoc teams during the competition and giving presentations. Indeed, having a more concrete, real-world problem could arguably get in the way of these goals.

Traditionally, competitions where the goal is the solution, rather than the journey, has been the realm of more senior students. These competitions pose open research problems and teams that do well will have developed a novel contribution to a real-world problem. Examples of such competitions include the DARPA Grand and Robotics Challenges, the World Robot Summit 2020 [14], and the RoboCup Rescue Robot League [15]. These competitions tend to require more resources to administer and compete in, both in terms of materials as well as expertise.

In a sense, developing these competitions is very much like developing standard test methods. The goal is to strike a balance in developing a test that is sufficiently abstract that it can be reproduced, understood, and disseminated reliably and fairly, while also being relevant to the real world task, with all the variability that this entails.

Related Open Source Robotics Initiatives

One way to lower the material and expertise cost of participation for new and existing teams into any of these competitions is to allow the teams to build on others' work. Different initiatives have been proposed to assist in this task.

Some competitions make use of specified or mostly specified parts. Examples include competitions that make use of construction kits, such as the FIRST Lego League and several of the RoboCup Junior competitions [16]. Other competitions, such as the FIRST Robotics Challenge [13], provide a specific, common kit of parts along with documentation and examples.

Construction kits that combine physical components with sensors, actuators, and computation, such as Lego Mindstorms, have been pivotal in bridging the gap between computer science and physical robots in the high school because they remove a lot of the complexity involved in actually building the robots that are necessary to embody code and algorithms. The use of such kits is also significantly safer for younger students than building robots in a more traditional manner out of metal, wood, or plastic. However, it is limited in its ability to build larger, more complex, more durable robots due to the need to limit designs and structures to those that are compatible with the particular build system. It is also difficult to teach more advanced concepts in design, particularly as it relates to design for manufacture. Dissemination and re-use of other teams' work can also be challenging with these kits due to the high level of design coupling between different parts of the robot. Thus, while such kits are a tremendously valuable tool to teach introductory robotics, it is difficult to build larger, more complex robots and to leverage other students' work.

In recent years, 3D printing and laser cutting have become much more widespread among high schools, particularly as open source equipment and software have lowered the financial and expertise cost. Practical, low cost 3D printers capable of printing robot components out-of-the-box, with minimal expertise, can be purchased for less than $300 USD, while larger printers, capable of printing whole robot parts without needing to glue them together afterwards, can be purchased for less than $1,000 USD. In a classroom environment, laser cutters have also become more commonplace and can often be more practical as they can produce larger (albeit flat) components much more quickly than 3D printers. Here too, prices have fallen with easy to use units of a practical size starting from $2,500 USD.

Recent years have also seen rapid advancements in the power, flexibility, availability, and ease of use of open source electronics such as Arduino [17] and Raspberry Pi [18] development boards. These advancements are in large part due to the fact that, with open source projects such as these, anyone can make improvements based on their area of expertise and share them with the broader community. As a result, it has become even easier to build embedded computation, advanced sensing, and reliable communications into classroom projects.

The widespread availability of these systems has resulted in a plethora of open source robotics initiatives, including our Open Academic Robot Kit [19]. The goal is to enable ad-hoc collaboration between students in different parts of the world and across year levels. For example, we have developed a basic platform that is intended to be easy to build upon, complete with basic electronics, sensors, and code [20]. A PhD student from Australia might implement a new vision algorithm that allows the robot to avoid obstacles using its camera. A high school student in Thailand might add a better arm design, while a makerspace group in the United States might contribute better wheels. These groups – and others – can benefit from each other's work.

Other open source robotics designs of interest to high school students include the Robotis TurtleBot 3 [21], Poppy [22], Vorpal Robots [23], and Yale OpenHand [24]. All of these designs share these common characteristics of providing students with a basic design with all components either 3D printed or easily available off-the-shelf, plus instructions and source code that allows them to "close the loop" on building an interesting robot that they can then extend. Some of them even have "standard" tasks that can be used as the basis of student competitions.

The Rapidly Manufactured Robot Challenge

The RMRC, as a sub-competition within the RRL, is designed to foster research and development among young students, including contributions to the open source community. The design of the competition and arena is therefore focused on providing students with opportunities to experiment, specialize in particular areas of interest, demonstrate their capabilities, and share these capabilities back to the competition and research community.

COMPETITION STAGES

The RMRC starts with teams qualifying based on their Team Description Materials (TDMs). Teams that are selected based on these materials come to the competition and proceed through two rounds. During the initial, preliminary round, the Standard Test Methods for Response Robots are laid out individually. Teams select test methods in which to evaluate their robots with the aim of achieving the highest metric possible within a prescribed 10 minute period. This is followed by one or more final rounds where the test methods are arranged in a maze or course with teams scoring points according to how many test methods they overcome in sequence.

Qualification

Teams are qualified to compete in the World Championships of the RMRC via three avenues. First, teams may qualify by submitting TDMs. These correspond to the Team Description Papers that are requested of the Major RoboCup Rescue Robot League teams (who are mostly undergraduate or graduate students), but in a more general form that makes it conducive to integration into high school media curriculum such as a website, blog post series, and/or videos. Teams may also be selected if they reached the finals in the previous year or if they place in regional competitions.

The TDM is required to cover the following topics, regardless of the format in which it is presented.

- Logistical info: Team Name, Organization, Country, Contact details, Website.

- Introduction summarizing:
    - The team.
    - The technical aspects that it focuses on.
- System description, describing:
    - Hardware.
    - Software.
    - Communications.
    - Human-robot interface.
- Application, describing:
    - Setup and packup of the robot and operator station.
    - Mission strategy.
    - Experiments and testing that have been done or will be done.
    - How the particular strengths of the team are relevant to applications in the field.
- Conclusion, summarizing:
    - What the team has learned so far.
    - What the team plans on doing between now and the competition.
- Appendix containing:
    - One table per robot outlining the components and estimated cost of the robot.
    - At least one picture, 3D rendering, or technical drawing of the robot.
    - A list of software packages, hardware, and electronic components that have been used, or plan to use, particularly those from the Open Source community, through the Open Academic Robot Kit or otherwise.
    - A list of software packages, hardware, and electronic components and designs that have

been, or plan to be, contributed to the Open Source community, through the Open Academic Robot Kit or otherwise.

- References (to other work that the team has made use of).

These materials are evaluated by a panel of high school and university academics. Teams are qualified not just for the potential to perform, but also for the potential to learn and for excellence in specific capabilities.

Preliminary Round

Teams that come to the World Championship first enter a preliminary round that runs over two full days. The goal of this round is to give teams the most number of opportunities to demonstrate their capabilities on the test methods that they are able to complete. This includes giving them time to experiment, to fail if necessary, and re-attempt.

The test methods are divided into two categories: those that relate to the ability of the robot to reach its destination and those that relate to its ability to perform a task once at the destination. We will refer to the former as the traversal test methods and the latter as the sensing and manipulation test methods, both of which are critical in measuring the performance of these systems as a whole, as they relate to their ability to perform in the response robotics application. The total scores achieved in each of these categories are multiplied together to yield the teams' final score.

Traversal test methods

The traversal test methods represent the ability of the robots to reach their destination in order to perform a task. These are generally maneuvering or terrain tasks such as centering between obstacles, climbing stairs (ASTM E2804-11 Standard Test Method for Evaluating Emergency Response Robot Capabilities: Mobility: Confined Area Obstacles: Stairs/Landings [25]), or overcoming rough terrain (e.g., ASTM E2826-11 Standard Test Method for Evaluating Emergency Response Robot Capabilities: Mobility: Confined Area Terrains: Continuous Pitch/Roll Ramps [26], ASTM E2827-11 Standard Test Method for Evaluating Emergency Response Robot Capabilities: Mobility: Confined Area Terrains: Crossing Pitch/Roll Ramps [27], and ASTM E2828-11 Standard Test Method for Evaluating Emergency Response Robot Capabilities: Mobility: Confined Area Terrains: Symmetric Stepfields [6]). These are all presented in the form of terrain pallets as shown in Figure 2. Each has a start and an end with the traversal challenge in the middle and points are scored for reaching each end of the pallet. One exception is the nodal manipulation (“Pipestar”) apparatus, which also exists in the arena as a specific test for manipulation-focused teams as shown in Figure 3. Robots may perform one or more of five tasks at each pipe for one point each: Precision touch (ASTM WK54272 Evaluating Ground Response Robot Dexterity: Touch or Aim), Rotation of the object (ASTM WK54273 Evaluating Ground Response Robot Dexterity: Rotate), Extraction of the object, Insertion of the object (ASTM WK54274 Evaluating Ground Response Robot Dexterity: Extract and Place), and Inspection of the interior of the pipe (ASTM WK54271 Evaluating Ground Response Robot Dexterity: Inspect). Approved standards are indicated by a label that begins with an "E" whereas draft test methods are considered work items and indicated by a "WK". These draft test methods are being refined in preparation for balloting as standards [28].

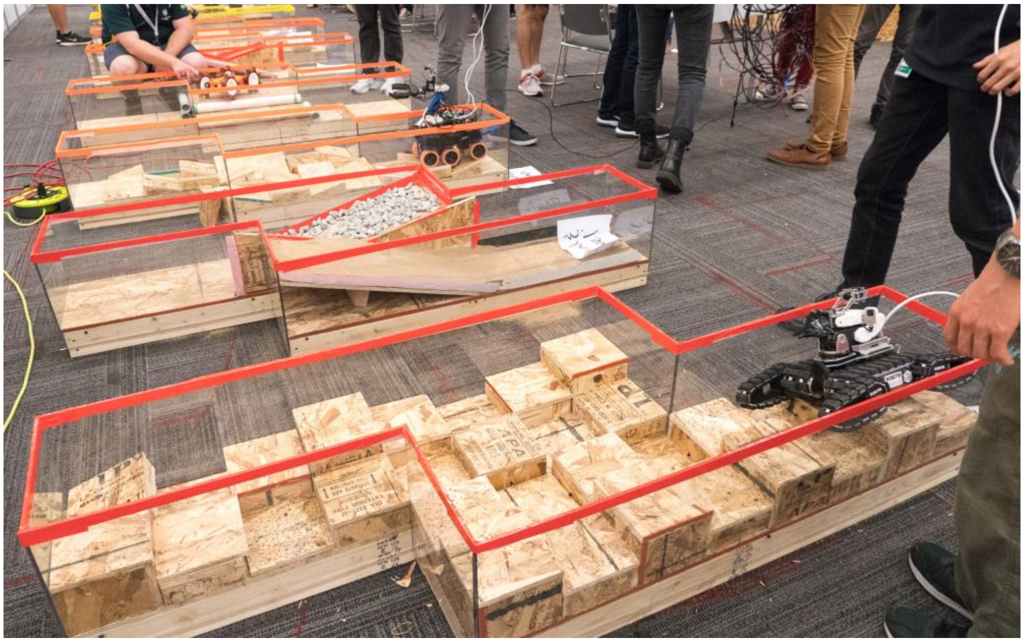

Figure 2: Terrain test method apparatuses arranged as individual lanes for preliminary trials.

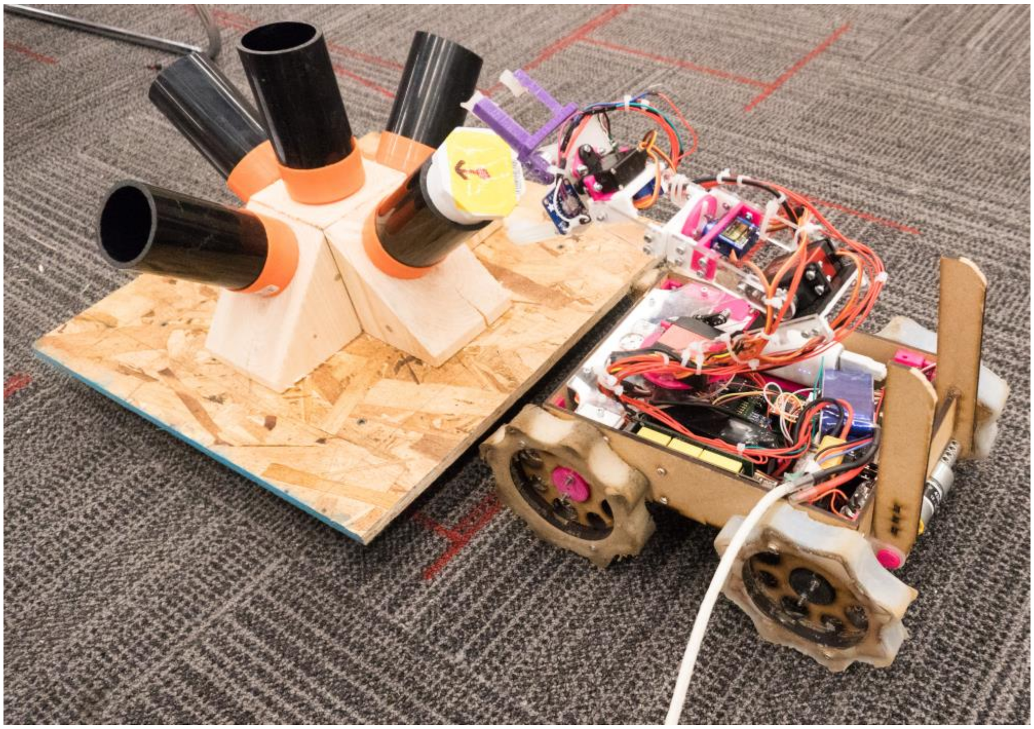

Figure 3: The Nodal Manipulation ("Pipestar") apparatus.

The tests are performed according to the ASTM International standard test method procedure [29] with the metric being the number of half-laps of the terrain pallet that the robot performs within the prescribed time, usually 10 minutes. These pallets are arranged individually as shown in Figure 2 so that they can be run in parallel. Points are assigned for each test method that a team successfully completes a measurement run in. Teams have the opportunity to try each traversal test method several times with their maximum metric for each test method counting towards their final total. Each test method's scores are normalized such that the top metric in that test method is equal to 100. Thus if a team is the only one to successfully achieve a measurement in a given test method, perhaps because it is particularly specialized or difficult, that team automatically gains 100 points for that test method. In contrast, a team must achieve excellence in an easier or more popular test to gain the same number of points.

A scheduling matrix, an example of which is shown in Figure 4, is drawn up. Teams are invited, in random order, to claim a slot representing a particular test method, at a particular time (in the figure, teams are denoted by a two-letter code appearing in the upper left corner). Once each team has claimed a slot, the cycle repeats with their second slot and so-on. The placement is constrained by the inability of teams to place two of their own slots on the same line (as they can only do one test at once), some test methods cannot run in parallel (because they share equipment), and the total number of taken slots on each line cannot exceed the number of referees available to administer each test. The order is then inverted for the following half-day. Once each team has claimed all the slots that they wish to, remaining spots may be used by any team to practice. Teams may also move slot claims to empty (future) slots or negotiate with other teams to swap. As tests are performed, the results are recorded in each slot, along with the name of the administrating referee.

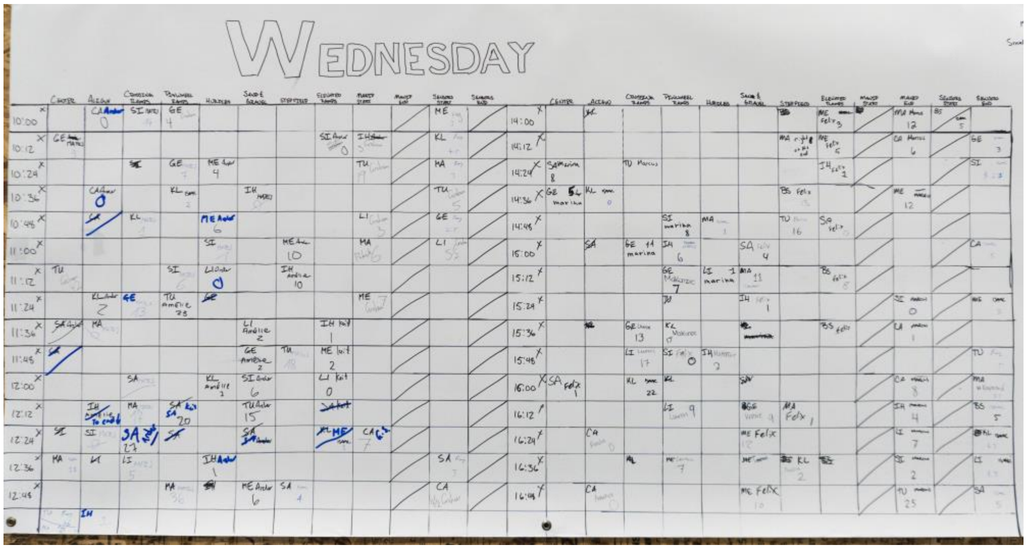

Figure 4: A scheduling matrix for the preliminary (standard testing) rounds.

To the maximum extent possible, teams are provided with the ability to run as many times as their own scheduling and reliability allows. This encourages teams to come prepared and to develop reliable systems. Runs are scheduled every half-day during team leader meetings in the morning and at lunch time. Each run is 10 minutes long with 5 minutes for changeover, yielding four runs per hour. Each half-day runs for around 3-4 hours and there are generally 4-5 referees to administer tests; thus there are generally around 96-160 test opportunities per day or 192-320 test opportunities across the qualification round. In the 2017 World Championships, being the first year that the RMRC was run as an open competition, six viable teams competed yielding over 100 standardized test results. With around 10-13 teams as anticipated going forward, this allows each team between 15 and 30 testing opportunities across the qualification round. There are generally around 10 test methods available, thus teams will generally not be schedule-limited in their ability to try test methods multiple times to achieve their best score.

Sensing and Manipulation test methods

The sensing and manipulation test methods represent the ability of the robot to perform its tasks once it arrives at its destination. These include tests of vision, directed perception, audio acuity, retrieving objects, pushing buttons, and turning valves. These tests are repeated every half-day, during one of the time slots selected in the matrix, to ensure that the capabilities are maintained through the competition. The result is used as a multiplier and applied to the scores of the team's runs for that half-day. This means that teams need to exercise care when driving their robots so that delicate sensors and manipulators (such as robot arms) are not damaged.

Finals

The scores from the Preliminary round are tabulated and around five teams selected. The specific cutoff score is decided by looking for a distinct gap in the preliminary scores. It should be undeniable that the worst performing team that goes through to the finals has performed significantly better than the best team that did not make the cut.

For the final rounds, the traversal test methods are rearranged into a maze as shown in Figure 5, with the arrangement decided in consultation with the teams that qualified. Teams each have between 10 and 15 minutes per run with 5 minute change-overs, depending on how many teams are admitted to the finals. Following a half-day break from the Preliminary rounds for arena reconfiguration and team practice, the Final rounds are run across two half-days. The aim is to allow each team to run at least five times through the arena over the course of the two half-days.

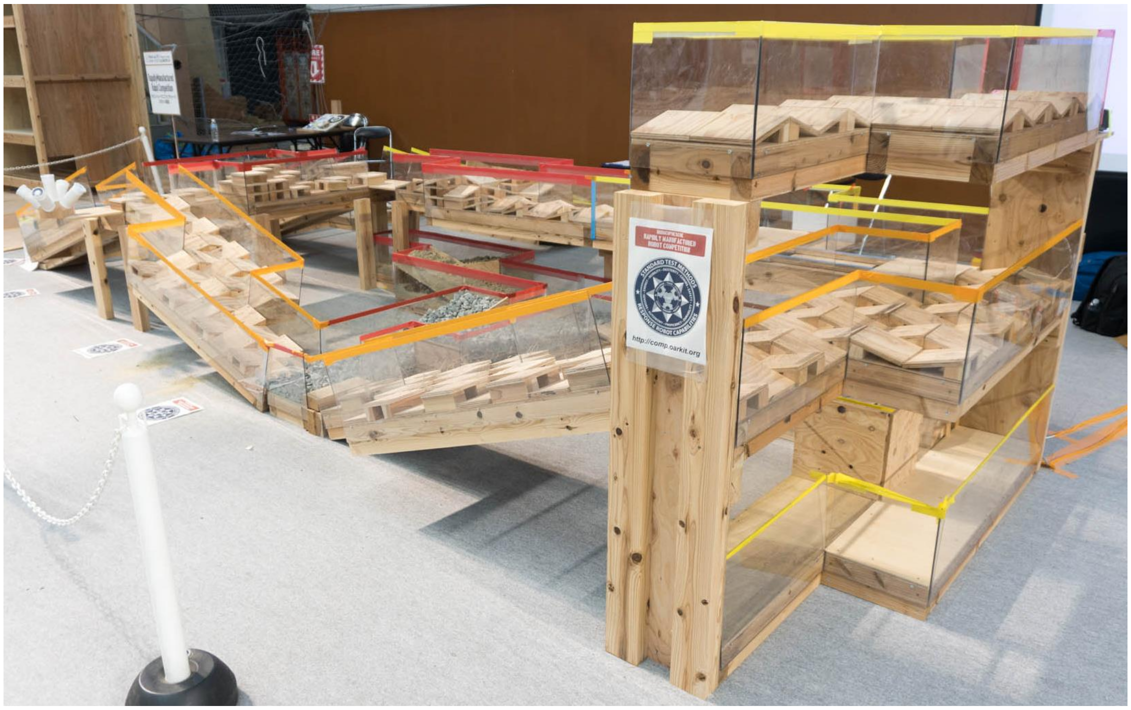

Figure 5: The terrain pallets arranged into a maze for finals.

During each finals run, teams are invited to start their robot anywhere in the arena and the goal is to accumulate as many points through the arena maze as possible. Each terrain pallet yields up to two points, one in each direction, with each point awarded when the robot either touches the end of the pallet or exits onto a connected pallet. As a result, teams need to be strategic in choosing their starting point and their path so as to maximize the number of points while minimizing excessive terrain traverses or the need for excessive risk early in their run. Teams are allowed to drop their worst-performing score, allowing teams to experiment with the different format. This score is then multiplied by their score in the Sensing and Manipulation test methods, which are performed once during the day.

ARENA AND TEST METHODS

The arena is made up of standard test method pallets, arranged first as individual test lanes for the preliminary rounds and then as a maze for the finals. It is important to note that these test method pallets are not simplified versions of the test methods. They are full test methods, built at the 30 cm scale to represent smaller, confined environments such as collapsed buildings, air conditioning ducts, and industrial plants. Currently the following test methods are implemented. Examples of these are shown in Figure 6, in order:

- Center Between Obstacles (no ASTM number assigned yet).
- ASTM WK53649 Evaluating Ground Response Robot Maneuvering: Align Edges.
- ASTM E2827-11 Standard Test Method for Evaluating Emergency Response Robot Capabilities: Mobility: Confined Area Terrains: Crossing Pitch/Roll Ramps [27].
- ASTM E2802-11 Standard Test Method for Evaluating Emergency Response Robot Capabilities: Mobility: Confined Area Obstacles: Hurdles [30].
- ASTM E2992/E2992M-17 Standard Test Method for Evaluating Response Robot Mobility: Traverse Sand Terrain [31].
- ASTM E2991/E2991M-17 Standard Test Method for Evaluating Response Robot Mobility: Traverse Gravel Terrain [32].
- ASTM E2828-11 Standard Test Method for Evaluating Emergency Response Robot Capabilities: Mobility: Confined Area Terrains: Symmetric Stepfields [6].
- Elevated ramps (no ASTM number assigned yet).
- Manipulation pipestar (supporting ASTM WK54272, WK54273, WK54274, and WK54271 as described previously).

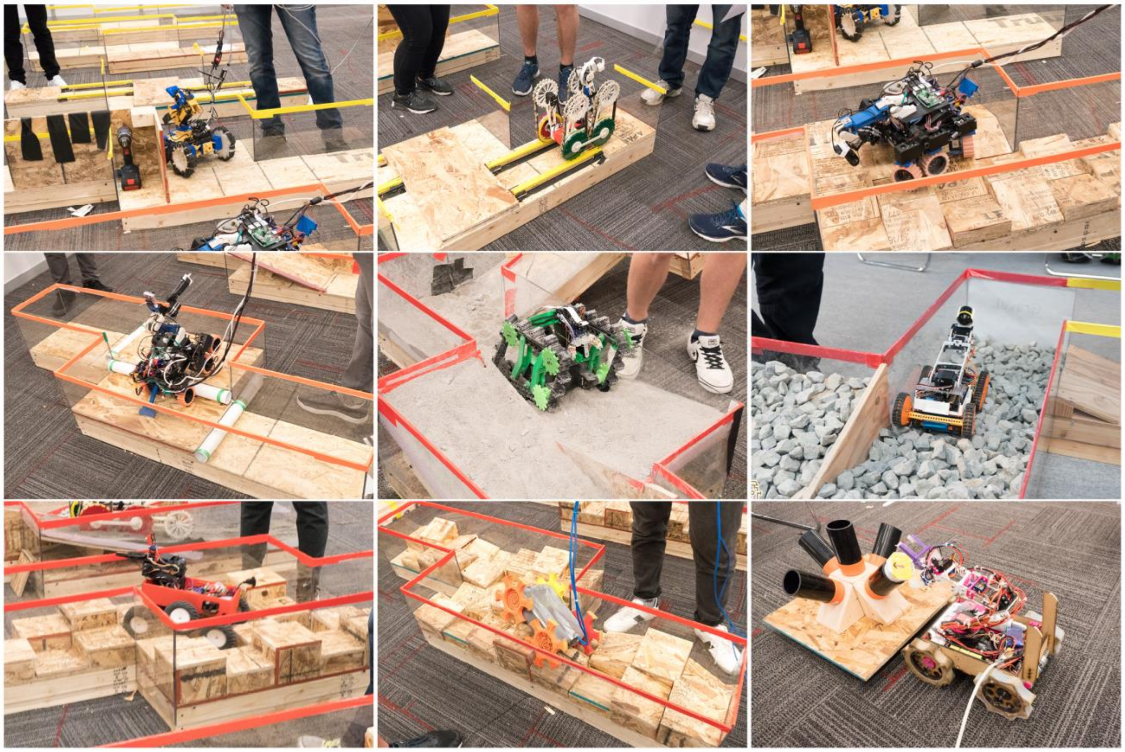

Figure 6: Examples of the different terrains represented in the RMRC, along with examples of rapidly manufactured (3D printed or lasercut) robots.

Sensor tests were embodied by the “Readiness Board”, as shown in Figure 7. This consisted of embedded versions of test methods for ASTM E2566-17a Standard Test Method for Evaluating Response Robot Sensing: Visual Acuity [33], ASTM WK57967 Evaluating Ground Response Robot Sensing: Thermal Image Acuity, ASTM WK60783 Evaluating Ground Response Robot Sensing: Audio Speech Intelligibility, and prototypical test methods for Survey Acuity, Motion Detection, CO_2 detection, and Hazardous Material Label Recognition. These are performed at a standard near-field distance of 40 cm (16 in) and each test is thresholded to represent a point each.

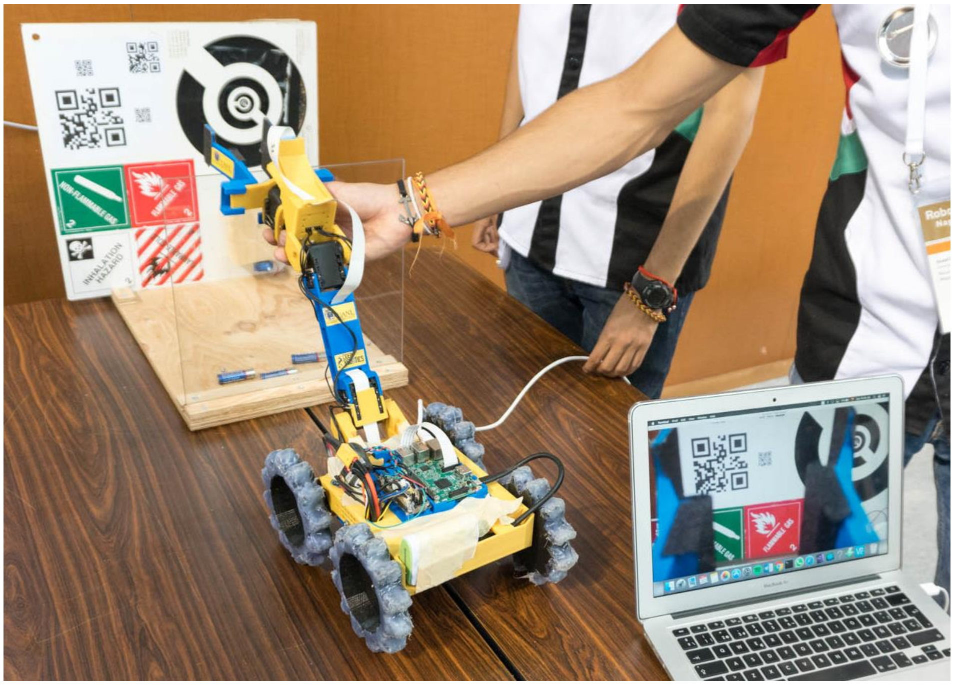

Figure 7: A robot performing the sensor "readiness" test.

Taken together, the terrains, manipulation test, and readiness board represent challenges that robots face getting to the site where they must work, manipulating what they must work on, and then observing it. Thus they each contribute to the scoring. During the preliminaries, there are 12 tests offered.

Four represent mobility and maneuvering challenges that all robots can attempt:

- Center Between Obstacles (no ASTM number assigned yet).
- ASTM WK53649 Evaluating Ground Response Robot Maneuvering: Align Edges.
- ASTM E2827-11 Standard Test Method for Evaluating Emergency Response Robot Capabilities: Mobility: Confined Area Terrains: Crossing Pitch/Roll Ramps [27].
- A variant on the above called Pinwheel Ramps.

Four represent advanced mobility tasks:

- ASTM E2802-11 Standard Test Method for Evaluating Emergency Response Robot Capabilities: Mobility: Confined Area Obstacles: Hurdles [30].
- ASTM E2992/E2992M-17 Standard Test Method for Evaluating Response Robot Mobility: Traverse Sand Terrain [31], and ASTM E2991/E2991M-17 Standard Test Method for Evaluating Response Robot Mobility: Traverse Gravel Terrain [32]. (combined for the preliminaries),
- ASTM E2828-11 Standard Test Method for Evaluating Emergency Response Robot Capabilities: Mobility: Confined Area Terrains: Symmetric Stepfields [6].
- Elevated Ramps (no ASTM number assigned yet).

Finally, two represent “payload” tasks:

- Manipulation pipestar (supporting ASTM WK54272, WK54273, WK54274, and WK54271 as described previously).
- Readiness board (supporting embedded variants of ASTM E2566-17a Standard Test Method for Evaluating Response Robot Sensing: Visual Acuity [33], ASTM WK60783 Evaluating Ground Response Robot Sensing: Audio Speech Intelligibility, ASTM WK57967 Evaluating Ground Response Robot Sensing: Thermal Image Acuity, and ASTM WK54755 Evaluating Ground Response Robot Sensing: Match Colors).

The latter two were repeated twice, once at the start of the preliminary day to evaluate the capabilities that robots started with and again at the end of the day to determine if any capabilities had been lost due to damage/wear during the rest of the testing.

The final runs are a combination of tests that together represent a mission. To ease the logistics of the competition, the readiness board is performed at the start and end of the day, representing the capabilities of the robot at the start and after any wear or damage during the day. This score is then multiplied by the score that the robot achieves during its run through the maze, including both the various terrains as well as the manipulation task.

The Open Academic Robot Kit

The aim of the Open Academic Robot Kit (OARKit) is to make it as easy as possible for a new team to enter the RMRC. The initial OARKit designs have all mechanical parts 3D printable on a low cost printer. All other parts are drawn from a relatively small set of components that are easily available by mail order and all designs, instructions, and source code are available online under an open source license. This way anyone, anywhere in the world, can follow the downloadable instructions and build a robot that can be used as a starting point for their competition entry.

The use of 3D printing for the mechanical structure, rather than a standard kit of parts, allows for much greater flexibility in the robot designs and the opportunity for students to learn proper structural design under manufacturing constraints. It also allows designs to be shared more easily as teams seeking to replicate a design need only own a suitable 3D printer and a cache of standard parts.

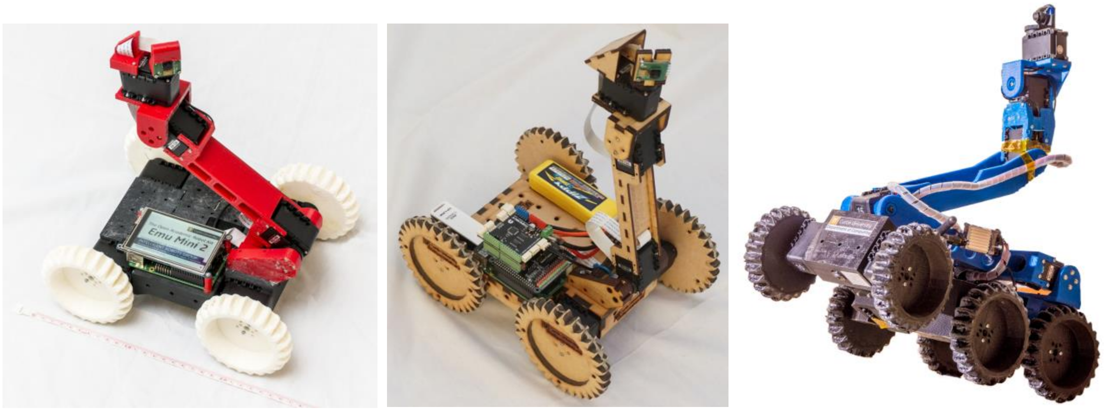

Figure 8: The initial robot designs from the Open Academic Robot Kit.

The first two designs in the OARKit are the “Emu Mini 2” (3D printed and lasercut) and the “Excessively Complex 6-Wheeled Robot”, both shown in Figure 8. These robots are not intended to be the best, or even particularly good, robots for tackling all of the challenges in the RMRC. Rather, they are intended to be good for building additional capabilities from. Over the four years since the OARKit project started, many teams have built variants. Most of these variants share the same parts as the original OARKit: Raspberry Pi for the computation, Arduino for embedded interfacing, and Dynamixel AX-12 servos for motion.

First published in 2014, the OARKit has already spawned a plethora of successors across high schools in Australia, the US, and Europe. Examples of these have appeared at RMRC competitions in the intervening years and some are shown in Figure 9.

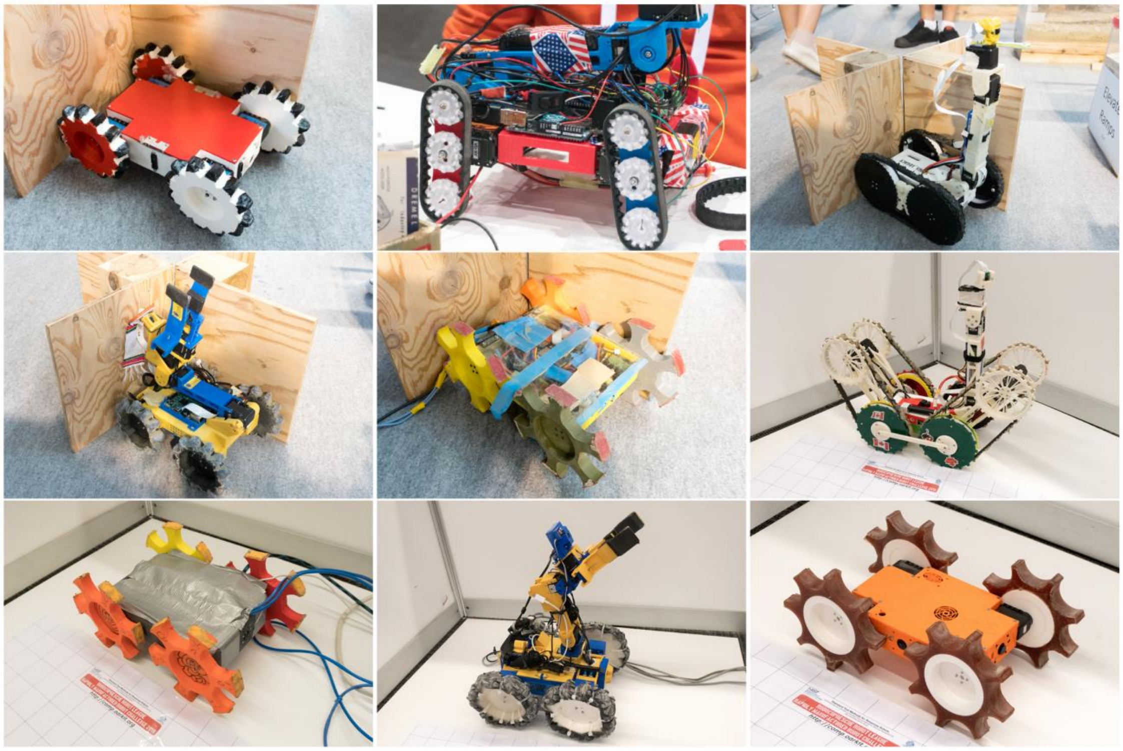

Figure 9: Examples of robots that were based (at least in part) on the original Open Academic Robot Kit designs.

Results

The RMRC has been run as an open competition during both the 2017 and 2018 RoboCup Rescue Robot League World Championships, held in Nagoya, Japan and Montreal, Canada, respectively. For the 2017 competition, 13 teams applied of which 10 were qualified and participated in the competition. Preliminary rounds were conducted over one and a half days, resulting in a total of 139 standard tests and five teams qualifying for the finals.

In 2018, 19 teams applied of which 13 were qualified either on the basis of team description materials or performance in the 2017 competition. 11 of those participated in the competition, completing a total of 297 standard tests over two and a half days and again qualifying five teams for the finals. The results of the 2018 preliminary competition are shown in Figure 10. To provide some anonymization, robots have been denoted by two-letter codes. Each robot's performance in each test was normalized such that 100 represented the (possibly equal) best performance in that test. The radar charts are ordered in descending overall performance and show how the performance of the robots change, both in terms of overall performance as well as in specific areas.

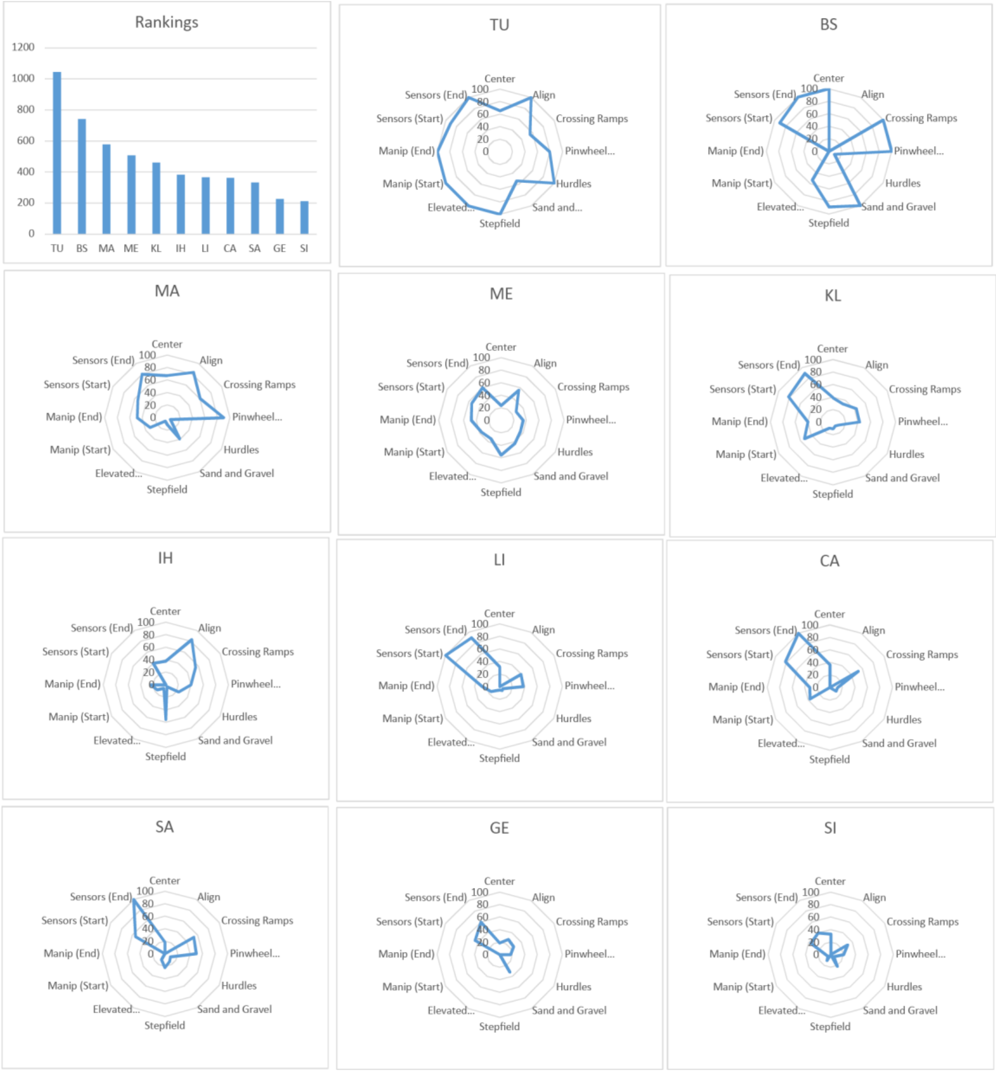

Figure 10: Results of each robot after the preliminary rounds of the 2018 competition. Radar plots for each test are normalized such that 100 represents the best performance in that test. Robots anonymized to two-letter codes.

CONCLUSIONS AND FUTURE WORK

The RMRC is still very much in development as a competition, after two years of open competitions and a preceding two years of trials. Yet we have already observed tremendous growth and maturity in the international community of teams that have developed around it over the last few years. In 2019, we will once again hold the RMRC, in conjunction with the broader RRL, in Sydney, Australia. There we will be refining the rules of the competition as well as the procedures of the test methods, in collaboration with our ASTM E54.09 colleagues. In particular, we will be addressing some issues relating to robot size, whereby several of the robots in the competition barely fit in the mobility test methods and thus the walls became a significant influence on their behavior. This would suggest that these effects either need to be included in the robot performance or otherwise some accommodation made to ensure that their influence is minimized.

Beyond the test methods, we will be providing opportunities for the RMRC and RRL to become more closely integrated again. When the confined space arena, the precursor to the RMRC arena, was first conceived, it was intended to be a “shortcut” into the more difficult areas of the RRL arena for smaller robots. This represented the access options that smaller robots might have in a real response situation that larger robots may not be able to take advantage of. Our plan in 2019 will be to introduce an intermediate arena of test methods at the 60 cm (24 in) scale that will be connected to both the RMRC and RRL arenas for the finals. This will allow robots from both competitions to attempt an intermediate scale before possibly transitioning into the others’ arena. The introduction of the intermediate sized arena may also address some concerns about the robots being too big for the arena, albeit with the disadvantage of making the arena larger and thus less cost effective for high school teams to reproduce.

Over the past several years, we have seen the original Open Academic Robot Kit robots proliferate and further develop as teams improve and share the designs. To further encourage contributions to the open source community, we will be adding a multiplier onto teams' preliminary scores, based on a report, document, or other resource that teams submit two weeks prior to the competition. This resource will be scored based on how useful it is for another team to replicate a particular feature or innovation that the team has developed.

The introduction of standard test methods into the RRL and associated RMRC has accelerated the development of robotics for emergency response and public safety. They have helped to communicate the challenges of the application to students and researchers. In turn, they have helped to communicate the prototypical capabilities within academia to the broader user and manufacturer community. In the process they have been critical in forming an interconnected community of researchers, manufacturers, users, and test developers. Further, the competitions have turned out to be ideal proving grounds for the development of standard test methods which has enabled the rapid passage of relevant standards through ASTM E54.09. This symbiotic relationship is a potential model other standard development efforts could use to educate, speed research and development, and disseminate standards through their communities.

ACKNOWLEDGMENTS

We would like to acknowledge the support of all of the mentors and students who participated in, supported, and contributed to this competition and initiative, without whom it would not be possible. We would also like to thank the volunteer referees and administrators who helped us to run the events and all of our collaborators under the ASTM International Subcommittee E54.09 on Response Robots (and the precursor Subcommittee E54.08.01) for their efforts in developing the underlying standard test methods. Finally we would like to thank our colleagues, particularly

William Billotte, Kevin Jurrens, Kenneth Kimble, and Elena Messina for their assistance in reviewing this paper. This work was performed in part under the financial assistance award 70NANB17H265 from the U.S. Department of Commerce, National Institute of Standards and Technology.

Summary

A novel methodology has been developed for extracting pyrolysis kinetic parameters from thermogravimetric analysis (TGA) data. The development of this methodology is motivated by a need to automate the determination of material properties for use in fire models. The algorithm with which the methodology is implemented is described. Aside from being fully automated, the resultant script has the advantage of being efficient—a full set of kinetic parameters is provided in less than 1 second. The script is verified against manufactured TGA data for one and two reaction mechanisms and the effects of reaction peak width and the distance between reaction peaks is examined. Validation is accomplished by applying the script to TGA data for Nylon 6,6, a flexible polyurethane foam, and polyvinyl chloride. The resultant kinetic parameters are tabulated, and plots of the actual and predicted TGA data show that the algorithm is quite effective for one, two, and three reaction mechanisms.

1 | INTRODUCTION

Computational fire models have proven to be effective at predicting the spread of heat and smoke in a wide range of building fire scenarios. However, such models still generally require user input describing the actual fire that is generating the heat and smoke. Computational predictions of flame spread and fire growth require somewhat detailed models of condensed phase physics, and a number of condensed phase pyrolysis models have been developed.[1-3] Such models have proven effective at modeling the burning rate of small slabs, but their application to flame spread calculations is more limited. Part of the problem is that these pyrolysis models require the specification of a large number of material properties. Furthermore, there are many different flammable materials that need to be considered in fire scenarios. Substantial progress in applying computational fire models to predict flame spread could be achieved by the development of both a streamlined methodology for characterizing the thermophysical properties of flammable materials as well as the creation of a publicly available database of such material properties.

One successful approach for characterizing materials is based on performing a number of milligram-scale and bench scale tests such as thermogravimetric analysis (TGA), differential scanning calorimetry (DSC), and the controlled atmosphere pyrolysis apparatus.[4] An example of a public database of material properties is found in the Validation Guide of the Fire Dynamics Simulator (FDS).[5] Currently, an international effort is underway to further develop experimental and modeling tools such as these in order to “advance predictive fire modelling”.[6] The present manuscript presents work based on a coordinated effort to develop a comprehensive database of material properties for use in fire models. This database will include both raw data from a suite of milligram-scale tests and a list of properties for each material that could be directly used as inputs for a fire model such as FDS. In order to generate these tables of material properties, automated computational scripts are required to robustly analyze raw data from small-scale tests. In this paper, we present such a script for calibrating a generalized pyrolysis kinetic model to TGA data. Previous work has looked at optimization algorithms[7] and Markov Chain Monte Carlo methods[8] for fitting TGA data, but these approaches are not fully automated for general multistep reaction schemes and can be relatively computationally expensive.

2 | THEORY

In TGA, the mass of a small sample of material is measured while heated according to a prescribed temperature program. Typically, the sample will be heated at a constant temperature ramp rate. If the sample mass and heating rate are sufficiently small, then the temperature and composition throughout the sample are approximately uniform. As the material is heated, chemical bonds are broken producing smaller molecules. Eventually, the products of pyrolysis become small enough to vaporize, and mass is lost from the system. Models of this process typically take the form of a system of reactions with unimolecular Arrhenius kinetics.

2.1 | Independent Unimolecular Reactions

In the following, focus is limited to systems of independent reactions. This generalized model could account for (a) a system of parallel reactions or (b) a system of series reactions in which the subsequent reactions occur at different temperatures. To begin, consider a system of N_r unimolecular reactions of the form

$$R_i \xrightarrow{k_i} \nu_i C + (1-\nu_i)G, i = 1, \ldots, N_r, \tag{1}$$

where R_i is the label for the reactant material, C is the label for the condensed phase products of the reaction, k_i is the reaction rate constant, ν_i is the residual mass fraction of the reaction, and G is the label for the gas species which escapes the sample. For the purposes of the following analysis, it is not necessary to distinguish between the condensed phase and gas phase products of the reactions. Additionally, consideration will be limited to constant heating rate TGA experiments in which the sample temperature increases at a constant rate, β. An Arrhenius model is assumed for the temperature dependence of the rate constant such that, for each reaction

$$k_i = \left(\frac{A_i}{\beta}\right) \exp\left(-\frac{E_i}{RT}\right), \tag{2}$$

where A_i is the pre-exponential, E_i is the activation energy, and R is the gas constant. Note that the heating rate has been directly absorbed into the rate constant in order to simplify the notation in the following analysis. Consequently, k_i is not strictly speaking the Arrhenius rate constant, but the kinetic pair (A_i, E_i) are the true Arrhenius pre-exponential and activation energy, respectively.

For the kinetic model described by Equations (1), the temperature rate of change of the mass of component i, m_i, is governed by

$$m_i' \equiv \frac{\mathrm{d}m_i}{\mathrm{d}T} = -m_i k_i, \tag{3}$$

along with the initial condition $m_i(T_0) = m_{0,\,i}$ where T_0 is the initial temperature of the TGA experiment (or any temperature prior to the onset of the reaction). The total sample mass of the sample is simply the sum of the individual component masses. The total mass loss rate must account for the generation of residual solid products of the reactions so that

$$m' \equiv \frac{\mathrm{d}m}{\mathrm{d}T} = \sum\nolimits_i (1-\nu_i) m_i'. \tag{4}$$

2.2 | Nondimensional form and approximate solution

It is convenient to nondimensionalize Equation (3), and the resultant nondimensionalization leads to an approximate solution which is valid for most materials. The peak mass loss rate may be found by differentiating Equation (3) with respect to temperature and setting the result equal to zero. Analysis of this peak condition yields the following results. Using $T_{\mathrm{p},\,i}$, $m_{\mathrm{p},\,i}$, and $m'_{\mathrm{p},i}$ to denote the temperature, mass, and temperature derivative of the mass corresponding to that peak, a characteristic width of the peak may be defined as

$$\Delta T_i \equiv \frac{-m_{\mathrm{p},i}}{m'_{\mathrm{p},i}} = \frac{RT^2_{\mathrm{p},i}}{E_i}, \tag{5}$$

where the second equality in Equation (5) is determined from analysis of the peak equation. The kinetic equations can be recast in terms of the peak temperature and the peak width parameters which are related to the Arrhenius parameters through

$$E_i = \frac{RT^2_{\mathrm{p},i}}{\Delta T_i}. \tag{6}$$

$$A_i = \frac{\beta}{\Delta T_i} \exp\left(\frac{T_{\mathrm{p},i}}{\Delta T_i}\right). \tag{7}$$

A simplified form of the kinetic equations may be obtained using the following nondimensionalization

$$\mu_i \equiv \frac{m_i}{m_{0,i}}. \tag{8}$$

$$\theta_i \equiv \frac{T - T_{\mathrm{p},i}}{\Delta T_i}. \tag{9}$$

The nondimensional kinetic equation for component i becomes

$$\mu_i' \equiv \frac{\mathrm{d}\mu_i}{\mathrm{d}\theta_i} = -\mu_i \exp\left(\frac{\theta_i}{\xi_i \theta_i + 1}\right), \tag{10}$$

with the boundary condition $\mu_i(\theta_i \to -\infty) = 1$ where $\xi_i \equiv \Delta T_i / T_{\mathrm{p},\,i}$ may be thought of as a shape parameter for the mass loss peak.

For the limiting case in which $\xi_i \rightarrow 0$, Equation (10) has the exact solution:

$$\mu_i = \exp[-\exp(\theta_i)], \tag{11}$$

or, in dimensional form,

$$m_i = m_{0,i}\exp\left[-\exp\left(\frac{T-T_{\mathrm{p},i}}{\Delta T_i}\right)\right]. \tag{12}$$

Note that Equation (12) predicts that that mass at the peak rate of temperature change is $m_{0,\ i}e^{-1}$ which is the same approximation derived by other authors.[9] Furthermore, the assumption of letting $\xi_i \rightarrow 0$ is equivalent to $RT_{\mathrm{p},\ i} \ll E_i$ which is the same assumption used to arrive at this approximation.

2.3 | Reaction Peak Analysis

Equation (12) may be used in conjunction with TGA data to get estimates of the kinetic parameters. The approach developed in the following makes use of the fact that if the peak temperatures, $T_{\mathrm{p},\ i}$, are known from the data, it is possible to use derivatives of Equation (12) to obtain estimates of ΔT_i and the total mass lost from the sample due to the reaction, Δm_i, from the data. Note that the total mass change associated with a reaction is

$$\Delta m_i \equiv m_{0,i}(1-\nu_i). \tag{13}$$

Taking the first three derivatives with respect to temperature of Equation (12) results in:

$$d_{1,i} \equiv (1-\nu_i)m_i' = \frac{\Delta m_i}{\Delta T_i}g_i\exp(g_i), \tag{14}$$

$$d_{2,i} \equiv (1-\nu_i)m_i'' = \frac{\Delta m_i}{\Delta T_i^2}g_i\exp(g_i)(g_i+1), \tag{15}$$

$$d_{3,i} \equiv (1-\nu_i)m_i''' = \frac{\Delta m_i}{\Delta T_i^3}g_i\exp(g_i)\left(g_i^2+3g_i+1\right), \tag{16}$$

where

$$g_i \equiv -\exp\left(\frac{T-T_{\mathrm{p},i}}{\Delta T_i}\right). \tag{17}$$

Note that the newly defined d-variables in Equations (14) to (16) represent the contribution of each component to the first three temperature derivatives of the total mass. Thus,

$$m' = \sum\nolimits_i d_{1,i}. \tag{18}$$

$$m'' = \sum\nolimits_i d_{2,i}. \tag{19}$$

$$m''' = \sum\nolimits_i d_{3,i}. \tag{20}$$

At the peak temperature, $g_i = -1$, and so Equations (14) to (16) yield

$$d_{1,i}\left(T_{\mathrm{p},i}\right) = -\frac{\Delta m_i}{e\Delta T_i}. \tag{21}$$
$$d_{2,i}\left(T_{\mathrm{p},i}\right) = 0. \tag{22}$$

$$d_{3,i}\left(T_{\mathrm{p},i}\right) = \frac{\Delta m_i}{e\Delta T_i^3}. \tag{23}$$

Equation (22) shows that the peak condition is in fact being satisfied. The solution of Equations (21) and (23) in gives

$$\Delta T_i = \sqrt{-\frac{d_{1,i}\left(T_{\mathrm{p},i}\right)}{d_{3,i}\left(T_{\mathrm{p},i}\right)}}, \tag{24}$$

$$\Delta m_i = -ed_{1,i}\left(T_{\mathrm{p},i}\right)\Delta T_i, \tag{25}$$

where using Equations (18) and (20),

$$d_{1,i}\left(T_{\mathrm{p},i}\right) = m'\left(T_{\mathrm{p},i}\right) - \sum\nolimits_{j\neq i} d_{1,j}\left(T_{\mathrm{p},i}\right). \tag{26}$$

$$d_{3,i}\left(T_{\mathrm{p},i}\right) = m'''\left(T_{\mathrm{p},i}\right) - \sum\nolimits_{j\neq i} d_{3,j}\left(T_{\mathrm{p},i}\right). \tag{27}$$

In the following section, an algorithm is presented for using Equations (24) to (27) in conjunction with TGA data to obtain a set of kinetic parameters.

2.4 | Description of algorithm

In order to use Equations (24) to (27), it is necessary to have the temperature derivatives of the TGA data. That is, given the set of TGA data points for (T, m), what are the corresponding values of m', m'', and m''' at each temperature? It was found that the Savitzky-Golay filter[10] proved to be effective in estimating the derivatives of noisy TGA data. Application of the Savitzky-Golay filter requires two parameters: (a) the order of the polynomial fit and (b) the number of data points used in the fit. A quadratic fit was used for the first temperature derivative, a cubic fit for the second derivative, and a quartic fit was used for the third derivative data. The number of data points used in the fit was chosen to be enough to cover a temperature window of 10 K for the first temperature derivative, 20 K for the second derivative, and 40 K for the third derivative. These parameters were determined by trial and error, and future work will examine optimizing the choice of these parameters.

Once the first 3 derivatives of the TGA mass data were determined, it is necessary to determine the number of reactions. Clear reaction peaks correspond to points at which $m'' = 0$ and $m''' > 0$. All such peaks are easily obtained from the filtered temperature derivatives. Only peaks in which the mass loss rate was greater than 15% of the maximum peak mass loss rate were identified as distinct reactions. If two reactions occur over similar temperature ranges, it is often difficult to observe a distinct peak in the mass loss rate. However, in some cases the presence of a shoulder in the peak is evidence of a partially obscured reaction. Partially obscured reactions were found by locating points where m'' is small and $m''' = 0$.

The preceding paragraph presents two criteria for identifying reaction peaks. Each of these points corresponds to a temperature at which the peak occurs. So at this point in the algorithm, all that is stored is a set of N_r temperatures, $T_{p,\,i}$ for $i = 1, \ldots, N_r$. The next step is to determine the kinetic parameters for each of these reactions.

For the single reaction case, the total volatile mass lost from the reaction is equal to the total mass lost by the TGA sample, or

$$\Delta m_1 = \Delta m_{\mathrm{tot}} \equiv m_0 - m_{\mathrm{f}}, \tag{28}$$

where m_0 and m_{f} are the initial and final masses of the sample. With only one reaction, Equation (26) gives

$$d_{1,1}(T_{\mathrm{p},1}) = m'(T_{\mathrm{p},1}), \tag{29}$$

and so, upon substitution into and rearrangement of Equation (25),

$$\Delta T_1 = -\frac{\Delta m_{\mathrm{tot}}}{e m'(T_{\mathrm{p},1})}. \tag{30}$$

If more than one peak is found, the process is complicated since the mass loss rate signals can overlap. An iterative approach has been developed in which an initial guess of all Δm_i and ΔT_i are used to compute Equations (26) and (27), and then the resultant values are used in Equations (24) and (25) to find updated values for these kinetic parameters. The process is repeated until convergence is achieved.

An important correction must be employed to insure that $\sum_i \Delta m_i = \Delta m_{\mathrm{tot}}$. Using Equations (24) and (25) for each reaction separately does not guaranty that this condition will be satisfied. In order, to identify a mass conserving mechanism an intermediate solution ΔT_i^* is found from Equation (24). The mass conserving peak widths would be those which satisfy:

$$\Delta m_{\mathrm{tot}} = \sum_i -e d_{1,i}(T_{\mathrm{p},i}) \Delta T_i. \tag{31}$$

The projection of the intermediate solution onto the space of solutions satisfying Equation (31) is found by:

$$\mathbf{\Delta T} = \mathbf{\Delta T}^* - \left(\frac{\mathbf{\Delta T}^* \cdot \mathbf{a} - \Delta m_{\mathrm{tot}}}{\mathbf{a} \cdot \mathbf{a}} \right) \mathbf{a}, \tag{32}$$

where $\mathbf{\Delta T}^*$ and $\mathbf{\Delta T}$ are simply the vectors formed from the temperature widths for the intermediate and mass conserving cases, and $\mathbf{a}$ is the vector whose elements are $a_i \equiv -e d_{1,\,i}(T_{\mathrm{p},\,i})$. The mass widths for an iteration are then found from the mass conserving temperature widths used in Equation (25).

The entire algorithm for finding the kinetic parameters of TGA data indicating several reactions is summarized as follows:

1 Estimate reaction mass changes using $\Delta m_i = \Delta m_{\mathrm{tot}}/N_r$ for each i.
2 Compute corresponding estimates of peak widths using $\Delta T_i = -\Delta m_i / e m^{'}(T_{\mathrm{p},\,i})$ for each i.
3 Compute $d_{1,\,i}$ and $d_{3,\,i}$ for each i using the previously determined values for Δm_i and ΔT_i.
4 Find initial estimates ΔT_i^* for each i using Equation (24).
5 Calculate mass conserving temperature widths using Equation (32).
6 Calculate mass conserving reaction mass changes using Equation (25).
7 Repeat steps 3 through 6 until Δm_i and ΔT_i converge.

It was found that even for the most complex scenarios considered that convergence was achieved after approximately 10 to 20 iterations making the algorithm extremely efficient. In the next two sections, the algorithm described in this section will be verified against manufactured data and validated against TGA data for several materials. In all cases, the algorithm requires less than 1 second of CPU time on a typical laptop computer to provide the complete set of kinetic parameters.

3 | VERIFICATION

It is possible to verify the algorithm described in the preceding section by testing it against numerically generated TGA data based on an assumed kinetic model. In this process, TGA data is manufactured by simulating a solution of Equation (4) using assumed parameter values. The algorithm was then applied to this manufactured data. The resultant calibrated kinetic parameters can be compared to the specified value, and predictions using the calibrated kinetic parameters can be compared to the manufactured data. In all cases, a heating rate of 10 K/minute was used along with an initial sample mass of $m_0 = 1$.

3.1 | One reaction

Three single-reaction cases have been considered. Each of these three cases specify a peak reaction rate temperature at 650 K, and the sample was assumed to fully volatilize so that $m_{\mathrm{f}} = 0$ and $\Delta m = 1$. In order to examine the effectiveness of the algorithm to handle a variety of data, three different characteristic peak widths were considered: $\Delta T = 10$ K, $\Delta T = 20$ K, and $\Delta T = 40$ K. The specified and calibrated parameters for these three cases are shown in Tables 1 to 3. Plots of the TGA mass and mass loss rate for the three cases are shown in Figure 1. It is clear that the quality of the calibrated reaction decreases with increasing reaction width. This observation is likely a consequence of the fact that the fitting algorithm is based upon an approximate solution of the kinetic equations that assumes a small value of $\xi \equiv \Delta T / T_{\mathrm{p}}$. As the value of ΔT increases, so does the value of ξ, and thus the validity of the approximation decreases.

TABLE 1 Kinetic parameters for the single-reaction verification case with ΔT = 10 K

3.2 | Two reactions

Three 2-reaction cases were also considered. For these cases, the effect of overlapping peaks was studied. For these scenarios, both reactions are assigned a characteristic peak width of 15 K. The normalized mass change associated with the first reaction is Δm_1 = 0.5, and that of the second reaction is Δm_2 = 0.3. In all cases, the midpoint between the two reaction peaks is 650 K. The difference between the cases is the distance between the peak temperatures. Three peak temperature differences were considered: 160, 80, and 40 K. The specified and calibrated parameters for these three cases are shown in Tables 4 to 6. Plots of the results of these three verification cases are shown in Figure 2. It is apparent that the algorithm captures the TGA signal well even as the peaks move close together. Although the plateau in the mass signal is overestimated, the mass loss rates are well captured—this is a consequence of the algorithm favoring mass loss rate matching over mass matching.

TABLE 4 Kinetic parameters for two-reaction verification case with $T_{p,2} - T_{p,1}$ = 160 K

of real materials. It is therefore important to assess the validity of the fitting algorithm against real TGA data.

In this work, TGA experiments were conducted on three polymers: Polyamide 6,6 (Nylon 6,6), a flexible polyurethane (PU) foam, and polyvinyl chloride (PVC). These materials are widely used in construction, residential, and transportation applications, and, collectively, they present a diverse range of decomposition behaviors (eg, single or multiple reaction peaks, discrete or overlapping reactions, and decomposition across a wide temperature range).

TGA experiments were conducted on these three materials in a Netzsch STA 449 F1 Jupiter. This apparatus continuously measures mass (using a microbalance with a 0.025 μg precision) and temperature (using an S-type thermocouple positioned directly beneath the sample crucible) of samples as they are heated through a well-defined temperature program in an anaerobic environment. A temperature calibration was conducted as per the manufacturer's recommendations[11] (using a set of 6 pure metals, with melting points between 156.6 and 961.8°C) to provide a relation between measured and actual sample temperature. The calibration was performed using the same crucible type, heating rate, and gaseous environment as was used during thermal analysis experiments on the polymeric samples. All TGA experiments were conducted within 3 months of this calibration.

The temperature program used for TGA experiments included an initial isotherm at an elevated temperature (below 100°C), during

which time the chamber was continuously purged with nitrogen. This ensured that the system was completely free of oxygen and that any residual moisture in samples was removed prior to dynamic heating and thermal decomposition. Following this conditioning period, samples were heated at a constant rate of 10 K/min up to 700 or 900°C. Throughout this program, the test chamber was continuously purged with ultra-high purity (UHP) nitrogen at 50 mL/min. All tests were conducted in open alumina crucibles.

At the start of each day of testing, a baseline test was performed in which an empty alumina crucible was subjected to the same heating program as was used during the thermal analysis experiments. This baseline history (mass vs temperature) was subtracted from the corresponding data obtained during experiments on the polymeric samples. All TGA measurement data presented in this work has been baseline-corrected in this manner. All samples were stored in a desiccator (in the presence of Drierite) for a minimum of 48 hours prior to testing. Immediately before testing, samples were removed from the desiccator, placed into alumina test crucibles, and weighed using a Mettler M3 analytical balance.

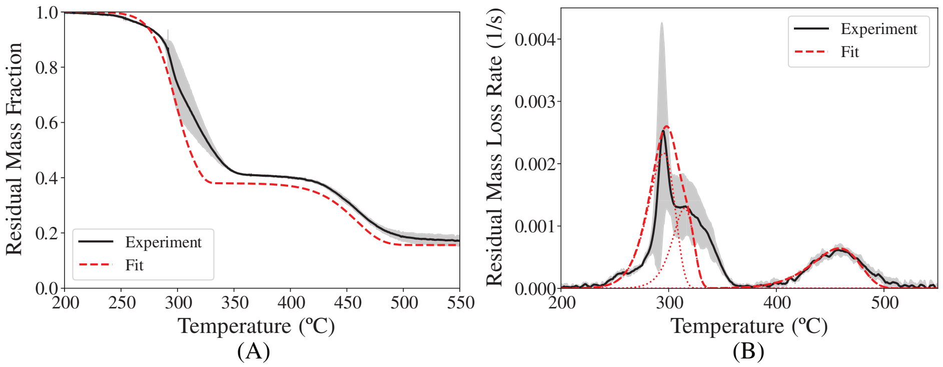

FIGURE 5 Experimental and calibrated TGA (A) normalized mass and (B) normalized mass loss rate for polyvinyl chloride. The gray area represents ± two SDs about the average mass

4.1 | Polyamide 6,6 (Nylon 6,6)

Polyamide 6,6 (Nylon 6,6) samples were obtained from Goodfellow (Reference number AM323100) in the form of injection molded slabs, which were then cryogenically ground to obtain a powder for testing. For each test, between 4.5 and 5.5 mg of this powder was weighed and then pressed flat into the base of an alumina test crucible. The temperature program included a 20-minute-long isotherm at 27°C followed by heating at a constant rate of 10 K/min to 900°C. Three replicate tests were performed, and the average mass data was used by the algorithm to determine pyrolysis kinetics.

The calibrated kinetic parameters are listed in Table 7. Plots of the TGA data and the fit resulting from the calibrated parameters are provided in Figure 3 along with a gray area representing +/− two standard deviations of the mass data about the average mass. Although the initial onset temperature and the peak mass loss rate are slightly overpredicted, the predicted TGA agrees quite well with the experimental data.

4.2 | Flexible PU Foam

PU foam samples were produced by Innocor Foam Technologies to meet the specifications of a "Standard Polyurethane Foam Substrate" described in ASTM-D3574-08.[12] This foam was purchased in the form of 8 cm thick slabs. Samples used for testing were cut from the center of these slabs into small, cylindrical pieces, between 3.0 and 5.0 mg in mass. These foam pieces were then compressed for a minimum of 72 hours before being pressed flat in the center of an alumina test crucible using a steel reshaping tool, just prior to testing. The temperature program included a 20-minute-long isotherm at 75°C followed by heating at a constant rate of 10 K/min to 700°C. Five replicate TGA tests were performed, and the average results were used to estimate kinetic parameters. The calibrated kinetic parameters are provided in Table 8. A plot of the experimental data along with the fit parameters is given in Figure 4. Again, the results predicted using the calibrated kinetic parameters agree quite well with the TGA data. In fact the predicted peak mass loss rates for both reactions are approximately equal to the experimental values.

4.3 | Polyvinyl Chloride

PVC samples were obtained from Interstate Plastics (manufactured by Vycom plastics: Type 1 PVC) in the form of 6-mm thick slabs. For each test, small, flat pieces between 4.5 and 5.5 mg in mass, were carefully cut from these slabs and placed in the center of an alumina test crucible. The temperature program included a 30-minute-long isotherm at 40°C followed by heating at a constant rate of 10 K/minutes to 700°C. Six replicates were performed, and the average TGA signal was used to calibrate the kinetic parameters. The algorithm predicts a three-reaction mechanism, and the calibrated kinetic parameters are tabulated in Table 9. The data and corresponding fits are shown in Figure 5. It is apparent that the fit is not as good as was obtained for the other two materials. This can be attributed to the relative noisiness of the experimental data along with the fact that the first two reactions are relatively close to one another. However, the peak mass loss rates for all three reactions is very well captured by the calibrated kinetic model. The adequacy of this, or any fit, ultimately depends on the ability of the calibrated parameters to make accurate predictions of burning rate and flame spread in fire models. Such a study is beyond the scope of this paper.

Further validation of the algorithm has been performed for 11 different vegetative fuels.[13] These vegetative fuels typically exhibited two to three reaction peaks within close proximity and with considerable noise in the data. As can be confirmed in the reference, the automated fitting algorithm described in this paper performed well even in these more challenging scenarios.

5 | CONCLUSIONS

A novel methodology has been presented for finding the kinetic parameters of pyrolysis from TGA data. The advantages of this algorithm are that (a) it is fully automated requiring no interaction from the user, (b) it is computationally efficient in providing the kinetic parameters in less than 1 second, and (c) it has been verified and validated. The need for such a methodology is driven by a demand for material properties needed as inputs for fire models of flame spread.

Verification was performed by applying the algorithm to manufactured data for several one and two reaction pyrolysis mechanisms. As expected by the underlying theory, it was found that the algorithm performed better for narrower reactions. Additionally, slightly better fits were obtained for well-separated reaction peaks. For the two-reaction scenarios, it was found that the algorithm can sometimes fail to exactly predict mass plateaus between reactions. This is a consequence of the fact that the methodology focuses primarily on capturing the mass loss rate as opposed to the sample mass. A focus on the mass loss rate is justified since flammability is governed by the rate at which combustible volatiles are generated rather than the current amount of mass remaining in the sample. The results of the different verification cases demonstrate that even in situations in which the mass signal is not perfectly captured, the mass loss rate is quite accurate.

Three different materials were used to validate the algorithm: Nylon 66, PVC, and flexible PU foam. All TGA tests for these three materials were performed at a heating rate of 10 K/minutes in a nitrogen environment with the samples placed in an alumina crucible. These cases proved to be a rigorous test of the algorithm since the materials varied in the number of reactions predicted as well as the noise in the underlying data. Kinetic parameters for all three of these materials were determined using the automated algorithm, and the resultant model predictions agreed with the data nicely. A natural extension of this validation process is to test the derived kinetic parameters for TGA at different heating rates. It would be useful to explore the applicability of the calibrated kinetic parameters for making predictions of TGA at lower heating rates, and this remains an avenue for future work. However, a simple heat transfer analysis[14] indicates that the validity of assuming a spatially uniform sample temperature breaks down for heating rates much greater than 10 K/minutes for typical TGA sample sizes. Consequently, data obtained at larger heating rates would include transient effects from thermal (and possibly mass) transport rather than just pyrolysis kinetics. Such a conflation of physical processes will likely inhibit the effectiveness of the derived parameters to make predictions of full-scale scenarios when used in conjunction with separately derived transport properties.

Although the algorithm has been verified and validated to some extent, more validation is always desirable in order to find the limits of applicability of the algorithm. The results presented in this paper are quite promising, but it would be desirable to make better fits for broader peaked reactions as well as for overlapping reactions that occur at very similar temperatures. Furthermore, as was seen in the validation cases, different materials can produce different amounts of noise in the raw TGA data. It would therefore be helpful to make the algorithm more robust against varying degrees of noise. These improvements are primarily related to the very first step in the algorithm which uses the Savitzky-Golay filter to smooth the data and find sufficiently smoothed derivatives. There are several parameters involved in this process that need to be optimized by further study.

Finally, the true test of the effectiveness of this novel methodology lies in its effectiveness at providing parameters that accurately predict burning rate and flame spread in fire models such as FDS. Future work will therefore involve developing similar procedures to use other microscale data such as DSC and microscale combustion calorietery to estimate the other parameters needed in fire models. Once a more complete program of automation is achieved, it will be possible to validate the procedures by comparing fire model results with experimental flame spread data of real materials. Such a process will take significant effort, but the present paper provides a critical first step in this direction.

Keywords: Decision Making, Egress Modeling, Human Behavior in Fire, Psychological Traits, Risk Perception

ABSTRACT

At what point does an individual perceive a growing fire as dangerous and decide it is necessary to take action? Studies of human behavior during emergencies have observed that when presented with situational cues that a hazard may be present, humans can fail to act on this information in a timely manner. Models of human behavior in response to fire-related emergencies explicitly account for potential delays in identifying and acting on the presented risk of a fire. For example, the protective action decision model incorporates the tendency of individuals to notice an aberrant signal, but fail to recognize the cue as indicative of the need to evacuate, until it has become more salient. Past research has indicated that variations in the disposition of individuals, such as psychological traits, can also influence responses to emergencies. The present study examines the extent to which responses to images of growing room fires were influenced by situational and disposition factors. Participants judged whether words reflecting normalcy, risk, or protective action applied to images of room fires that varied in intensity. Psychophysical models of responses revealed, as the visual extent of the fires increased, deviation from normalcy words were first reliably judged to apply, then risk, and finally protective action, in line with models of human evacuation behavior. Individual differences in a specific dispositional trait, self-reported discomfort when exposed to sensory stimuli, was significantly related to performance: those who reported greater negative affect with sensory stimulation took longer to identify a growing fire as indicative of risk. The presence of moderate correlations between performance and other dispositional measures suggests future studies with greater statistical power may observe additional relations. Results of the current study lend support to the presence of a normalcy bias: even though participants noticed small fires and identified the scene as abnormal, they did not reliably view them as a risk until they grew larger. Furthermore, in line with evacuation models, once participants judged the fire cues to be a risk, fire size further increased before participants judged a protective action was applicable. The corroborating evidence in the present study suggests that psychophysical and observational data align with models of human evacuation behavior.

INTRODUCTION

A growing number of fire and life safety codes used around the world provide performance-based design options [1]. To ensure adequate provisions for occupant life safety, egress calculations are

Leventon, Isaac; Bonny, Justin. "Influence of Dispositional and Situational Factors on Human Perceptions of Fire Risk." Paper presented at Interflam 2019, London, UK. July 01, 2019 - July 03, 2019.

increasingly part of performance-based analyses [2]. The role of human behavior in egress calculations can vary from simple models that assume occupants will display identical responses with regard to pre-evacuation behavior (e.g., prescribed delay times in hydraulic based models [3]) to more comprehensive models that account for individual differences in occupant decision making processes (e.g., perception of hazards, and identification and assessment of risk [4–6]). Review papers of human behavior in fire stress the need to accurately assess pre-movement time (i.e., the time between first exposure to fire cues and movement towards a safe place) and have noted that it may be a more important element of required escape time than the time needed to move to a safe place [7,8]. Further, studies of real emergencies have shown that there is a connection between pre-evacuation time (delays in evacuation) and the number of fire deaths or injuries [8]. Unfortunately, multiple studies have highlighted that pre-evacuation behavior receives comparatively less attention than the actual process of evacuation behavior [9–12].

Pioneering efforts identified behaviors that are now recognized as key human responses to fire by surveying individuals after they had experienced a fire event and investigating the actions taken (as distinct from movement) when they encountered a fire in a building [13,14]. Later work would seek to better understand factors affecting human response (and related timing) in real fires including (but not limited to) occupancy [9,15], cues received [10], and occupant action prior to fire cue [11]. However, the fidelity of human behavior in response to fire cues incorporated within computational models that simulate egress is still limited [16] and further research is still needed to identify the underlying processes that produce these observable human behaviors in fire [12]. Including behavioral theories of human decision making regarding the timing of pre-evacuation actions and research linking influential factors (e.g., individual characteristics and environmental cues) to occupant decision making (e.g., identifying threats, perceiving risk, and selecting appropriate protective actions [17]) can improve these models. Greater understanding of how fire is identified as an imminent risk, a specific aspect of human decision making, could improve models and calculations of required safe egress time (RSET).

Models of occupant responses to fire emergencies suggest that specific factors can influence the perception of cues and assessment of the inherent risk of a situation. A specific model that has been applied to human behavior during emergencies, the Protective Action Decision Model (PADM), places an emphasis on the early processing of cues indicative of danger. According to this model, human responses to indicators of a present or imminent emergency depend on a series of processes where environmental cues can be perceived and considered when making decisions about how to respond [18]. When applied to fire-related emergencies, earlier processes are composed of perceiving environmental cues related to the emergency, with subsequent processes involving identifying whether these cues are indicative of risk, and later processes focusing on the decision making regarding taking protective action [17]. Studies of human behavior during emergency evacuations have observed that humans, at times, fail to perceive signs of a hazardous event as indicative of risk [19]. When applied to fire-related emergencies, the PADM explicitly incorporates biases to account for the potential delays in identifying and acting on the presented indicators of risk. Specifically, applications of the PADM to fire-related emergencies incorporate the tendency of individuals to fail to recognize aberrant signals (e.g., smoke) as abnormal; this is known as the normalcy bias [17]. This type of bias can shape initial perceptions as to whether changes in the environment are out of the ordinary and can lead to delays in responding to an emergency [17]. Previous research suggests that perception of cues as indicative of risk can be influenced by dispositional (e.g., psychological traits of the individual) and situational (e.g., environmental) factors [20]. This likely also extends to decision making regarding whether such cues warrant taking protective action [21]. When examining the impact of situational and dispositional factors on decision making, research that has applied the PADM to fire emergencies has predominantly used post hoc evaluations of human behavior during emergencies and interviews of individuals affected by emergencies as sources of data [19,20]. This leaves open questions regarding the extent to which perceptions and judgments when viewing fire cues are influenced by dispositional traits and situational factors.

In the present research, psychophysical models were used to assess at what point individuals viewing images of a developing fire reliably perceived a risk was present and required protective action. Participants viewed images selected from four full-scale compartment fires conducted in realistic, fully-furnished settings (two kitchen and two bedroom fires) and subsequently made judgments about the state of the room. Situational factors were varied by manipulating the stage in fire development that the image was taken from (pre-ignition to flashover) and by varying the type of judgment. Specifically, participants indicated whether a word prompt from select categories did or did not apply to the displayed image. Words were selected to generally reflect earlier versus later processes of the PADM, namely assessment of threat credibility, cues as indicators of a threat, and assessing need for protective action [22] – 'normal' or 'ordinary' (normalcy), 'danger' or 'emergency' (risk), 'evacuate' or 'flee' (protective action). The images ranged from rooms that did not contain flames or smoke, to rooms that had small fires that produced smoke, to rooms that had reached flashover. Psychometric functions were then fitted to collected responses to assess the point during fire growth at which participants reliably judged a word applied to the scene. To evaluate the extent to which variations in dispositional traits influenced judgments, participants also completed a series of questionnaires that assessed temperament (reactivity and self-regulation to changes in environment) and risk-taking tendencies. Individual differences in these factors have been observed to correlate with real-world behaviors such as risky driving [23] and pedestrian behavior [24], and recreational drug use [25]. Variations in temperament reflect differences in the way individuals react and self-regulate to changes in the environment, rooted in biological processes [26]. The focus of theories of temperament on the processes by which individuals respond to environmental factors suggests that individual differences in temperament may shape the ways in which individuals respond to fire cues. Furthermore, with risk taking involving actions that place an individual at an increased chance of experiencing harm [25], it was anticipated that risk-taking tendencies may also influence reactions to environmental indicators of an emergency. Correlational analyses examined whether individual differences in the psychometric curves were connected to variations in these psychological traits.

The anticipated impact of this research is two-fold. First, the novel application of psychophysical models to fire risk perception aimed to address concerns regarding past qualitative and rating-scale research when investigating the impact of situational factors [20]. It was predicted that judgments of growing room fires would align with earlier and later processes associated with human responses to emergencies: participants would initially detect environmental cues indicative of a deviation from normalcy, then interpret more intense fire cues as indicative of risk, and finally judge that the growing fire would require protective action. If successful, the novel approach can be systematically used to study the influence of multiple factors on fire risk perception. Second, the results can be used to inform models of risk perception in emergency scenarios. The development and evaluation of such comprehensive models could enable competent model users to predict key evacuee behaviors, and account for individual differences in dispositional traits, rather than directly prescribing such behaviors, a priori, for a given scenario.

METHOD

Participants

The responses from a total of 40 participants (5 males; age: mean, $M = 20.55$, standard deviation, $SD = 2.34$) were included in the present study. The majority of participants identified as being black ($N = 37$ including 4 Hispanic) with others identifying as white ($N = 2$ including 0 Hispanic) and of mixed race

(*N* = 1 including 0 Hispanic). Participants were recruited from undergraduate psychology courses at a mid-sized university in the Baltimore-Washington metropolitan area in the United States. Recruiting materials for the study emphasized that, as part of the study, participants would be viewing real images of room fires. For completing the study, participants received course credit. The research protocol was approved by an institutional review board and abided by the Declaration of Helsinki.

Hardware and Software

All study materials were presented on a laptop computer (39.6 cm diagonal screen) running the Windows 10 operating system. The judgment task was coded and presented via the Tobii Pro Lab (Tobii AB) software system. A custom Unity3D program was used to administer questionnaires.

Procedure

After providing written informed consent, participants were presented with the judgment task. Participants then completed three questionnaires and were provided with a debriefing form. Participants completed the study in about 35 to 45 minutes.

Judgment Task

Images presented during the judgment task were selected from four video clips of fires in realistically furnished rooms. Each video clip contained a room scene: specifically, two bedroom scenes and two kitchen scenes. A sequence of nine still images were extracted from each video clip such that the apparent size or intensity of the fire increased from no fire or smoke present, to low intensity (e.g., no flames, little smoke), and to high intensity (e.g., large flames, heavy smoke). Images were edited to occlude any labels that included timestamps or watermarks. The final set of images were 1024 x 768 pixels. Figure 1 plots each sequence of images (for each of the bedroom and kitchen scenes) viewed by participants in this study.

During the task, a set of words was presented with each still image (pseudorandom order). Words visually presented to participants during the judgment task were selected to reflect earlier versus later processes associated with human responses to emergencies. Specifically, two words reflecting normalcy (‘ordinary’, ‘normal’), risk (‘danger’, ‘emergency’), and protective action (‘escape’, ‘flee’) were identified during a literature search and pilot testing.

Images were presented full-sized on a black background followed by words presented on a black background in a white font. For the task, participants were presented with room fire images and were asked whether a presented word did or did not match the image. During each trial, participants were first presented with a fixation point (800 ms) that was replaced by an image of a room fire which remained on-screen for four seconds. Afterwards, a word was presented and remained on-screen until participants made a keypress response as to whether the word matched the previously presented image (‘Y’ key = does match, ‘N’ key = does not match) and the next trial began.

Blocks of trials that contained different words were presented in a pseudorandom order. At the beginning of each block, instructions were presented to the participants indicating the word that they were to use to judge each image (within-subject factor). Within each block, all room fire images were presented in a pseudorandom order (within-subject factor; 36 trials total per block; 216 total trials across blocks). Participants were randomly assigned to complete one of three different trial orders.

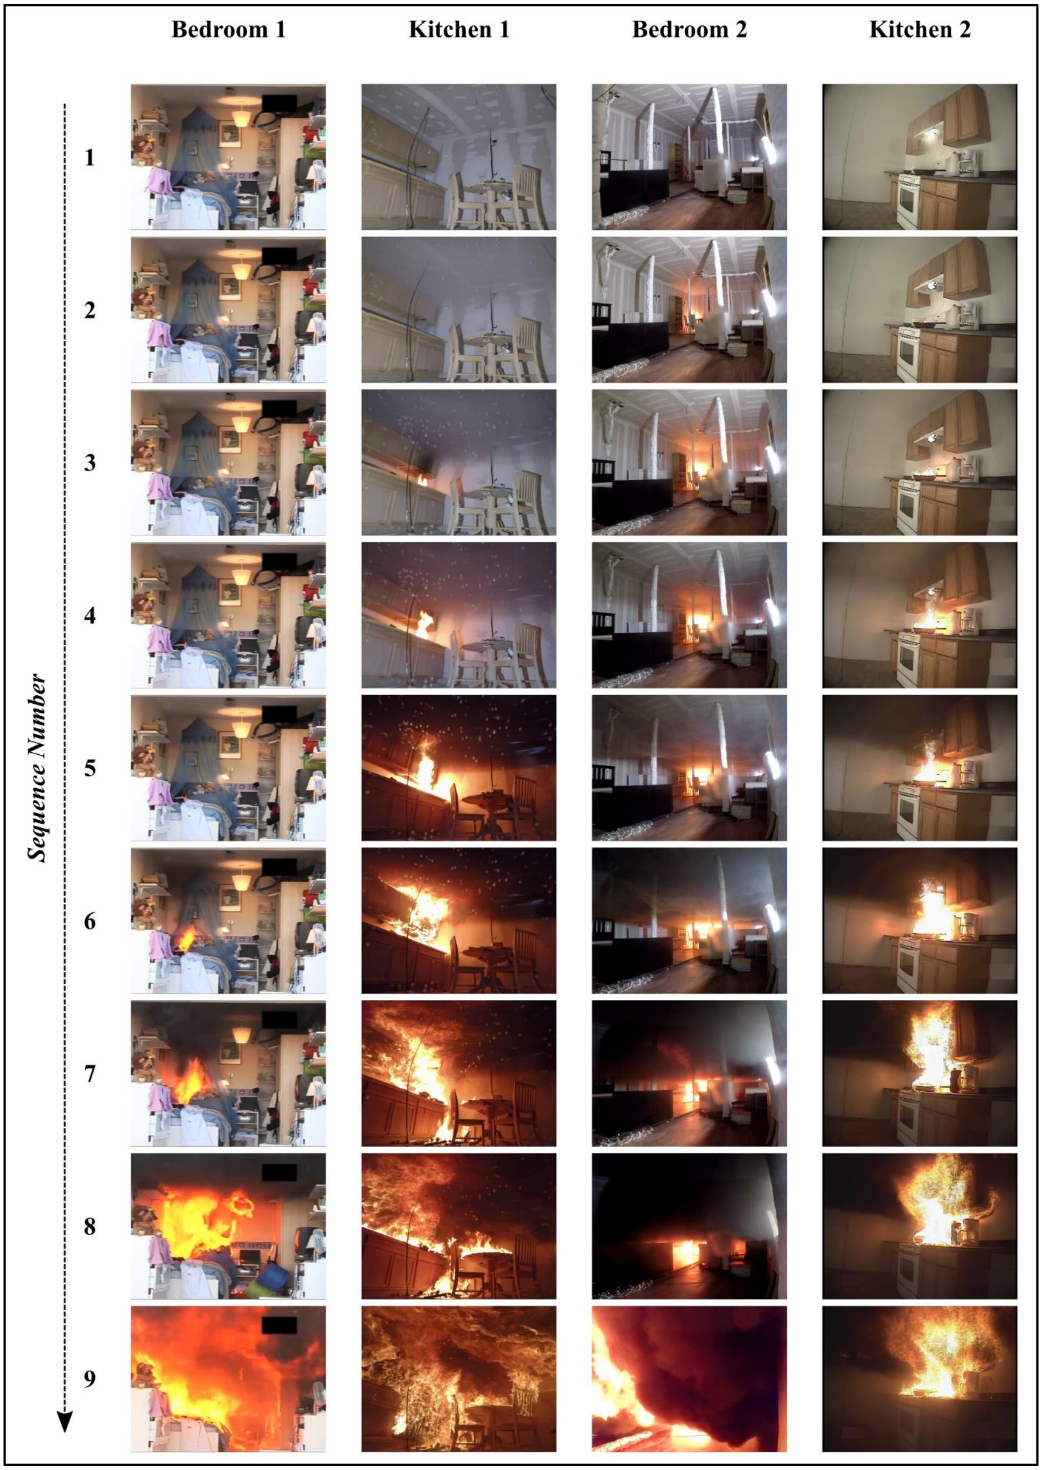

Figure 1. Room fire images presented during the judgment task. The images were selected to display no fire or smoke (#1), low intensity fire, up to high intensity fires (#9). Immediately after each image, a word was presented and participants judged whether the word applied to the image.

Demographic Questionnaire

A series of questions asked participants to provide select demographic information (e.g., age, sex, race). Participants were asked to select from the following options for each demographic factor: biological sex (‘male’, ‘female’), race (‘Asian’, ‘black’, ‘Native American’, ‘white’), and ethnicity (‘Hispanic or Latino’, ‘Not Hispanic or Latino’).

Adult Temperament Questionnaire – Short Form (ATQ-S)

This 77-item questionnaire has been used in previous research to reliably assess different aspects of adult temperament [26]. For each item, individuals judged the extent to which a statement described themselves using a 7-point Likert-type scale (1 = extremely untrue of you; 7 = extremely true of you; e.g., “Sometimes minor events cause me to feel intense happiness.”). If an individual judged a statement to be not relevant, they could respond “not applicable” (this was replaced by the sample mean for that item, following previous research [26]). The responses to the adult temperament questionnaire (ATQ) were compiled into four factor scores, each with subfactors; higher scores indicated higher levels of the factor. Of interest to the present study were the following subfactors: fear (negative affect from anticipated negative event), discomfort (negative affect from sensory stimulation), attentional control (ability to focus and shift attention), and neutral perceptual sensitivity (ability to detect low intensity stimuli) [27].

Risk-Taking Questionnaire 18 Items (RT-18)

Composed of 18 items, the RT-18 has been observed to reliably assess the extent to which young adults engage in risky behaviors [25]. For each item, participants indicated whether they agreed or disagreed that a statement applied to themselves. Scores were summed into two subscales, behavior (extent to which individuals engage in risk-taking behavior; e.g., “I sometimes do “crazy” things just for fun.”) and assessment (extent to which individuals engage in behavior without consideration; e.g., “I often do things on impulse.”), with higher scores indicating higher risk-taking tendencies (scores ranging from 0 to 9 for each subscale).

RESULTS

Task Responses

Prior to analysis, responses for normalcy words were reverse coded to reflect deviation from normalcy, in alignment with responses for risk and protective actions words (resulting responses: normalcy, no risk, no protective action = 0; deviation from normalcy, risk, protective action = 1; $\alpha = 0.05$, two-tailed for all analyses). To assess the extent to which responses to room fires changed as fire size increased and varied with the type of word being applied to an image, a logistic regression was used to model the transition of responses from ‘does not match’ (0) to ‘does match’ (1). Using the ‘glmer’ R package, a generalized liner mixed model (‘logit’ link; ‘bobyqa’ optimizer) with fixed effects of sequence number, word type, and an interaction between sequence number and word type was fitted to the response data with random intercept factors of participant, specific word, and scene, and a random slope and intercept for sequence number by scene.

Using an analysis of deviance, significant main effects of sequence number, $\chi^2(1) = 70.936$, $p < 0.001$, word type, $\chi^2(2) = 70.947$, $p < 0.001$, and interaction effect between sequence number and word category, $\chi^2(2) = 29.871$, $p < 0.001$, were observed. The significant main effects suggested that word prompts were more likely to be judged to apply with later sequence images (i.e., as the fire developed) and, overall, deviation from normalcy prompts were more likely to be judged to apply than ‘risk’ or protective action prompts. The significant interaction between the word type and the sequence suggested that the rate of change of the applicability of that word with respect to sequence number varied by word type. Linear contrast codes used to examine the interaction between sequence number and word category were based on the PADM model, namely that the rate of change for deviation from normalcy (contrast code: 1) would be greater than identifying risk (contrast code: 0), followed by taking protective action (contrast code: -1; analysis used 'glht' R-package). Post-hoc tests revealed a significant effect for the planned contrasts, $z = 4.204$, $p < 0.001$: the largest rate of change was observed for deviation from normalcy, a smaller rate of change for risk, and the smallest rate of change for protective action (see Figure 2).

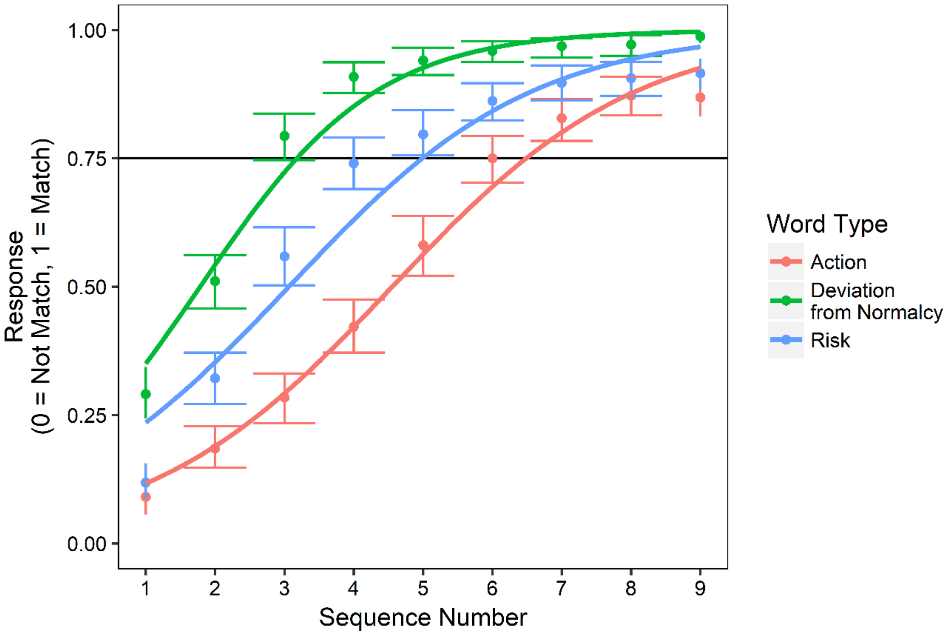

Figure 2. Response patterns on judgment task across word types. Data points reflect mean performance for each image sequence number (95% confidence interval error bars). Solid lines reflect logistic curves fitted to the data points for each word type. The horizontal line reflects 75% performance.

Threshold and Questionnaire Scores

To examine individual differences in performance on the judgment task, models were used to estimate psychophysical thresholds for each word type. Specifically, for each participant, the thresholds estimated the sequence number at which the participant reliably responded (75%) that a word matched subsequent images [28]. To do so, for each participant a logistic regression with sequence number as the predictor and response as the dependent variable was fit for each word type. Due to a poor fit, six participants were dropped from further analysis. Similar to analyses of task responses, planned contrasts using a linear mixed model (random intercept for participant) revealed a linear increase in threshold for word types, $t(58.948) = 7.400$, $p < 0.001$, with participants waiting later in the sequence to reliably judge images as indicating requiring protective action compared to risk, while waiting less for deviations from normalcy compared to risk. Correlational analyses using the Pearson r statistic examined whether relations were present between individual variations in word type thresholds and scores on the ATQ and RT-18 (see **Error! Reference source not found.**). Significant positive correlations were observed between deviation from normalcy and risk thresholds and between risk and protective action thresholds (trend for positive correlation between deviation from normalcy and protective action thresholds). A significant positive correlation was observed between the temperament factor ‘discomfort’ and risk threshold. Although not statistically significant, moderate correlation coefficients were observed between a subset of additional temperament factors and thresholds.

DISCUSSION

In the present study, the extent to which judgments of developing room fires were influenced by situational and dispositional factors was assessed. Performance on the judgment task varied with situational factors, the apparent size of the room fire and word type (i.e., words indicating either, normalcy, risk, or protective action). This pattern of performance aligns with the PADM, suggesting that participants viewed the room fire scenes as indicative of emergencies. Across all word types, as the intensity of the fire cues increased, participants were more likely to judge that words applied to the image. However, the point during the developing room fire at which participants reliably judged that a word matched an image varied by word type. Both logistic model analyses and threshold estimates indicated that participants initially detected fire cues as indicative of a deviation from normalcy (between the second and third images in sequences), then indicative of risk (between the third and fourth images), and finally judged that fire cues indicated required protective action (between fourth and fifth images). This pattern of performance generally aligns with earlier and later stages of the PADM [17] as well as previous observational and self-report evidence collected from fire-related emergencies [20].

Overall, the observed impact of situational factors on judgments of room fires suggests that judgments of presented visual fire cues can be used to examine how humans perceive a fire-related emergency.

When examining performance on the judgment task, participants varied in the point at which they viewed the developing room fires as indicative of risk and requiring protective action. Specifically, individual differences were present in the estimated thresholds for deviation from normalcy, risk, and action, which reflected the point across sequences that participants reliably viewed images as matching the presented words. This provides further evidence that individuals vary in their perceptions and judgments of fire-related cues. When examining connections between word type thresholds, the strongest correlations were between risk and protective action, and deviation from normalcy and risk. These connections align with previous applications of the PADM to fire-related emergencies in two ways. First, the strong positive correlation between risk and protective action thresholds indicates that participants who judged images with less intense fire cues as indicative of risk also judged images as indicative of protective action with less intense cues (and vice versa). This aligns with the stages of the PADM which suggest that when individuals decide a situation poses an imminent risk, they are more likely to take protective action [17]. The correlation between deviation from normalcy and risk thresholds supports previous research indicating that normalcy biases can influence the point at which individuals identify cues as indicative of an emergency [21]; individuals who were later to judge a deviation from normalcy required more intense fire cues before judging the cues as indicative of a risk. Although this aligns with the PADM, a key aspect of the model is the extent to which individuals perceive an emergency as posing a risk to themselves and others [22]. The extent to which participants in the present study simulated themselves, or others, within the images of the room fires may have influenced whether they perceived the fire as posing a risk to themselves or others. This could account for some of the individual differences in thresholds observed in the present study.

When examining individual variations in dispositional traits and judgments of room fires, weak connections were observed. In the present study, temperament and risk-taking measures were selected since previous research has observed that individual differences in these self-reported measures have been connected to real-word behaviors. Of the measures included, the temperament factor discomfort was significantly correlated with variations in risk threshold. Specifically, individuals who had higher discomfort scores took longer to identify images as indicative of risk. With higher levels of discomfort reflecting greater negativity towards sensory stimulation (e.g., greater negative reactions to more intense visual stimulation [27]), this relation suggests that individual differences in dispositional traits may affect perceptions of risk cues in the environment. The lack of statistically significant effects between judgments of room fires and other dispositional traits included in the present study raises questions about the extent to which the present study was able to detect such relations. Specifically, the extent to which participants viewed the images of a fire as posing a risk to other persons may have moderated connections with dispositional traits. Future research that increases the perception that the room fires pose an imminent risk to humans may be better suited to determine whether temperament of individuals influences judgments of fire emergencies.

Future Considerations and Directions

The results of the present study provide initial evidence that judgments of still images of developing room fires align with past observations of human responses to emergencies. Although the words used during judgments for the present study were selected to reflect earlier versus later decision making processes present in the PADM, it remains to be determined which stages or phases of the model the words most directly align with. Earlier phases of the PADM focus on the perception of cues in the environment that are indicative of an emergency with later phases emphasizing the interpretation of the cues [22]. Although the sequence in which words were judged to apply to developing fires generally aligned the order of PADM phases, questions remain regarding the extent to which participants interpreted the words selected to reflect risk and protective action as indicative of a threat to others. By design, the fire cues included in the present study were limited to visual forms and did not include human occupants. With evidence that decision making during emergencies can be influenced by the perceived risk of the hazard to the self and others, this may have influenced the judgments of participants. Future research that utilizes more realistic or immersive cues and/or information sources (e.g., virtual reality) and more descriptive emergency scenarios may be able to increase the perceived risk to the self and others. For example, with evidence that using virtual reality can increase perceived presence in an environment [29], presenting a three-dimensional virtual room fire, with the participant situated inside the room, may be able to increase perceived presence and sense of risk to the individual. Alternatively, providing participants with scenarios that emphasize the potential risk to others (e.g., describing a bedroom room fire as occurring adjacent to another bedroom where a child is currently sleeping), could lead to a different pattern of responses and relations to dispositional traits. Additionally, the stimuli in the present study were strictly within the visual modality. When conducting interviews with survivors of fire emergencies, many report that cues within other sensory modalities, such as smell, were noticed in addition to visual cues [8]. Open questions remain as to whether patterns in performance observed in the present study would be observed when using fire cues of different, or multiple, sensory modalities.

The stimuli selected for the present study focused on bedroom and kitchen fires that were video recorded as part of controlled burns. Although the videos were of real fires, some aspects of the videos may have led participants to view the rooms as atypical. For example, the angle of the video camera (e.g., near floor) and inclusion of measurement devices and recording instruments in a subset of the videos may have made it difficult for participants to visualize themselves as present in the room. Future research should include additional room fire scenes that are likely to be familiar with the targeted population of participants. Furthermore, there were differences across the room scenes with regard to the visual extent of the fires and sequence number. To account for differences in the rate at which visual cues of fire intensity changed across room fire scenes, mixed models that included a random effect of scene were utilized. Although this statistical procedure was used to minimize the effect of cross-scene differences, future research should more systematically match visual cues of fire intensity across different rooms and environments. Furthermore, the words included in the present study were selected to reflect different stages of the PADM, but future research could include a range of words, or phrases, to examine the impact on judgment performance.

Overall, the present study provides a decision-making task for examining how individuals judge fire cues in different situations. With evidence that judgment performance aligned with the PADM, future research can make use of the paradigm to continue to examine different facets of human perception and processing of cues present during fire, and non-fire, emergencies.

Abstract— Human Body Communication (HBC) is an attractive low complexity technology with promising applications in wearable biomedical sensors. In this paper, a simple parametric model based on the finite-element method (FEM) using a full human body model is developed to virtually emulate and examine the HBC channel. FEM allows better modeling and quantification of the underlying physical phenomena including the impact of the human body for the desired applications. By adjusting the parameters of the model, a good match with the limited measurement results in the literature is observed. Having a flexible and customizable simulation platform could be very helpful to better understand the communication medium for capacitively coupled electrodes in HBC. This knowledge, in turn, leads to better transceiver design for given applications. The platform presented here can also be extended to study communication channel characteristics when the HBC mechanism is used by an implant device.

Keywords- Human body communication, Computational human body models, Capacitive coupling

I. Introduction

Human Body Communication (HBC) is one of the wireless technologies defined by the IEEE 802.15.6 standard on body area networking [1]. In HBC, the human body is used as a communication medium between a pair of transmitter and receiver electrodes that are placed on the body surface. The low complexity and energy consumption are among the reasons that make this technology attractive for wearable and implantable devices. Also, as the transmitted data is mostly confined to the human body area, there is less chance of unauthorized access; and therefore, better security is expected compared to other wireless technologies used for body area networks. In the literature, the general technology has also been referred to as Body Channel Communications (BCC) or Intra-Body Communications (IBC). These non-RF communication mechanisms include capacitive (or equivalently electric field) and galvanic signal coupling.

In the capacitive coupling method, the electrical signal that is applied to the human body (i.e. forward path) is capacitively coupled through the air or the environment where the body is located (i.e. return path). Alternatively, in the galvanic coupling method, the human body would act as a waveguide for the signal that is injected by the alternating current into the body. The term HBC, as outlined in the IEEE802.15.6, mainly refers to the capacitive coupling methodology. The underlying concept behind HBC is the fact that in the presence of a weak electric field, the human body can act as a signal guide to capacitively couple two electrodes that are in contact with the body surface. The coupling through the body is achieved with much less attenuation compared to the free space. There have been several studies by researchers to better understand and characterize the HBC channel in the past 10 years. These studies are mostly in the form of measurement campaigns considering different scenarios. As the environment around the human body (and possibly the body posture) directly affects the wireless link between two HBC electrodes, some discrepancies are often observed among the physical measurement results reported in the literature. Also, due to the variables and parameters that could impact the return path, developing a comprehensive simulation platform that can adequately model the HBC channel is quite challenging. Methodologies that have been used to investigate the electric field propagation mechanism and modeling the underlying body channel include RC circuits, Finite-Element Method (FEM), Circuit-coupled FEM as well as FDTD (Finite Difference Time Domain) method to model the communication link [3 - 8].

Circuit models representing the HBC channel have been developed in [5, 6]. The reported results for the channel gain (or equivalently pathloss) in the range of 1 to 100 MHz show a bandpass profile with a peak somewhere in the 40-60 MHz interval. In [7], the authors have developed a circuit-coupled finite-element method (FEM) model of the HBC channel. A multi-layer FEM model was used to represent the human forearm. The parasitic effects of the printed circuit board (PCB) and the return path were modeled as circuit elements. While measurement results for the channel attenuation versus frequency still showed a bandpass profile, simulation results show monotonically increasing with a much milder bandpass profile for various parameters values. In [8], the authors concluded that measurements of the pathloss in HBC systems strongly depend on the instrumentation configurations. Using a small battery-powered transmitter and receiver to measure pathloss, they showed that inclusion of any additional ground plane, even isolated by baluns, serves to underestimate the resulting path loss by up to 33.6 dB. Their pathloss results again showed a bandpass profile with a peak around 70-75 MHz.

The common element in most of the results published in the past several years is the passband profile shape of the channel attenuation in HBC within the range 1-100 MHz. As pointed out earlier, depending on the instrumentation or methodology that was used for channel measurement, the

Sayrafian, Kamran; Krhac, Katjana; Noetscher, Gregory; Simunic, Dina. "A Simulation Platform to Study the Human Body Communication Channel." Paper presented at IEEE Engineering in Medicine and Biology Conference (EMBC 2019), Berlin, DE. July 23, 2019 - July 26, 2019.

location of the peak frequency in the passband profile varies from 40 to 70 MHz. In addition, discrepancies are also observed on the average magnitude of the forward transmission coefficient. This is due to the specifics of the model used for the parasitic return path in the HBC system. Our objective in this research was to develop a simple parametric FEM-based model that 1) can capture the fundamental concept of HBC operation/channel; 2) can be adjusted to emulate a specific measurement scenario; and 3) can be easily extended to study implant HBC channel.

The rest of the paper is organized as follows. Section II describes a computational 3D human body model that is used for this study along with a simple model of the HBC electrodes and communication links. Section III provides simulation results for several on-body scenarios and a brief discussion on comparison with existing physical measurements in the literature. Finally, conclusions and our plans for future work are described in section IV.

II. Simulation platform

Modeling of a HBC channel is a challenging task due to the many parameters that can possibly affect the characteristics of the communication link. Among those, we can point to size and shape of the electrodes, locations and the distance between the RX/TX electrodes, separation between the signal and ground plates of each electrode, body posture, dielectric properties of the human tissues that are in contact with the electrodes and possibly the environment surrounding the human body.

A novel 3D immersive platform to study wireless channels in body area networks has been developed at the Information Technology Laboratory of the National Institute of Standards & Technology (NIST) [2]. A 3D computational human body model is one of the main components of this platform that can be customized for the desired application. The body model includes frequency dependent dielectric properties of 300+ parts in a male human body. These properties are also user-definable if specific changes or modifications are desired. The human body model has a resolution of 2 mm. To study HBC, this computational model has been augmented with a skin shell that fits over the exterior body mesh. In addition, variable fat shells (reflecting skinny, average and obese persons) have been added to the model. This will allow us to study the potential impact of the fat layer on the forward path attenuation of a HBC channel.

The electrodes were modeled as two metal plates; one in contact with the skin and the other located directly above and floating in the air. To ensure the full contact of electrodes with the skin tissue in the body model, a small patch (i.e. brick) of skin material has been added directly underneath the electrode to unite the signal plate with the skin exterior. This ensures that the surface of the electrode and the skin are fully coincident. Size, plate separation, distance between the receiver/transmitter electrodes are design variables; and therefore, the impact of each one of these parameters can be easily investigated in our model. Figure 1 shows an example of two electrodes placed on the right arm of the human body model in our platform.

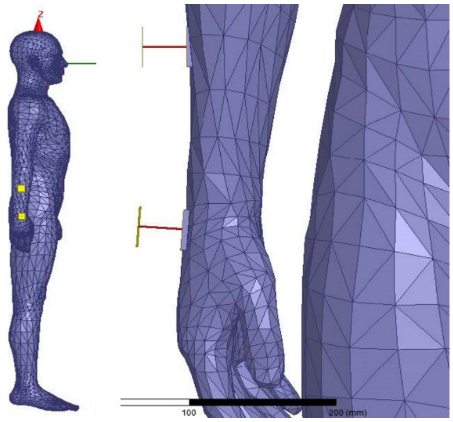

Figure 1. HBC electrodes on the right arm

The biggest complexity in modeling the HBC channel is incorporating the impact of the parasitic return path and characteristic impedances of the electronic circuits generating the signal (or in case of physical measurement, parasitic of the probe PCB). In our FEM-based model, the coupling of the electrodes through the air (i.e. return path) is modeled by a capacitor (C_{Ret}). This is similar to the circuit or circuit-enabled models proposed in [7]. However, we have implemented the capacitive return path using RLC boundaries methodology in ANSYS. The signal leakage path between the electrode plates has also been modeled with capacitor C_L. The characteristic impedance of the source has been modeled by a cascade of resistor R_T and inductor L_T. These elements are schematically shown in Figure 2.

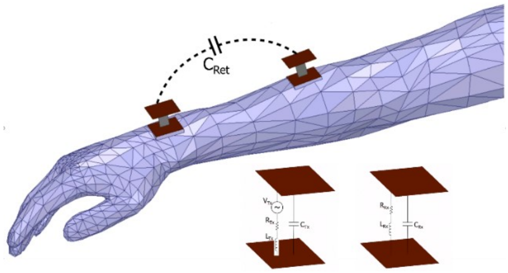

Figure 2. System schematic

Using ANSYS HFSS[1] electromagnetic solver, a variety of different quantities such as the magnitudes of the electric field (inside, on the surface and outside of the body) and the Scattering parameters (e.g. S_{21}) between the two electrodes can be calculated. For example, Figure 3 highlights the basic principle of HBC by displaying the electric field distribution. Fig. 3(a), on the left, shows the distribution of the magnitude of the electric field when the transmitting electrode is not in contact with the human body (i.e. operating in the air). On the other hand, when the electrode is place on the human arm (as

[1] HFSS is a product of ANSYS, Inc. HFSS has been used in this research to foster research and understanding. Such identification does not imply recommendation or endorsement by the National Institute of Standards and Technology, nor does it imply that this product is necessarily the best available for the purpose.

seen in Fig. 3(b)), the electric field extends over the entire body surface. This ensures much higher received signal strength; and therefore, better communication channel between the two electrodes. A signal frequency of 50 MHz has been used for the result shown in Figure 3.

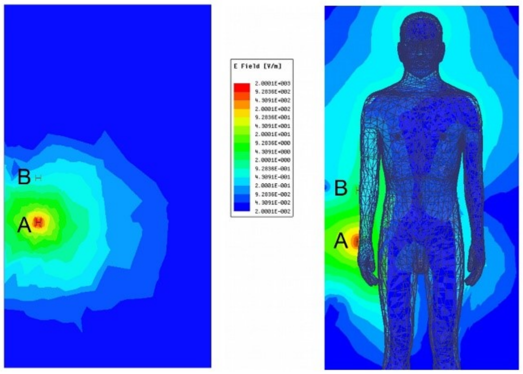

Figure 3. Electric field distribution around the transmitter electrode (a) without the human body (b) with the human body

The HBC platform mentioned above enables us to run different parametric studies to find the matching values of the parasitic elements as well as investigate the impact of electrodes size, location, and body placement for various applications. In the next section, we point out to some of these results.

III. Results

The frequency range of interest in HBC is typically 1-100 MHz. Higher frequencies could result in the human body acting as an antenna and are also susceptible to external radiation [9]. Therefore, for frequencies higher than 100 MHz, significant channel variation and lower efficiency of the communication system can be expected. Using the simulation platform discussed in the previous section, the HBC channel attenuation can be measured by the forward transmission coefficient S_{21} for various scenarios. As mentioned earlier, limited measurement results in the literature indicate a bandpass profile with varying location of the peak frequency. The bandpass profile is mostly influenced by the capacitive leakage path as well as the parasitic inductance L_{Tx}.

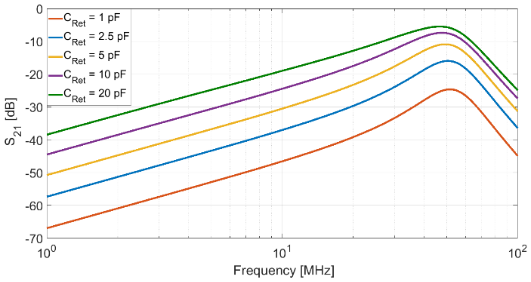

Figure 4. Forward transmission coefficient for various C_{Ret}

To show the impact of these parameters, consider the scenario depicted in Figure 1 with a distance of 15 cm between the two electrodes on the arm. Figure 4 displays the simulation results for various values of the capacitive return path (C_{Ret}) when L_{Tx}=225 nH. Similarly, Figure 5 reflects the impact of varying L_{Tx} while C_{Ret} is fixed. As observed, the bandpass profile shape and values for the S_{21} can be tuned and optimized to match the physical measurement results published in the literature. In fact, for 15 cm separation between the electrodes, C_{Ret}=5 pF, L_{Tx}=220 nH and C_L=35 pF, the simulation results match well with the reported physical measurement results in [5, 6]. The source and load impedances were assumed to be 50 Ohms. We also investigated the S_{21} results for distances of 30 cm and 45 cm as the receiver electrode was moved further up the arm and closer to the shoulder. The same values for the parasitic capacitance and inductance resulted in the best match with the reported measurements in [3, 4].

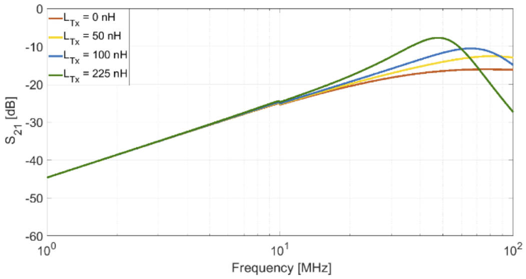

Figure 5. Forward transmission coefficient for various parasitic inductance

Looking at the results for electrode separations of 15, 30 and 45 cm, a slight degradation of the S_{21} versus distance is observed (see Fig. 6). However, the parasitic capacitance representing the return path seems to be the same. The S_{21} degradation is due to the higher attenuation of the forward path, i.e. the path through the body. For the three scenarios considered so far, the forward and return path distances are approximately the same as the receiver electrode is moved away from the transmitter along the straight human arm. It is worth noting that there could be scenarios where the forward and return path distances are quite different, for example, when the electrodes are located on the left and right wrists, and the arms are held straight down along the body (or even close to each other in front of the body).

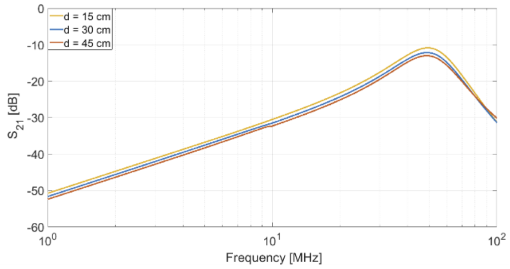

Figure 6. Forward transmission coefficient for various electrodes distances

To the best of our knowledge, there are no results in the literature that highlights the impact of this discrepancy between forward and return path distances. Our conjecture is that the parasitic capacitance could be a function of the return path distance. For example, if the electrodes are located on the separate wrists, the magnitude of S_{21} will change as the person under experiment move his hands closer or farther away from each other. Also, another ambiguity regarding the forward path distance is whether this distance is considered as the shortest path through the human body (i.e. in-body distance) or on the body surface. For example, consider two HBC electrodes, one located on the chest area while the other is on the back side of the body. Depending on how the electric field is distributed, the length of the forward path could be the straight line through the body connecting the electrodes or the distance around the body surface separating the two electrodes. To better understand this issue, we first need to eliminate the impact of the return path which can be accomplished by short-circuiting the ground plates of the electrodes with a perfect conductor. This was first done for the scenario in Figure 1 and the resulting S_{21} versus frequency (which is now representing only the attenuation through the forward path) is shown in Figure 7.

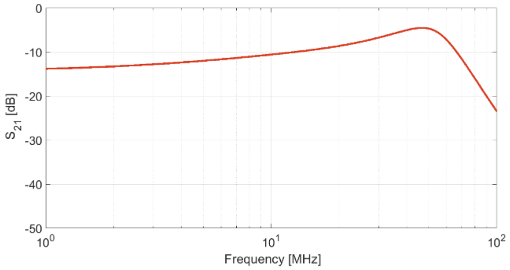

Figure 7. Forward path attenuation for the scenario shown in Fig. 1

As observed, the body seems to be a uniform attenuator (for frequencies below 100 MHz) with approximately 10-15 dB loss when the distance between TX and RX electrodes is about 15 cm. This level of attenuation was also observed through physical measurement in [7].

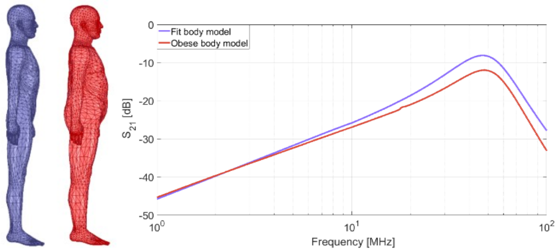

Figure 8. Forward transmission coefficient for various body shapes

The material properties of the body tissues that are along the forward path of the HBC channel can also impact the signal attenuation. To observe this, we conducted a simulation using two body models representing a fit versus obese person (see Fig. 8). The electrodes were placed on the stomach area where a heavier concentration of fat exists. The electrode separation was chosen to be 20 cm. The S_{21} for the two human body models are shown in Figure 8. The result indicates higher attenuation for the obese person, which can be explained by the lower conductivity of the fat tissue versus muscle for the frequency range of 10 to 100 MHz.

IV. Conclusions and Future Work

A FEM-based parametric simulation platform including a full 3D computational human body model has been presented in this paper. The S_{21} results match the bandpass HBC channel attenuation profile reported in the literature with appropriate adjustment of the model parameters. The platform allows researchers to further study the HBC channel by considering variable electrode size and plate separation, placement on the body, as well as designing virtual experiments to better understand the impact of variable return path distance for a fixed forward path through the human body. The authors also intend to continue this research by further extending the computational human body model to include various postures. Further studies on the distribution of the electric field inside the body would also be necessary to investigate the potential impact of using HBC on implant devices such as pacemakers.

Also, as mentioned earlier, low complexity and energy consumption of HBC will also make this technology an attractive alternative for implantable devices. Since implants are completely located inside the human body, physical measurements are no longer possible to examine the channel. Therefore, a simulation platform including a full human body model will be very useful to study and characterize the implant HBC channel. The implant communication link is less affected by the environmental variables as both forward and return paths are confined within the human body. Development of the platform discussed in this paper is the first step toward a comprehensive study of the implant HBC channel.

Abstract. We present a strategy for identifying and correcting for aberration effects in Spherical Neutron Polarimetry. The transformation of the neutron beam polarization vector due to scattering from a material is determined with Spherical Neutron Polarimetry. This neutron scattering technique measures the three cardinal components of the scattered polarization for any chosen cardinal direction of the incident polarization for a given Bragg reflection. As a consequence, the instrumentation required for this technique is desired to be capable of measuring the three-dimensional polarization vector over the sphere. As with all instrumentation, the field of measurement is subject to aberration which must be characterized.

1. Introduction

Spherical Neutron Polarimetry (SNP) is a neutron scattering technique that measures the nine elements of the polarization property tensor of a material [1]. These nine elements are derived from the three-dimensional neutron beam polarization vector with Cartesian components $P_j = (I_+ - I_-)/(I_+ + I_-)$, for $j = 1$, 2 or 3 corresponding to X, Y or Z. The terms, $I_\pm$, correspond to the measured intensity of the $\pm 1/2$ spin eigenstates of the neutron angular momentum in the j^{th} direction. This measurement technique was first fully realized in 1989 at the Institut Laue-Langevin [2] and has since been revised, [3] expanded upon [4, 5] and developed elsewhere [6]. Figure 1 illustrates in a three step process the general layout of SNP. In the first step, the polarization direction of the incident polarized neutron beam is set to one of the j^{th} Cartesian directions. In the second step, this oriented polarized beam scatters, through Bragg reflection from a crystal, which changes the neutron beam's initial momentum, $\mathbf{k}_1$, to some final momentum, $\mathbf{k}_2$. In the third step, for a given Bragg reflection, the axis of measurement is set to measure one Cartesian component of the scattered neutron beam. Orienting and measuring all possible directional combinations yields the nine component polarization property tensor for that material at a specific Bragg reflection.

The Cartesian axis of measurement and orientation is fixed relative to the scattering vector, $\mathbf{Q}$, which specifies a Bragg reflection and is defined as the change in momentum between the incident and scattered neutron beams (i.e., $\mathbf{Q} = \mathbf{k}_2 - \mathbf{k}_1$). We call this frame of reference the Q-frame. To easily move a neutron detection apparatus about a crystal and thereby measure

Tosado, Jacob; Chen, Wangchun; Rodriguez, Efrain E. "A Strategy for Handling Aberration in Spherical Neutron Polarimetry." Paper presented at 12th International Conference on Polarised Neutrons for Condensed Matter Investigations Journal of Physics: Conference Series, Abingdon, GB. July 03, 2018 - July 06, 2018.

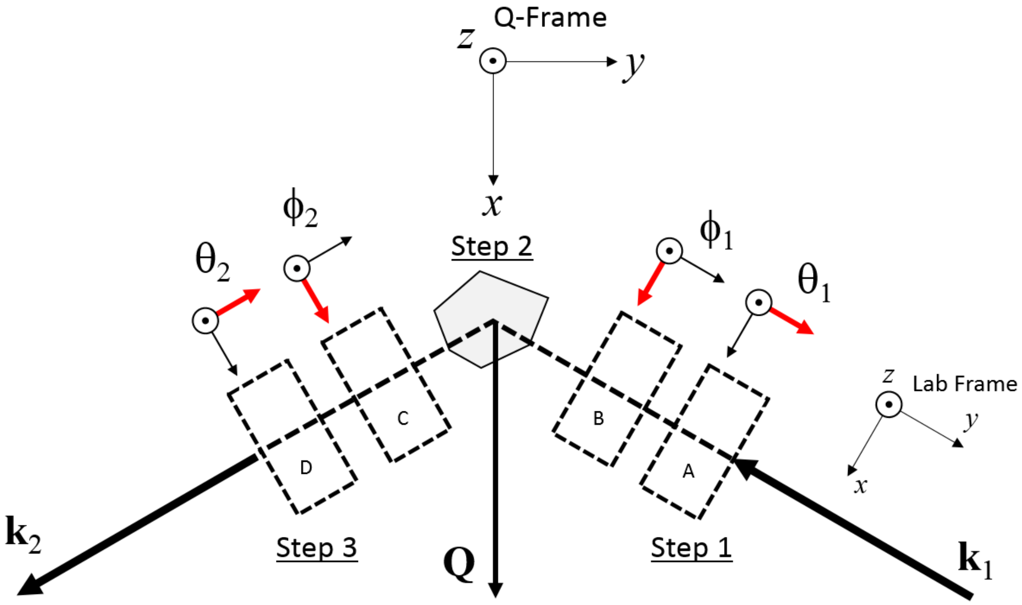

Figure 1. Coordinate system of the SNP setup as seen from the Q-frame. Here, the XY-plane is the scattering plane. The relative placement of polarization control instrumentation is outlined with boxes. Adjacent to each box, the respective local coordinate system and local control parameter are depicted. For each local coordinate system, the axis of rotation for the control parameter is highlighted in red. The letters distinguish the instrumentation as follows: **A)** Local rotation about the y_1 axis, $R_{y_1}(\theta_1)$ **B)** Local rotation about the x_1 axis, $R_{x_1}(\phi_1)$ **C)** Local rotation about the x_2 axis, $R_{x_2}(\phi_2)$ **D)** Local rotation within the XZ-plane, $B_{xz}(\theta_2)$

different **Q**, the possible directions of **Q** are typically restricted to rotations about a single axis fixed in the lab frame. The lab frame may be thought of as being aligned with, $\mathbf{k}_1$, the direction of the incident neutron beam. The resulting plane through which **Q** rotates defines what is called the scattering plane.[1] The Cartesian directions are then typically labeled X, Y and Z where X is parallel to **Q**, Z is vertical and perpendicular to the scattering plane and, Y completes the orthogonal set. Upon scattering, the neutron beam's initial state polarization is transformed by interacting with the magnetic structure of the crystal to some final state polarization. That transformation is defined by the Blume-Maleyev tensor [7].

2. Calibration

The instruments that orient the incident polarization and set the direction of the measurement axis each have local independent coordinate systems. Through calibration, the local coordinate system of each instrument is transformed into the Q-frame. As such, calibration requires the precise mutual alignment of each coordinate system and the precise characterization of distortions inherent within the SNP apparatus. Each SNP component device(s) can be identified with respect to the polarization degree of freedom that it controls and/or measures. As a result,

[1] Throughout this article we generally assume that the scattering plane is level with the floor of the laboratory. This is an important assumption in that it places real restrictions on the overall geometry of an SNP apparatus which naturally influences the potential distortion in the measurement.

there are four main devices corresponding to four degrees of freedom: two degrees for the incident beam and two degrees for the scattered beam, which must be mutually aligned. To understand alignment one can describe the measurement of a single component, P_j, of the polarization vector in terms of the rotation of an initial state polarization vector and its dot product with the measurement axis in the Q-frame. This is given by the relationship,

$$P_j = \mathbf{B}(\Theta_2, \Phi_2) \cdot T \;\; R(\Theta_1, \Phi_1)\mathbf{P}_o \tag{1}$$

Here $\mathbf{P}_o$ is the initial state polarization, T is the Blume-Maleyev tensor, $R(\Theta_1, \Phi_1)$ is the net rotation of the initial state polarization by the instrumentation and $\mathbf{B}(\Theta_2, \Phi_2)$ is the axis of measurement. The spherical coordinates $\Theta_{1,2}$ and $\Phi_{1,2}$ are angles about the Q-frame Y and X axes, respectively. Implicitly, T, Θ_1, Φ_1, Θ_2 and Φ_2 are all dependent on $\mathbf{Q}$. For simplicity we will first consider one value of $\mathbf{Q}$ and later discuss other directions. From Equation 1 the three steps of Figure 1 can be distinguished mathematically as,

Step 1.	$R(\Theta_1, \Phi_1)\mathbf{P}_o$	Directing the incident polarization
Step 2.	T	Scattering from a crystal
Step 3.	$\mathbf{B}(\Theta_2, \Phi_2)$	Measurement of the scattered polarization

The first part in calibration is to remove effects due to magnetic scattering from a crystal so as to isolate the character of the apparatus. This can be achieved by either removing the crystal from the SNP apparatus altogether and measuring the polarization of the purely transmitted beam or by measuring the scattered polarization of a pure nuclear Bragg peak. In either case, having all effects resulting from magnetic scattering properly removed will reduce T to the identity operator.

To understand the calibration of each component instrument we first decompose the rotation operator, $R(\Theta_1, \Phi_1)$, into three operators: $R_{in}(\mathbf{Q})$, $R_{y_1}(\theta_1)$ and $R_{x_1}(\phi_1)$ where, $R(\Theta_1, \Phi_1) = R_{in}(\mathbf{Q})R_{x_1}(\phi_1)R_{y_1}(\theta_1)$. Here, $R_{y_1}(\theta_1)$ and $R_{x_1}(\phi_1)$ represent a rotation about the local y_1 and x_1 axes, respectively, and $R_{in}(\mathbf{Q})$ represents the net transformation into the Q-frame. In Figure 1 the relative orientations of the local axis as seen from the Q-frame are depicted. The measurement axis decomposes likewise into three operators: $\mathbf{B}_{xz}(\theta_2)$, $R_{x_2}(\phi_2)$, and $R_{out}(\mathbf{Q})$ where $\mathbf{B}(\Theta_2, \Phi_2) = \mathbf{B}_{xz}(\theta_2)R_{x_2}(\phi_2)R_{out}(\mathbf{Q})$. Here $\mathbf{B}_{xz}(\theta_2)$ is a local planar measurement field in the XZ-plane, $R_{x_2}(\phi_2)$ is a local rotation of the scattered polarization into that field, and $R_{out}(\mathbf{Q})$ is the net transformation out of the Q-frame. To simplify matters further, we only consider the transmitted beam method for calibration such that T, $R_{in}(\mathbf{Q})$ and $R_{out}(\mathbf{Q})$ each reduce to the identity operator.[2] The measured polarization of the purely transmitted beam is now,

$$P_j = \mathbf{B}_{xz}(\theta_2)R_{x_2}(\phi_2) \cdot R_{x_1}(\phi_1)R_{y_1}(\theta_1)\mathbf{P}_o \tag{2}$$

From this Equation we can define two domains on either the incident polarization or on the measurement of the scattered polarization. The first is the domain of control, which describes all possible orientations of the incident polarization,

$$\mathbf{S^2}_{con} = \{(\theta_1, \phi_1) \;\mid\; 0 \le \theta_1 \le 2\pi, \;\; 0 \le \phi_1 \le \pi\} \tag{3}$$

The second is the domain of measurement, which describes all possible orientations of the measurement axis $\mathbf{B}$,

$$\mathbf{S^2}_{mes} = \{(\theta_2, \phi_2) \;\mid\; 0 \le \theta_2 \le 2\pi, \;\; 0 \le \phi_2 \le \pi\} \tag{4}$$

[2] The operators R_{in} and R_{out} are a very simple way of mathematically visualizing the coordinate transformation of $\theta_{1,2}$ and $\phi_{1,2}$ into the Q-frame.

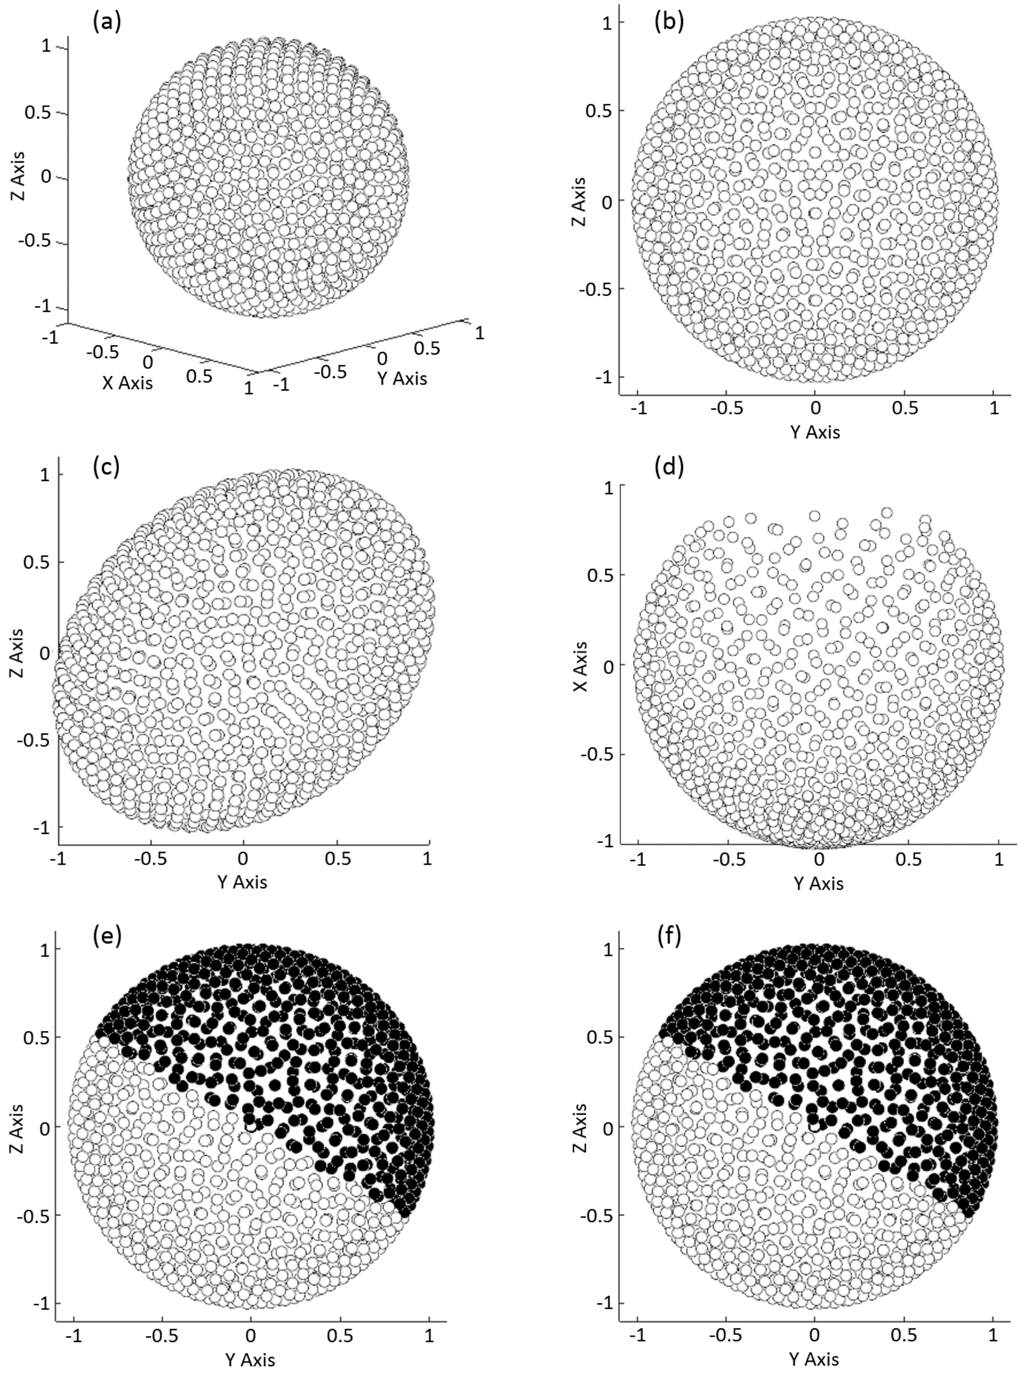

Figure 2. Simulated SNP measurement field. (a) and (b) Measurement field with no misalignment. (c) Misalignment applied by setting $\alpha_1 = 30^o$ (d) Misalignment applied by setting $\alpha_2 = 30^o$ (e) Misalignment applied by setting $\beta_1 = 30^o$ (f) Misalignment applied by setting $\beta_2 = 30^o$. In Figures (e) and (f) the data is segregated into two hemispheres with black and white face circles. This is to show clearly the effect of misalignment, which is identical in these two cases.

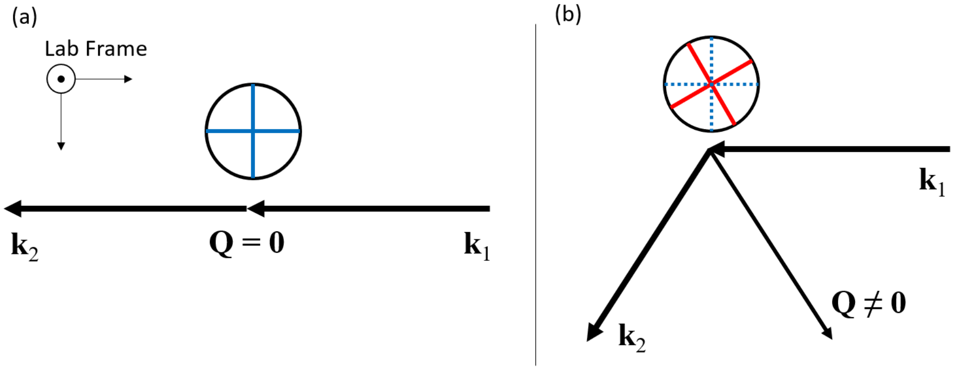

Figure 3. Orientation of the Q-frame for different values of $\mathbf{Q}$ as seen in the lab frame. (a) The transmission configuration during calibration and, (b) Crystal measurement. The blue cross (solid & dashed) indicates the Q-frame orientation for $\mathbf{Q} = 0$ and the red cross indicates the Q-frame orientation for $\mathbf{Q} \neq 0$.

Table 1. (Left) The opposing angles required for measuring the j^{th} vector component over the control domain. (Right) The opposing angles required for measuring the j^{th} vector component over the measurement domain.

	θ_2	ϕ_2
X	$\pi/2$	0
Y	0	$\pi/2$
Z	0	0

	θ_1	ϕ_1
X	$\pi/2$	0
Y	0	$-\pi/2$
Z	0	0

For each element of either $\mathbf{S^2}_{con}$ or $\mathbf{S^2}_{mes}$, Equation 2 will produce a vector $\mathbf{P} = \sum_j P_j \ \hat{\mathbf{e}}_j$ from three cardinal orientations corresponding to $j = 1$, 2 or 3 of the two opposing angles. The angles of these three opposing orientations for both the control and measurement domains are shown in Table 1. As an example, a measurement of some vector $\mathbf{P}_G$, from the control domain $\mathbf{S^2}_{con}$, first requires the setting $(\theta_1, \phi_1)_G$ to access the G^{th} point in that domain. Then one must independently measure the X, Y and Z components by setting (θ_2, ϕ_2) according to the Table 1 values for the $\mathbf{S^2}_{con}$ domain. When properly aligned, the resulting range of vectors, $\mathbf{P}$, for each domain ideally form a spherical field of radius P_o centered at the origin. Figures 2(a) and (b) illustrate a three-dimensional plot of the ideally aligned perfectly spherical measurement field resulting from the $\mathbf{S^2}_{mes}$ domain. In this context, misalignment can now be characterized by the Q independent phases α_1, β_1, α_2 and β_2, which add to the local control coordinates, i.e.,

$$P_j = \mathbf{B}_{xz}(\theta_2 + \alpha_2) R_{x_2}(\phi_2 + \beta_2) \cdot R_{x_1}(\phi_1 + \beta_1) R_{y_1}(\theta_1 + \alpha_1) \mathbf{P}_o \tag{5}$$

From Figure 2 one can see how the addition of these phases distorts the sphere. Figure 2(c) shows the resulting distortion in the measurement field (or equivalently the control field) when $\alpha_1 = 30^o$. From Figure 2(d) the distortion is entirely different when the same misalignment angle, $\alpha_2 = 30^o$, is applied. In contrast to these, Figures 2(e) and (f) show a tilting of the spherical field when the same 30^o misalignment is applied to either β_1 or β_2 separately. In all of these cases, switching the sign of the misalignment mirrors the distortion and, combinations of misalignment superpose. These phases can be deduced by an iterative comparison of measured data with simulation. The phases are then corrected for by electromechanical means within the hardware until the apparatus is well described by Equation 2 alone. We therefore define misalignment to be any distortion in either the control or measurement fields that is well described by Equation 2.

Physically, alignment through measuring either the control or measurement fields acts to maximize the transmission of polarization through the SNP apparatus along the cardinal directions of the Q-frame. The control and measurement fields, while both spherical, differ in that they describe different aspects of the SNP functionality. For example, consider Figure 3. Here, two values of $\mathbf{Q}$ in the lab frame are depicted, one for $\mathbf{Q} = 0$ and one for $\mathbf{Q} \neq 0$. For both values of $\mathbf{Q}$ the orientation of the corresponding spherical field is also depicted. The $\mathbf{Q} = 0$ case (Figure 3(a)) was used for alignment and is described by Equation 2. During the measurement of a crystal, $\mathbf{Q}$ will most likely be non-zero and the resulting Q-frame will be rotated relative to the Q-frame used for alignment (refer again to Figure 3(b)). Consider that at most six points of the measurement field are needed for any given $\mathbf{Q}$. In the lab frame, this amounts to the vertical poles and a great circle within the scattering plane of the measurement field. Practically, only these regions of the measurement field need to be well described by Equation 2. This is not so for the control field. Nuclear-magnetic scattering, at values of $\mathbf{Q} \neq 0$, would result in a scattered polarization directed away from the Q-frame cardinal axes [8]. If the control field is distorted in that direction and is fixed to the lab frame, then that distortion will propagate to any polarization measurement when the direction of scattered polarization coincides with that distortion, regardless of how spherical the measurement field is.

To emphasize the diference between the measurement and control fields we must first consider two other forms of distortion in addition to misalignment, noise and aberration. Noise we characterize as the expected variation in the spherical field due to the compounded Poisson error of the neutron detection process [9]. Aberration, in contrast, we define as distortion which is greater than the noise and is not well described by misalignment (i.e., Equation 2). As an example of noise, first consider Figures 4(a) and (c) which shows a simulation of 1024 discrete measurements on the $\mathbf{S^2}$ domain where Figures 4(b) and (d) are respective Mollweide projections of Figures (a) and (b). We use the Mollweide projection to visually retain the relative proportionality of the point distribution when compared to the three-dimensional plots [10]. In Figures 4(a) and (b) the average noise level is twice as large as the angular sampling period (i.e., the average angular distance between points in $\mathbf{S^2}$). Consequently, the noise is the dominant signal and the sampling period satisfies the Nyquist-Shannon sampling limit [11], meaning that this spherical field is noise limited. The noise level, displayed in Figures 4(c) and (d), has been reduced by an order of magnitude but the sampling period is unchanged (i.e., an equivalent 1024 points have been used). In this case, the noise fluctuation is small and features resulting from any other distortion may only be resolved if the Nyquist-Shannon sampling limit is met. This means that the spherical field for this reduced noise level is now Nyquist-Shannon limited. In other words, the angular resolution provided in Figures 4(c) and (d) is now adequate to resolve aberration in the spherical field occurring at large enough angular scales.

Now consider an example of aberration in the control field, for $\mathbf{Q} = 0$, depicted in Figures 5(a) and (b). We imagine this type of aberration being brought about by artifacts in either the laboratory or the sample environment. By mapping such an aberration, as in Figure 5(b), real space correlation to known artifacts would potentially allow the source of the aberration to be identified and removed. Figure 5 is a simulation where the noise level here is equivalent to that used in Figures 4(c) and (d). This simulated aberration appears in a decrease in polarization within the upper octant of the control field. Figure 5(b) shows that the aberration is localized within that octant and does not intersect the cardinal planes. If this aberration is now fixed relative to the lab frame then, for some value of $\mathbf{Q} \neq 0$, the cardinal planes would intersect it resulting in a loss of transmitted polarization. Figure 5(c) through (e) show the projections

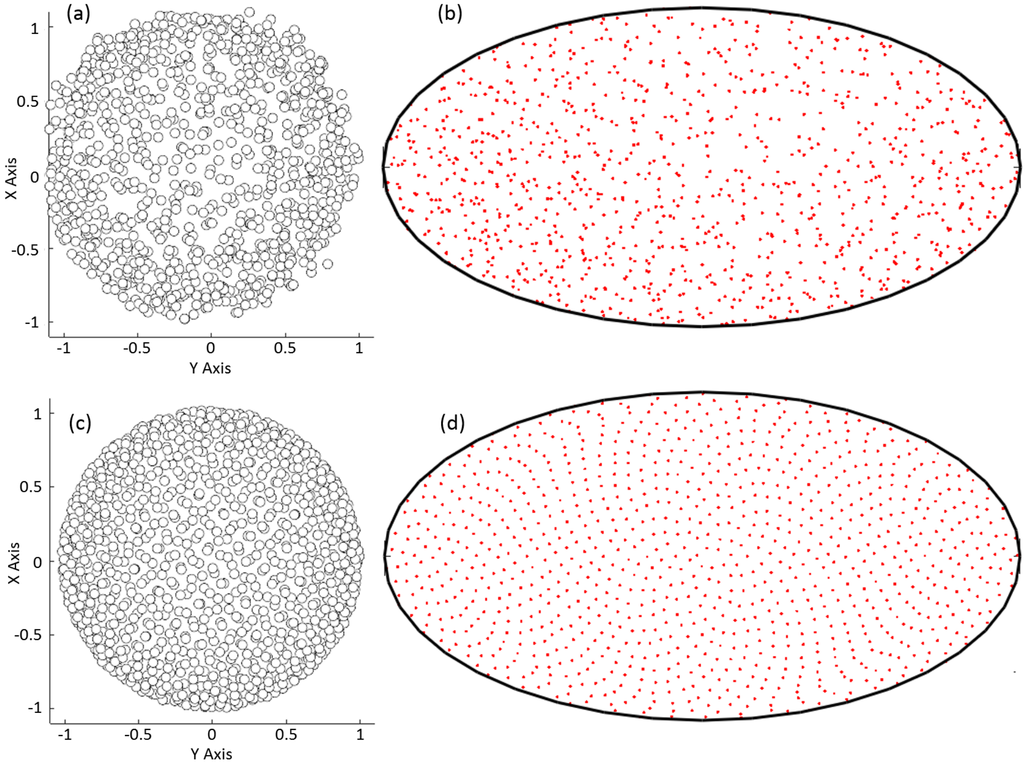

Figure 4. Simulation of the spherical field for two noise levels plotted in 3D and as a 2D Mollweide projection. (a) and (b) Noise Limited Data where the noise level is twice a large as the sampling period. (c) and (d) Nyquist Limited Data where the noise level is much smaller than the sampling period.

of this aberrated control field onto the cardinal planes for $\mathbf{Q} = 0$. Since the polarization in each projection follows the great circle (outlined in black) of that respective projection plane, the resulting measurement field will appear to be undistorted. Again, this is because only the undistorted X, Y and Z directed polarizations of the control field are used in constructing the measurement field. Therefore only a spherical measurement of the control field through the aberrated region will fully account for that distortion.

To characterize the type of aberration depicted in Figure 5 we now explore a strategy that involves expanding the measurement field in terms of a finite series of spherical harmonics. Techniques similar to this have been used to model three-dimensional data for Computer Generated Imaging (CGI) [12].

$$P(\theta, \phi) = \sum_{n=0}^{N} \sum_{m=-n}^{n} \epsilon_{nm} Y_{nm}(\theta, \phi) \tag{6}$$

Equation 6 describes an expansion of the magnitude of the measured polarization on the $\mathbf{S^2}$ domain in terms of the spherical harmonics $Y_{nm}(\theta, \phi)$ with coefficients ϵ_{nm} for degree n and order m. Here the maximum degree, N, is determined by the total number of measurements

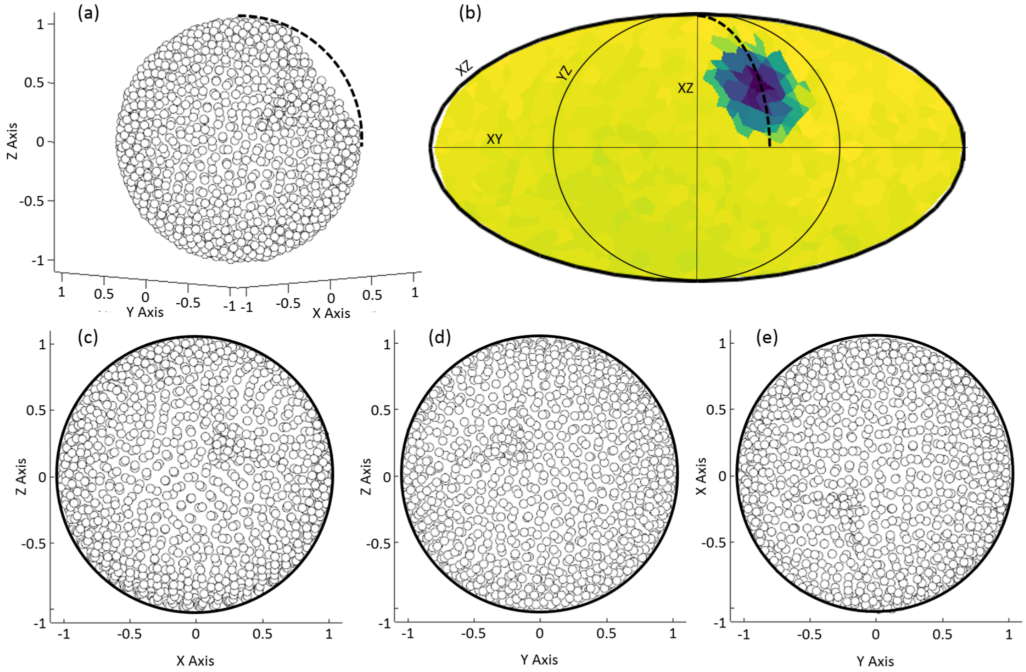

Figure 5. Simulated aberration. The noise level is equivalent to Figure 4(b). (a) A three-dimensional plot showing a decrease of polarization relative to the control field. The dotted line indicates the undistorted polarization. (b) Mollweide projection of of the simulation showing that the distortion is localized within one octant of the sphere. Here arcs and lines indicate great circles and are labeled according to the respective plane that contains them. The dotted line of (a) is also shown. (c-e) Projections of the simulation onto the planes labeled in (b). Great circles act as a guide for the eye.

taken, similar to discrete Fourier analysis.

To apply this expansion, we first begin by correcting for angular aberration. Angular correction serves to regularize the spherical field for harmonic decomposition by Equation 6. The operation we suggest here is a simplified form of image warping and we refer to Wolberg (1990) , for a more in depth treatment [13]. This is a procedure which first involves calculating the set of spherical angles, $\{A_k, B_k\}$, from the set of vectors, $\{\mathbf{P}_k\}$. Each A_k and B_k then correspond to the expected angles, a_k and b_k, set by the instrumentation such that the resulting angular aberration is the respective difference,

$$\delta_k = A_k - a_k, \qquad \rho_k = B_k - b_k \tag{7}$$

To later apply this to an arbitrary measurement we may linearly interpolate between angles such that for an arbitrary pair of measured angles, (γ, ζ), which, for example, are in the intervals, $A_k \leq \gamma \leq A_{k+1}$ and $B_k \leq \zeta \leq B_{k+1}$, the calculated aberration for those angles is,

$$\Delta_\delta = \Big|\frac{\gamma - A_k}{A_{k+1} - A_k}\Big|(\delta_{k+1} - \delta_k) + \delta_k \tag{8}$$

$$\Delta_\rho = \left|\frac{\zeta - B_k}{B_{k+1} - B_k}\right|(\rho_{k+1} - \rho_k) + \rho_k \tag{9}$$

The corrected angles for an arbitrary measurement are then,

$$\Theta = \gamma - \Delta_\delta \tag{10}$$

$$\Phi = \zeta - \Delta_\rho \tag{11}$$

With the angular distortion removed, correcting for radial distortion is more straight forward. This is accomplished by describing the set of magnitudes, $\{P_k\}$, of the calibration data with Equation 6. A correction to an arbitrary measurement, $P_{measured}$, with spherical angles Θ and Φ is then,

$$C(\Theta, \Phi) = \sum_{n=1}^{N} \sum_{m=-n}^{n} \epsilon_{nm} Y_{nm}(\Theta, \Phi) \tag{12}$$

such that,

$$P_{corrected} = P_{measured} - C \tag{13}$$

The corrected polarization described in Equation 13 is subject to the innate Poisson error of the calibration data, $\{\mathbf{P}_k\}$, and this error will propagate to the corrected polarization. We suggest that the error in $\{\mathbf{P}_k\}$ be kept to a level much smaller than that used for routine measurement.

3. Discussion

Thus far we have considered the limited case where both the control and measurement fields, measured at one value of **Q**, are fixed to the lab frame and are therefore Q-dependent. This dependency is described simply by a rotation of these fields about the Z-axis (Figure 3). In this sense, calibration requires characterization of one control and measurement field. Experimentally, we estimate that the measurement of a single spherical field would take about 20 hours for a neutron flux on the order of $2 \times 10^6/\text{cm}^2/\text{s}$. The simplicity of this kind of Q-dependency may be somewhat of an ideal since the modern SNP apparatus requires movement of instrumentation in the lab frame to measure different **Q**. An actual Q-dependency may be more complicated requiring field characterization at more than one **Q**. In any case, the strategy we have outlined for characterization of the control and measurement fields would not change.

Finaly, it must be pointed out that SNP calibration typically involves only measuring vector components along great circles within the control and measurement fields [4, 14, 5]. To date, there has been no attempt to characterize variation in an SNP apparatus over a spherical domain. As a result, it is not clear in what context aberration will significantly affect SNP measurements. For minor aberration in the control field, that is an aberration on the order of 2% above the noise, we expect aberration to have the potential of severely effecting measurements of weak nuclear-magnetic reflections. For these reflections, the nuclear component may be significantly stronger than the magnetic and, any loss in intensity could wrongfully suggest that the signal is purely nuclear.

META-DATA FOR IN-SITU MONITORING OF LASER POWDER BED FUSION PROCESSES

Shaw C. Feng[1], Yan Lu, and Albert T. Jones
Engineering Laboratory
National Institute of Standards and Technology
Gaithersburg, MD 20899

ABSTRACT

Increasingly, a wide range of in-situ sensors are being instrumented on additive manufacturing (AM) machines. These sensors collect a variety of data that is used to monitor process performance and part quality. The amount, type, and speed of the collected data are unprecedented. Consequently, several data-related, standards issues are impeding the use of both data analytics and tool integration. Those issues include registration, curation, organization, storage, and management. This paper focuses on registration. It proposes the use of meta-data as a foundation for new interface and exchange standards. Standards that will facilitate the use of several types of in-situ sensors that monitor laser powder bed fusion (L-PBF) processes. The paper also includes an example data model that captures the properties and relationships among those meta-data. The data elements in that model provide industrial users with the capabilities and formats to capture, exchange, and share L-PBF process data.

1. INTRODUCTION

The value of parts fabricated using additive manufacturing (AM) continues to grow. Current market projections estimate that by 2025 that value will be approximately $7.65B in North America and $21.5B worldwide [7]. However, there are still hurdles impeding the widespread acceptance of AM as a reliable and cost-effective production technology. These hurdles are due primarily to the high variability in the quality of AM-produced parts. Quality problems include undesired pores or cracks, dimensional inaccuracies, poor surface finish, and inhomogeneous mechanical properties.

Factors causing quality problems include variable material properties, improper process settings, and the dynamic build environment. Many ongoing research efforts are being conducted to understand the impacts of those factors both individually and collectively. These efforts typically focus on two tasks: 1) identifying the material-process-structure-property relationships and 2) using those relationships to improve both process control and part quality. Both tasks rely on a variety of in-situ monitoring sensors for their success. That variety includes imaging sensors, thermal sensors, video cameras, acoustic sensors, ultrasonic sensors, and vibration sensors. The data coming from those sensors are characterized by volume, variety, velocity, and veracity [13]. A systematic organization of that data is needed for both real-time monitoring and off-line design and planning. The benefits of registering data are 1) accessing validated data with known time, locations, and approvals, 2) data alignment and fusion, 3) detecting defects traceable to process, material, equipment parameters, and 4) validating AM process models using validated data.

This paper describes our efforts implementing one important aspect of meta-data for in-situ monitoring of laser powder bed fusion processes. Meta-data are data types that describe how data were collected, including scanning strategy, sensor types, sensor configuration, calibration, and setup parameters. Meta-data is for AM data registration. AM data registration involves 1) a data curation process by which the context of the data (i.e., meta-data) is captured as well as 2) a unique data object identifier. This identifier can be used for generation of a persistent object identifier from a trusted registration authority. Registration is necessary to compare and fuse multi-sensor, in-situ monitoring data.

Most of this paper focuses on data collected by four types of sensors during a powder bed fusion (PBF) process. The four sensor types are imaging, thermometry, acoustic emission, and acceleration. Although profilometry is another possible sensor type, it still being studied. It will be added to our categorization when more detailed studies are available. Details in meta-data are in data elements in this paper.

Our proposed data elements approach is to link the in-situ data with product, process, and resource information. This paper also provides the XML representations of several data elements related to the raw monitoring data we collected by the sensors.

Feng, Shaw C.; Lu, Yan; Jones, Albert T. "Data Registration for In-Situ Monitoring of Laser Powder Bed Fusion Processes." Paper presented at International Mechanical Engineering Congress and Exposition, Salt Lake City, UT, US. November 11, 2019 - November 14, 2019.

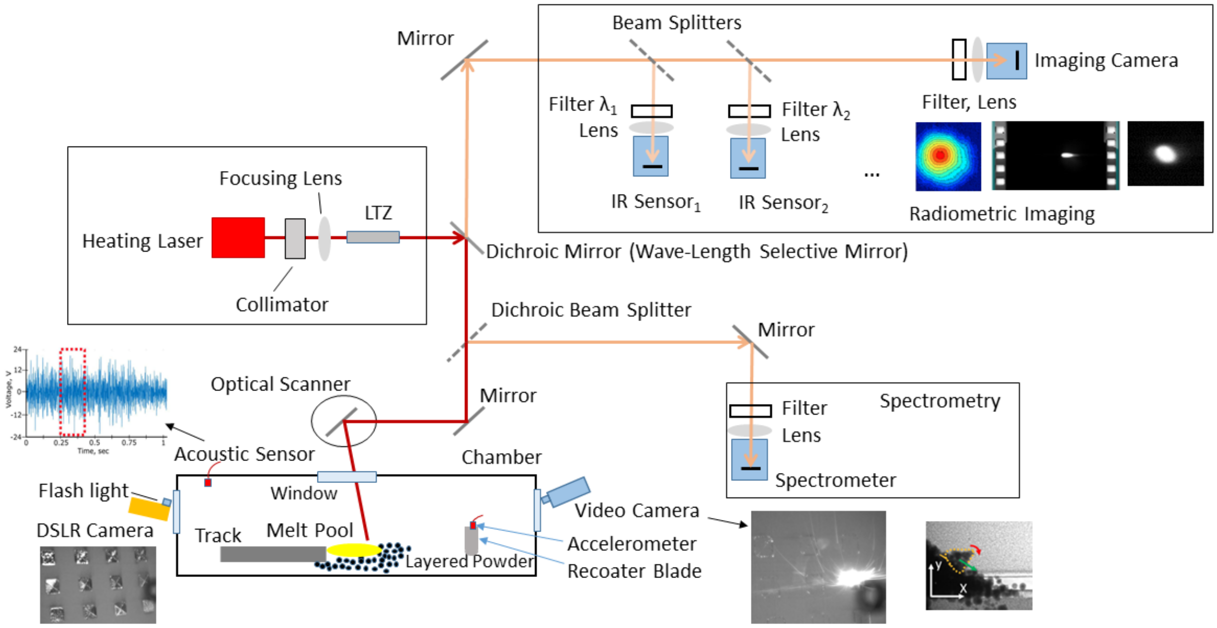

Figure 1 Schematic diagram of sensors for in-situ monitoring of L-PBF

These representations are key to 1) implementing and replicating our approach for data registration and 2) enabling the future standards on common data formats and data exchange.

The paper has six sections. Section 2 reviews related publications in in-situ monitoring. Section 3 describes data elements for in-situ process monitoring. Section 4 prescribes a data model based on the identified data elements to enable implementations. Section 5 provides an example and discuss the usage of the data model. Section 6 concludes the paper.

2. REVIEW OF IN-SITU MEASUREMENT RESEARCH

To develop a data model for data registration, we need to understand the current use of sensors for in-situ monitoring. The section provides a review of sensors, data fusion, sensor categorization, and research needs. Recently, researchers have been integrating L-PBF sensors and developing techniques to evaluate the data they provide.

2.1 Sensors for In-situ Process Monitoring

In-situ process monitoring, which is necessary for real-time control, is enabled by sensors and data analytics. In this paper, we focus on only four types of in-situ monitoring sensors: co-axial imagers, off-axis imagers, acoustic sensors, and accelerometers (see Figure 1). Co-axial sensors, which share the same axis as the laser beam, are optical sensors that can generate images of temperatures or melt-pool geometries. For the temperature measurement, a multi-wavelength pyrometer can provide more accurate temperature data. For the melt-pool geometry measurement, 2-D images are used to measure melt-pool dimensions. Moreover, a spectrometer can be used to analyze energy peaks and spatters in the melting process [2].

Off-axis sensors include Digital Single Lens Reflex (DSLR) cameras, acoustic sensors, and accelerometers. A DSLR camera can take images of the powder bed each time it is triggered. A combination of flashlights from different angles and illuminations can detect anomalies on each scanned layer [11]. A high-speed camera can record the laser-scanning process including melting, solidifying, and tracking. Acoustic sensors, which generate sound signatures in the frequency domain, can detect anomalies in the scanning process [15].

These different sensor types have different sensor capabilities. Lane et al. [9] characterized sensor capabilities using three metrics: spatial resolution, temporal resolution, and sensitivity. The authors' goal was to evaluate the capabilities of various sensors to determine how well they can detect defects and irregularities in AM processes. Yadroitsev et al. [19] described sensors used in the selective laser-melting process. The authors listed sensors to measure powder-material properties, process parameters, and their relationships to the instabilities in the process that can lead to defects. The same authors also characterized various defects on tracks and part surfaces.

Smith et al. [16] showed acoustic parameters used in spatially resolved, acoustic spectroscopy to detect near-surface defects such as pores, cracks, and voids. Depond et al. [3] developed a low-coherent, laser-scanning interferometry sensor and showed sensor parameters to measure powder layer-surface roughness. Bertoli et al. [1] estimated cooling rates using high-framerate video and multi-physics simulations. They reported consistency between the solidification shown in picture frames and the simulations. Heigel and Lane [8] measured melt-pool temperatures and dimensional characteristics using an infrared camera outside the chamber with temperature calibration. Hooper [9] demonstrated in-line measurements of melt-pool temperature and cooling rates using a coaxial laser and imaging design.

Fisher et al. [5] also used a coaxial sensor for monitoring melt pools. In the paper, the authors identified metrics for using the data from that sensor – including the cross-sectional area, the temperature changes, and the plate temperature. In addition to sensors for characterizing melt-pool temperatures, there are sensors for measuring individual parameters, such as melt-pool sizes. Tan et al. [17] listed specific material and process parameters to model the melting process. They also proposed a temperature-measuring technique using a pyrometer.

There is the fifth type of sensors: chamber environment sensors, e.g., inert gas flow meter, inert gas pressure sensor, and CO_2 concentration sensor. They are located outside the view shown in Figure 1 and not used to measure the melt pool or scanned layers.

2.2 Sensor Fusion In-Process Monitoring Data

As a new attempt at monitoring AM fabrication processes, researchers are now using several different sensor technologies simultaneously and fusing the resulting data. Foster et al. [6] used staring-video cameras and coaxial cameras to collect data for monitoring melt-pool characteristics. Additionally, in that same paper, the authors surveyed existing, ultrasonic, in-process sensors that can be used to detect pores and delamination. In a survey focused on direct energy-deposition processes, Reutzel et al. [14] described measurements of melt-pool geometry and temperature. The authors made geometric measurements based on images taken by a single-color camera in the infrared (IR) range. Temperature measurements, however, were based on images taken from a dual-color camera. The authors aligned the images with built-in reference marks in addition to the part design.

Everton et al. [4] described specific sensors and sensing techniques for monitoring part buildup, layer-by-layer, in L-PBF processes. Purtonen et al. [12] focused on optical sensors and acoustic sensors. Optical sensors included photodiodes, spectrometers, Charged Coupled Device (CCD) and Complementary Metal Oxide Semiconductor (CMOS) imaging sensors, acoustic sensors, pyrometers, and infrared cameras. Acoustic sensors included microphone and signal analysis software in the frequency domain for detecting anomalies in melting. Sensor fusion has been increasingly a research topic for better understanding of AM processes.

2.3 Sensor Categorization

In this paper, we aggregate currently available sensors developed for in-situ, L-PBF monitoring as shown in Tables 1 (a), (b), and (c). The leftmost column lists what is being monitored. Items in the list includes the entire melt pool, a freshly coated layer, a newly scanned layer, workpiece, chamber, and blade. The top row in each table lists available sensor types. The list includes still image cameras, video cameras, infrared cameras, pyrometers, thermocouples, sonic sensors, ultrasonic sensors, strain gages, accelerometers, CO2 sensors, air-pressure gages, and air-flow meters. These sensors belong to the following five types: photogrammetry, thermometry, acoustic emission, mechanical sensing, and chamber environment sensing.

Table 1 (a) Sensor categories and defect detection – photogrammetry

		Photogrammetry (still image or video)	
		Unstructured light (CMOS, CCD cameras)	Structured light (CMOS, CCD cameras)
Meltpool		Meltpool shape irregularities, e.g., key hole and size too small. Track irregularities, e.g., under melting, over melting, metal balls, and discontinuity	N/A
Layer	**Freshly coated**	Waviness, voids	Same as left with more contrast
	Scanned	Track discontinuity, cracks, voids, and spatters. Coated powder layer irregularities, e.g., streaks, waviness, and metal obtrusion	
Workpiece		N/A	N/A
Chamber		Plume, spatter, spark	N/A
Blade		N/A	N/A

2.4 Research Needs for Data Elements for Registration

Clearly, a variety of sensors are being used for in-situ monitoring of different AM processes. Those sensors provide a plethora of data, including images, video clips, temperature data, and acoustic signals. While the data from individual sensors are important, correlations among those data can be extremely valuable. Sensor data must be registered in a data repository providing metadata before the data can be applied for analysis and correlated for decision making. The data correlations are necessary to determine the state of the powder-fusion process, the material microstructure, and the fabricated part. For example, without correctly aligning measurements in the spatial and temporal domains, conflicting predictions can be made on the part quality

Table 1 (b) Sensor categories and defect detection – thermometry

		Thermometry				
		Radiometry			**Non-radiometry**	
		Infrared imaging IR camera with filter (still or video)	**Pyrometry**		**Thermocouple**	**Thermometer**
			Single bandwidth (Pyrometer)	**Multi-bandwidth (multi-bandwidth pyrometer)**		
Meltpool		Melt pool temperature profile	Melt pool temperature (with correction of emissivity) to detect under/overheating problems	Same as left, but calibrated with near true temperature black body	N/A	N/A
Layer	**Freshly coated**	N/A	Powder bed temperature	Temperature monitoring	N/A	
	Scanned	N/A	Powder bed temperature	Same as left		
Workpiece		N/A	N/A	N/A	Temperature monitoring	N/A
Chamber		N/A	N/A	N/A	N/A	Temperature monitoring
Blade		N/A	N/A	N/A	N/A	N/A

Table 1 (c) Sensor categories and defect detection – acoustic emission, mechanical sensing, and chamber environment sensing

	Acoustic emission		**Mechanical sensing**		**Chamber environment sensing**		
	Sonic (microphone)	**Ultrasonic (Ultrasonic sensor)**	**Strain (Strain gage)**	**Acceleration (Accelometer)**	**CO_2 concentration gaging**	**Air pressure gaging**	**Air flow metering**
Meltpool	N/A	N/A	N/A	N/A	N/A	N/A	N/A
Layer	Sparking anomalies	N/A	N/A	N/A	N/A	N/A	N/A
Workpiece	Cracking	Crack, void detection	Thermal and residual stresses	N/A	N/A	N/A	N/A
Chamber	N/A	N/A	N/A	N/A	CO_2 concentration	Air pressure	Air flow
Blade	N/A	N/A	N/A	Waviness on the powder layer, Metal Obtrusion due to lamination	N/A	N/A	N/A

Metadata for capturing the ‘context’ of that data, both in the product development lifecycle and in the material and equipment supply chains, is also needed for qualification. That context should include three types of information related to individual sensors and their configuration, to the design, build, post-process, and inspection activities, and to material, equipment and personnel. This information is necessary for downstream applications, such as data analytics, and will enable users to analyze the data correctly. Data correctness reduces wrong decisions to be reached during and after L-PBF.

AM dataset registration as a research topic continues to expand. Nevertheless, the current limitations of that research are still impeding the use of advanced data analytics, which can be used to accelerate the understanding and control of AM processes. Current limitations include both a missing data identifier for tracing raw data objects and a lack of meta-data for data fusion and analytics. First, raw data objects from in-situ sensors are often stored in isolation: either on local computers, laboratory servers, or mobile drives. Since these data objects lack standardized syntax or semantics, each data object may not have a persistent identifier assigned. This makes it very difficult to trace the origins of the data objects where they are located. This, in turn, impedes the fusion of data objects collected from different monitoring systems and stakeholders.

Second, estimating the correlations among various sensor-data types is very difficult since there is no information to link the data correctly in both time and space. In the following sections, we present a data registration approach to contextualize AM in-situ data sets. The approach has the potential for standardization that will facilitate the integration of AM lifecycle data integration. Lastly, there is no contextual information for the product’s lifecycle. This is one of major barriers for part qualification and verification to ensure AM product quality.

Multi-modal, nondestructive sensors collect a variety of data objects for monitoring AM processes. Comparing, fusing, and correlating these data objects to the original AM design, the current microstructure, and the final part quality is a major problem. The quantity and quality of different data types are also causing curation, organization, and administration problems that can limit the usage of those data objects. In our view, data registration is focused on contextualizing data in time and space (see Figure 2) for capturing the meta information necessary.

Figure 2 shows a picture of how in-situ data can be registered geometrically onto a voxel model. The additional data necessary to do this are shown on the right-hand side of Figure 2. For example, the laser-scanning strategies are critical since the scanner-motion control and laser-control commands provide fundamental references to contextualize in-situ data sets both spatially and temporally. The rest of the Section describes data elements that are needed for registering in-situ monitoring data, including scanning paths, melt-pool monitoring (MPM) images and videos, layer-wise images, and signals in acoustic emission.

Unfortunately, registering spatial-temporal data is not enough to guarantee better process control. Control requires a transformation of the raw sensor and calibration data into the same coordinate system. Control also requires linking all in-situ data to the design, geometry, tolerance, material, and inspection information.

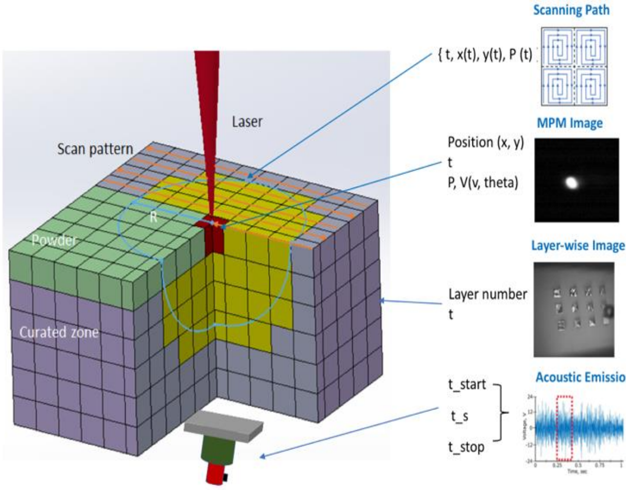

Figure 2 Registering AM data using a voxel model

3 Data Elements for In-situ Process Monitoring

3.1 Laser-scanning-strategy Data Elements

Laser-scanning strategies can provide both temporal and spatial references for the spatiotemporal alignment of in-situ measurements from different sensors. The scanning-strategy registration method is process-oriented, based on the xy2-100 protocol used in some open AM systems. The xy2-100 files provide the laser-spot positions, laser power, and camera-trigger timing [20]. This method is used primarily to register the position and the time when the image is taken by a camera. Required data elements are shown in Table 2. The scan starting time can be used as the temporal reference to align the data in the time domain, e.g., acoustic data.

Table 2 Process-oriented Data Elements

Data Element	Description
Build ID	unique identification of the associated build
Part ID	unique identification of the associated part
Scanning ID	unique identification of the data element
Layer number	the powder layer number
Command time (t)	the time that a position command is sent
Scan position (x, y)	the commanded location of the laser beam
Laser power (P)	the power of the laser beam
Scanning speed (V)	the scanning speed of the laser beam

The metadata shown in Table 2 can be provided by an open-architecture AM system, e.g., the AM Metrology Test Bed from the National Institute of Standards and Technology[2]. For commercial AM systems, part-oriented scanning strategies are used to scan the layer with minimized scanning time with acceptable part quality. The strategy specifies scan paths and process parameters based on partitions of the layer and is vendor-dependent and proprietary, so the registration of this kind of scan strategies is not discussed here.

3.2 Layer-wise images

Layer-wise images are dominating the current datatypes used in monitoring AM processes. There are two methods for registering layer-wise images: an individual image or a folder of images. The two methods are described below.

3.2.1 Registering an Individual File

When there is a limited number of individual images on a pre-scanned or post-scanned powder layer, each image can be registered with the data elements in Table 3 to provide the necessary meta information.

Table 3 Image Data Elements

Data Element	Description	
Image (or Movie) Name	the name of the image or movie	
Image (or Movie) ID	a unique identification (ID) number of the image or movie	
Build ID	the ID of the build for the part	
Layer number	the layer number of this image	
Time	the time it was taken	
Folder Path	the directory path for locating the folder that this image or movie was saved	
Flash condition	if flash lights are used, a description of the flash light angle relative to the layer	
Sensor ID	the identification of the image sensor	
Sensor description	sensor type (e.g., InSb, CMOS, Photoiode), purchase data, wavelength ranges, lens distortion information, and other specifications, including filters.	
Sensor configuration ID	Sensor configuration description must have the following tags	
	Original window size in pixels	mm x mm
	Cropped	(y/n)
	Pixel pitch	(µm/pixel)
	Magnification	magnification factor
	Viewing angle	(degree)
	Bit depth	the number of levels on grayscale or color scale
	Shutter Speed	the amount of time that the shutter is open for taking an image (s)
	Optical filter bandwidth	minimum and maximum wavelengths in nm
	Sensor calibration information	the date of calibration, the method of calibration, and person who performed the calibration

3.2.2 Registering a Folder of Images

When there is a large number of individual images on a pre-scanned or post-scanned powder layer, the images may be organized in a file folder. In this case, users should register all the folders with all the optical images from the first layer to the last layer. Data elements are in Table 4.

Table 4 Image Folder Data Elements

Data Element	Description
Build ID	the ID of the build
Folder path	the path of the file directory of the folder
Layer range	the start layer and the end layer included in the folder
Start time	the time that the first image was taken
Stop time	the time that the last image was taken
Flash configuration enumeration	the enumeration of the index of flash lights and their configuration descriptions
Image prefix	the prefix of an image in the folder
Flash condition	the condition of an indexed flash light
Sensor ID	the ID of the sensor
Sensor description	the description should include the type of sensor, the purchased date, sensor specification, and the information on lens distortion
Sensor installation	the view angle
Sensor setting and configuration	description of settings and configuration of the sensor
Configuration ID	ID of a sensor configuration
Image size in both X and Y directions	pixel by pixel
Cropped	(y/n)
Pixel pitch	(µm/pixel)
Magnification	the magnification factor
Viewing angle	the angle relative to the build plate normal
Bit depth	the number of levels in grayscale or color scale
Shutter Speed	the amount of time that the shutter is open for taking an image (s)
Optical Filter Bandwidth	minimum and maximum wavelength in nm
Sensor calibration information	the description of sensor calibration

3.3 MPM Data Elements

In this section, we focus on registering still images and video files since they are used by metrologists for process monitoring.

[2] https://www.nist.gov/el/ammt-temps

Since melt-pool monitoring often requires high-speed cameras, which can capture thousands of images per layer, we recommend users register images in a folder. Data elements are in Table 5.

Table 5 An Image in the Folder (Data Elements)

Data Element	Description	
Image Name	the name of the image	
Image ID	a unique identification number of the image	
Build ID	the ID of the build	
Triggering Time	the time when the camera is being triggered to take the picture based on the scanning program in xy2-100	
Instant laser power	the laser powder (W) at the time of image taken	
Frame Rate	frame per second (fps) if it is a movie	
Folder Path	the directory path for locating the folder that this image was saved	
Sensor ID	the identification of the image sensor	
Sensor description	sensor type, purchase data, specifications, lens distortion information, etc.	
Sensor installation	installed date, installer	
Sensor configuration ID	Sensor configuration description must have the following tags	
	Original window size in pixels	mm x mm
	Cropped	(y/n)
	Pixel pitch	(nm/pixel)
	Magnification	magnification factor
	Bit depth	the number of levels in grayscale or color scale
	Shutter Speed	the amount of time that the shutter is open for taking an image (s)
	Optical filter bandwidth	minimum and maximum wavelengths in nm
	Sensor calibration information	The date of calibration, the method of calibration, person who performed the calibration, and the calibration data

3.4 Acoustic Emission Data Elements

Acoustic sensors can capture the sparking and cracking sound generated in L-PBF. That sparking sound is generated by laser heating. Metal cracking is due to thermal stress. The acoustic emission data is a time series of signals. The file elements can be found in Table 6.

Table 6 Acoustic Emission Data Elements

Data Element	Description
File name	the name of the file
Uniquely generated ID	ID of the data
Start Time	Time of recording started
Stop Time	Time of recording stopped
Sampling interval	Time interval between two samples
Sensor location	The location of the acoustic sensor in the chamber
Setting	Acoustic sensor setting information

3.5 In-situ Measurement Uncertainty Quantification

There is always uncertainty in the data collected from sensors. Knowing the sources of that uncertainty is critical to applications such as data analysis and model validation. Uncertainty sources can be registered in categories in Table 7.

Table 7 Uncertainty Sources

Sensor Type	Uncertainty Source
Camera	• view angle variation due to installation • magnification factor variation due to the viewing angle • instantaneous Field Of View (iFOV) due to viewing angle • FOV due to viewing angle • Variation in the focus of lens
Laser spot	• The location relative to the build plate coordinates in the X and Y directions
Galvo Scanner	• The actual laser spot position in the X and Y directions relative to the build plate coordinates in the X and Y directions can deviate from the command position.
Image	• The laser (spot) is moving while the camera is taking a picture. Melt pool keeps changing during the exposure. Uncertainty is embedded in the shape and size of the measured melt pool.

4 Data Model for Meta-Data

To implement the identified data elements in Section 3, we developed a data model using the XML Schema language [18]. XML Schema was chosen based on the following reasons: (1) data structures in XML enabling efficient search/query, (2) predefined data types satisfying a variety of our modeling needs, (3) XML files validation using XML schema, and (4) available tools for implementation. The user community can implement the data registration method using XML tools with the schema described in this Section. Our choice does not imply that XML Schema is the best language for data modeling. Every modeling language has its capabilities and shortcomings.

Figure 3 Data schema for scanning process

The data elements and attributes in the schema are based on the classification and data elements described in Section 4. In-Situ_Monitoring is the root element. It has four sub-elements: Scanning_Process, Layer_Imaging, Melt_Pool_Imaging, and Acoustic_Singnals. In the paper, we only describe a group of data elements for scanning process (Section 5.1) and another group for layer imaging (Section 5.2) as two examples. We create attributes to uniquely identify the data element. Note that attributes are not shown due to the limitation of the paper length. We create sub-elements to describe details of the data element.

4.1 Scanning Process Data Elements

As described in Section 3.1, a scanning process is for a specific build with a scanning strategy. The main data element is Scanning_Process, and it thus has two sub-elements: Build_Info and Scanning_Strategy. Figure 3 shows a graphical representation of Scanning_Process elements and its two sub-elements. Build_Info has two attributes, BuildID and Total_Number_of_Layers (not shown). Two sub-elements, Build_Time and Layer_Thickness provide detailed descriptions of Build_Info. Similarly, Scanning_Strategy has attributes to uniquely describe the data element. Three sub-elements to provide detailed information on Scanning_Strategy: Laser, Part_info, and G-code. Furthermore, Laser and the Part_info have attributes and sub-elements.

4.2 Layer Imaging Data Elements

As described in Section 4.2, Layer_Imaging is the main element for layerwise images registration and six attributes and three sub-elements, as shown in Figure 4. Like the description in the previous section, attributes uniquely describe a data element. The data element can have one or more sub-elements that provide detailed information about the data element. Six attributes (not shown) are Image_Name, Image_ID, Time_Taken (the time when the image was taken), Folder_Path (the path to locate the folder where the image is saved), Flashing_Condition (a description of flash lighting, including number flash lights and their locations and flashing directions), and Still_Image_of_Movie (to indicate the registered item is a set of images or a movie).

Layer_Imaging_Sensor is one of three sub-elements and has two attributes and three sub-elements. Two attributes are Sensor_ID and Sensor_Description. Three sub-elements are Pixel_Pitch, Bit_Depth, and Sensor_Size. They all have quantity and unit as their attributes. Layer_Imaging_Sensor_Configuration has three attributes (not shown) and six sub-elements. Three attributes are Sensor_Configuration_ID, Sensor_Configuration_Description, and Cropped_or_not (for indicating whether the image is cropped or not). Six sub-elements are Magnification (the magnification factor of the lens), Shutter_Speed (camera shutter speed), View_Angle, Optical_Filter_Bandwidth, Original_Window_Size_in_Pixel, and Cropped_Window (an indication whether the window is cropped or not). Layer_Imaging_Sensor_Calibration_Info (to provide relevant information on the calibration of the sensor).

5 Sample Use Case

The data schema presented in Figure 3 and 4 were instantiated to capture the meta data which describe the scan command and in-situ tower camera based layerwise monitoring data set generated from a 3d build using an open architecture powder bed fusion system- NIST AMMT[3]. A Python program is created to register the layerwise image against the galvo position. Figure 5 shows a function diagram of the program.

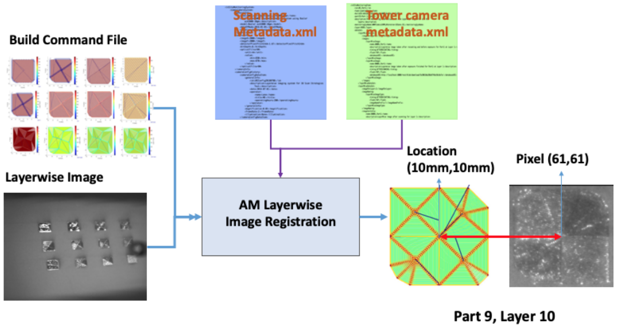

Figure 5 Use case for XML-based meta data

The tower camera metadata.xml file provides camera intrinsic and extrinsic parameters to remove the projection from the layerwise images and convert the image to the build platform coordinates. The Scanning Metadata.xml deciphers the build command data from which the contours of each part are extracted and used to segment the parts and convert the pixels of the image into galvo positions. The output of the functions are the registered after-exposure images of each part. Figure 5 shows the registered Part 9 layerwise image at Layer 10. Pixel (61, 61) corresponding galvo location at (10mm, 10mm).

6 Conclusion and Future Work

The use of laser powder bed fusion, L-PBF, technology to fabricate complex, metal parts in several industries has been steadily growing. As a result, the demands on both the quality and reliability of those parts have increased. Academic researchers and real-world manufacturers have implemented in-situ sensors to monitor L-PBF processes and to detect potential anomalies in the part.

The target audience of the paper are the practitioners who rely heavily on standards, interfaces and tools to integrate different systems and data. The work in this paper enables the future standards on common data exchange formats which will play critical role in implementing the scientific results from the academia and integrating and analyzing AM sensor data.

This paper focuses on defining a key element of those standards: meta-data. Specifically, this paper proposes new data elements, which can be used to characterize the properties and relationships among the data types captured by those sensors. Characterizing those properties and relationships requires a schema model; we have included a small number of examples of such a model.

Future work will be in three areas. One is to include other types of in-situ sensors emerging in the future, such as pyrometer and ultrasonic sensor. Second is to extend the number of schema model, standardize the resulting models, and integrate them with other existing schemas, such as powder material and machine schemas. We expect that these standards will lead to better implementations in the L-PBF user community. Third is to characterize data and meta data on image calibrations and define data elements. Specifically, a data model on methods and calibration instruments needs to be included in the developed data model. The data model will enable users of the data to compensate distortions in an image and quantify uncertainties in measured data.

DISCLAIMER

The work presented in this document is an official contribution of the National Institute of Standards and Technology (NIST) and not subject to copyright in the United States. Certain commercial systems are identified in this paper. Such identification does not imply recommendation or endorsement by NIST. Nor does it imply that the products identified are necessarily the best available for the purpose.

PHYSICS–BASED SIMULATION OF AGILE ROBOTIC SYSTEMS

Pavel Piliptchak*, Murat Aksu, Frederick M. Proctor, John L. Michaloski
National Institute of Standards and Technology
Gaithersburg, MD

ABSTRACT

Development and testing of industrial robot environments is hampered by the limited availability of hardware resources. Simulations provide a more accessible and readily modifiable alternative to physical testing, but also require careful design to maximize their fidelity to the real system. In this paper, we describe new progress in building an entirely physics-driven simulation of the Agility Performance of Robotic Systems (APRS) Laboratory at the National Institute of Standards and Technology (NIST). To maximize the accuracy of physics-based interactions in this environment, we develop several general-purpose improvements to the simulation of parallel grippers and multi-object collisions. We use pick-and-place tasks from the APRS Laboratory as well as generic benchmarks to verify the performance of our simulation. We demonstrate that our proposed improvements result in more physically-consistent simulations compared to standard implementations, regardless of the choice of physics engine or simulation parameters.

Keywords: robotics, agility, grasping, pick-and-place, simulation

1 INTRODUCTION

Simulations are invaluable tools in developing industrial robotic systems. In situations where hardware resources are limited or costly to use, simulations can provide a test-bench for developing controllers, debugging software, and testing various work-space configurations [1]. One of the limiting factors to using a simulation in place of a real system is how well it replicates the physical dynamics of the real system. This discrepancy has inspired the development of new rigid-body physics engines that tackle specific problem areas, such as numerically stable contacts and joint articulations [2–4].

However, existing robotics simulators are not a one-size-fits-all solution. A significant amount of effort needs to be put into defining contact behavior, inertia matrices, friction coefficients, and numerical solver parameters to ensure acceptable performance [5]. This effort becomes increasingly laborious as the simulated environment becomes more complex.

In this work, we use the Robot Operating System (ROS) [6] and the Gazebo [7] robotics simulator to build an entirely physics-based simulation of the APRS Laboratory, an environment designed for evaluating the capabilities of robots performing industrial pick-and-place tasks [8]. This environment is fairly difficult to replicate with standard simulators due to the large number of small, low-mass objects that the robot must accurately manipulate. Along the course of building this simulation, we developed several practical and general-purpose improvements to simulating two important components of our pick-and-place task (namely parallel grippers and multi-object collisions).

This work presents the following contributions:

1. A complete simulation of the APRS Laboratory that integrates with existing APRS software
2. A simple controller for simulated parallel grippers that improves grasp stability
3. A method for simplifying contacts between many relatively stationary objects in simulation

In the following sections, we will (1) discuss relevant experiments in physics-based simulation at NIST and abroad; (2) describe the design of our APRS Laboratory simulation; (3) describe our two improvements mentioned above; and (4) present experiments verifying the benefits of these improvements.

2 RELATED WORK

Despite the popularity of Gazebo for robot simulation, there have been comparatively few publications that use it for physics-based grasping and manipulation—particularly in full-fledged, realistic environments. The most notable example is the Defense Advanced Research Projects Agency (DARPA) Virtual Robotics Challenge (VRC) which required grasping as part of several subtasks [9, 10]. Simulations have also been used for the dexterous manipulation of cloth [11], pick-and-place tasks [12], and dexterous reinforcement learning agents [13]. The robots in these simulations generally use high degree-of-freedom (DOF), anthropomorphic hands. They also generally handle palm-fitting objects rather than smaller objects that require fingertip-only grasps. In contrast, the APRS simulation robots use parallel grippers and manipulate peg-like objects with diameters that are under 1 cm.

Another angle of research has been verifying the physical accuracy of the physics engines themselves [14–16] with some works emphasizing grasping in particular [17, 18]. Often, this research seeks out general benchmarks that measure either: 1) how the engine's compute speed scales with simulation complexity; 2) how well the engine conserves energy/momentum; or 3) how far the engine deviates from some ground-truth behavior for a simple dynamical system. We verify the accuracy of the APRS simulation using similar methods (to be discussed in the Experiments section), but focus on benchmarks that are relevant to grasping and pick-and-place tasks. We do not make claims about the general accuracy of the tested physics engines.

NIST has also pursued research in verifying the physical accuracy of robot simulators [19, 20]. This earlier work focused on the simulation of the Talon Robot using the older Karma Physics Engine. The evaluation metrics used in this work were based primarily on mobility with limited discussion of grasping. In contrast, our work simulates a pick-and-place task using Gazebo's variant of the Open Dynamics Engine (ODE) [2, 5]. It focuses more finely on grasp stability and simulator performance.

3 SYSTEM OVERVIEW

In this section, we give a high-level overview of our APRS simulation. We will begin by reviewing the objectives and design of the physical APRS Laboratory. Following this, we will present the design of our simulation along with its interfaces to the existing APRS architecture.

APRS Architecture

The APRS Laboratory seeks to study and measure the "agility" of robotics systems, which widely refers to a system's retasking capability, robustness to failures, and interoperability [8]. As part of this research effort, the APRS Laboratory implements an archetypal agile robotics system that operates on a simple pick-and-place kitting task.

The system consists of a Fanuc LR-Mate 200iD and a Motoman SIA20F robot. These two robots are positioned on opposite sides of a conveyor, which carries several part trays containing gears. These gears must be moved by the robots (both equipped with parallel gripper end-effectors) to a specified kit tray. As the robots perform the kitting task, the system experiences several mock failures, such as a robot breaking down or a part being misplaced.

Reacting to these failures requires an agile approach to sensing, planning, and control—the details of which can be found in [8]. To briefly summarize:

1. The APRS Laboratory maintains an ontology describing relevant kitting objects and concepts
2. An overhead camera system is used to locate instances of objects described in this ontology
3. A planner uses the ontology and instance information to generate a high-level action plan
4. Low-level controllers execute this plan on the robots

In the described architecture, replacing the physical system with a simulation requires three steps: replicating the camera system, replicating the robot grasping dynamics, and creating an interface between the high-level plan and the low-level virtual controllers used by the simulated robots. Virtual sensors were explored in [21], while implementing a shared interface and achieving accurate dynamics is this work's focus.

Simulation Framework

The APRS simulation framework is built primarily using ROS, which is an open-source suite of robotics-related software packages that are interconnected through a shared message-passing framework. Out of the box, ROS packages provide us with the kinematic descriptions of the robots, joint controllers, joint-state information, forward/inverse kinematic solvers, and collision-aware trajectory planning. ROS can also be extended by writing new packages, which is how we implement the kinematic descriptions of the conveyor and parallel grippers in the system.

We use Gazebo, an open-source robotics simulator, to dynamically simulate the system. Gazebo is designed to be compatible with many of ROS's components, including the robot kinematic descriptions, joint controllers, and joint-state publishers. Gazebo also supports multiple physics engines and allows users to tune the behavior of each engine's numerical solver. We will provide a detailed discussion our choice of physics parameters and physics engine in the "Experiments" section.

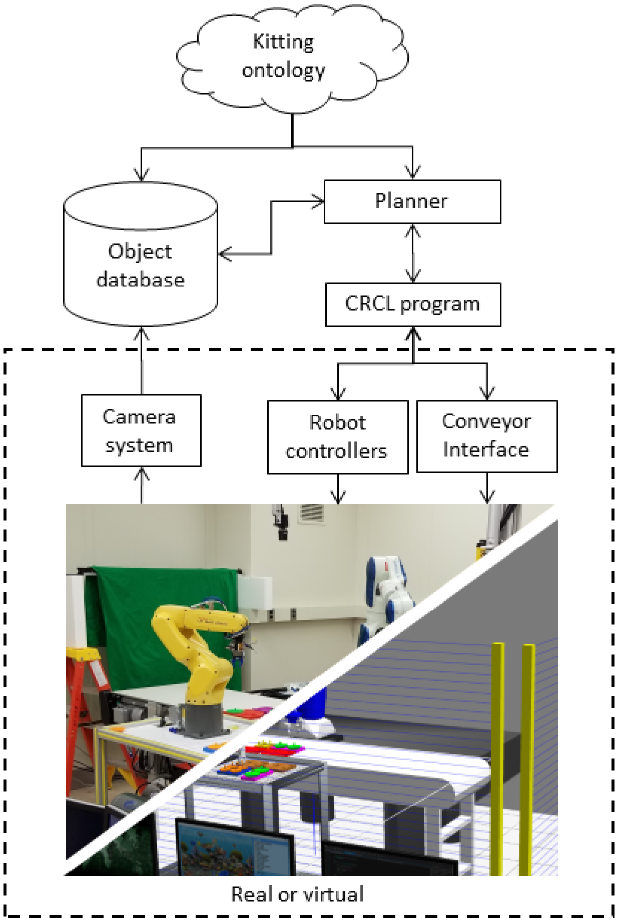

FIGURE 1: APRS system architecture
Components enclosed in dashed box are swappable

Like ROS, Gazebo's functionality can be extended—this time with user-defined plugins, which give access to nearly all aspects of the simulator's physics, sensing, and communication systems. We use plugins to implement both robots' grippers, and the light curtain. The light curtain is implemented as a collection of Gazebo built-in laser rangefinders, whose values are unified into a single output using a plugin. The gripper actuation is handled entirely by a plugin described in the Physics Improvements section. Defining custom behavior using plugins has virtually no performance overhead and can be done in only a few lines of code (as shown in Algorithms 1 and 2).

Our conveyor is implemented using both a ROS controller and a Gazebo plugin. It is modeled as a single planar surface controlled by a linear actuator. The surface needs to apply force to carried objects as though it were moving, while appearing approximately stationary itself (to approximate a realistic conveyor). This is accomplished by using a ROS controller to control the actuator's velocity while using a Gazebo plugin to periodically reset the position of the surface after any small displacement.

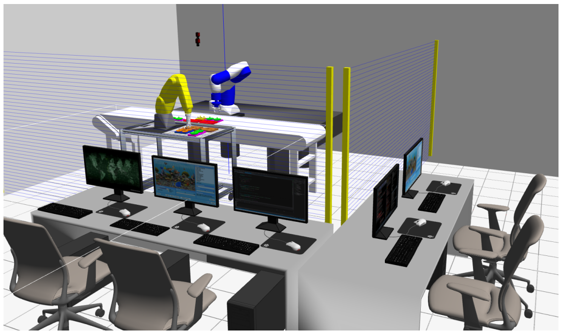

FIGURE 2: The simulated APRS Laboratory

Shared Interface

The physical APRS Laboratory performs low-level control of each robot using proprietary controllers, and operates the conveyor by using a programmable logic controller (PLC) running a Modbus server [22]. These heterogeneous interfaces are unified using the Canonical Robot Command Language (CRCL) [23]. After the APRS architecture synthesizes a high-level plan, this plan is converted into the corresponding CRCL primitives, which are then sent to the appropriate device (either the robot, gripper, or conveyor).

To integrate the simulated robots' controllers with the APRS architecture, we implement a conversion from CRCL primitives to ROS messages, which can be used to specify controller targets and trajectories. The resulting CRCL2ROS library converts CRCL-formatted commands to the ROS-compatible protobuf format [24].

For conveyor commands, we forego using the CRCL2ROS library in favor of re-using the Modbus interface already in-place for the physical conveyor. To do this, we implement a Modbus server in software using the `libmodbus` C++ library [25]. In the physical system, the Modbus server controls the conveyor's velocity by writing to the appropriate registers on the PLC. In the software implementation, the Modbus server controls the simulated conveyor's speed and direction by writing a velocity target to its ROS controller.

4 PHYSICS IMPROVEMENTS

Having established the overall design of the APRS simulation, we will now present two simulation improvements that form the main contribution of this paper. Each improvement targets a component of the simulated system that is prone to unstable, physically unrealistic behavior. “Stability” will be defined and tested more precisely in the “Experiments” section, while this section will focus on the conceptual description of each improvement. We want to stress that these improvements are agnostic to the physics engine used and are simple to implement provided the physics engine supports a programming interface (this is handled by Gazebo’s plugin system in our case).

Parallel Gripper Control

The APRS robots perform grasping using pneumatic parallel grippers. A typical approach for defining parallel grippers in software involves mimic joints, where one joint “mimics” a second joint by maintaining its relative position and velocity in joint-space. Unfortunately, many physics engines do not define a joint constraint that describes this mimic behavior directly. Because of this, a popular ad-hoc approach is to use external control plugins [26]. This approach implements a proportional-integral-derivative (PID) force controller that uses the mimic joint’s relative joint position as the feedback term. However, there are two problems with using such a control scheme for parallel grasping.

- The output force is 0 N when the error feedback is 0 (i.e., when the gripper’s fingers are symmetrically positioned). During grasping, this creates asymmetric forces on the gripper that either cause the grasp to fail or the mimic joint to be pushed to an asymmetric position so that the force generated by the controller matches the force of the original joint.
- Since the original joint’s controller has no knowledge of the mimic joint, there is no guarantee that the gripper’s fingers will remain symmetric throughout a trajectory if they experience different external forces. For example, if an obstacle blocks the mimic joint but not the original joint, the resulting finger positions would not be symmetric like they would be in the real gripper.

To address these shortcomings, we implement a new control scheme operating on both joints simultaneously:

$$F_1 = F_c + k_p(p_2 - p_1), \tag{1}$$

$$F_2 = F_c + k_p(p_1 - p_2). \tag{2}$$

Here, F_i is the force output for each joint; p_i is the joint-space position of each joint; F_c is a constant force shared by both joints; and k_p is a proportional gain. Using this controller, both joints maintain an identical non-zero force during grasps and are driven to symmetric positions by mimicking each other, satisfying both problems.

This control scheme has an elegant physical interpretation: the F_c term emulates the force generated by the gripper’s piston, and the $k_p(\cdot)$ term emulates the normal forces of the gripper’s actuator linkage.

While this controller was developed with pneumatic gripper’s in mind, it can easily be extended for approximating any mimic joint(s). Given some collection of N mimic joints, a single-joint force-controller F_j, and a relative joint-error force-controller F_s, we can define the control of joint $i \in \{1 \ldots N\}$ as:

$$F_i = F_j(p_i) + \sum_{n \in \{1 \ldots N\} \setminus \{i\}} F_s(p_n - p_i). \tag{3}$$

In our gripper implementation, $F_j(\cdot)$ was chosen to be the constant force F_c. $F_s(\cdot)$ was chosen to be a proportional controller.

Contact Simplification

The kitting tasks performed by APRS robots involve handling dozens of small objects such as gears and trays. This introduces two challenges to simulation. The first challenge is simulation stability. The stacking of objects, especially objects with large inertia-ratios, is known to cause instability due to over-constraining the linear complementarity problems (LCPs) that are solved by the physics engine at each time step [5]. The second challenge is compute speed, which deteriorates as the number of contacts to simulate increases.

To improve both stability and computational performance, we implement a Gazebo plugin for automatically simplifying contacts between relatively stationary objects. The approach is straightforward in concept:

1. Use Gazebo’s built-in `ContactSensor` class to find existing contacts and their contact forces
2. Determine whether the objects in contact are stationary relative to each other
3. Create a virtual, fixed joint between objects satisfying the stationary criteria and disable collisions between them
4. Destroy the virtual joint and re-enable collisions if the objects are no longer stationary, resuming normal behavior

Effectively, this replaces a dynamics problem for the physics engine with a much nicer statics problem for the plugin. The sensing of forces, creation and destruction of joints, and enabling and disabling of collisions can be handled entirely through Gazebo’s programming interface. This only leaves the question of how to define the stationary criteria.

For our purposes, two objects are considered stationary if their relative velocity and acceleration are 0. These criteria work fine for creating a virtual joint, but are problematic for deleting it since the virtual joint constrains the relative velocity and acceleration of the objects to be 0. However, we can observe the force needed for the virtual joint to satisfy these constraints and use that as part of the criteria.

More precisely, we can define the net force F_σ on a relatively stationary object as:

$$F_\sigma = F_E + F_C + F_V = 0, \tag{4}$$

where F_E is the external, non-measurable force, F_C is the contact force, and F_V is the virtual joint force. Since only one of either contact forces or joint forces are active at any one time, this equation becomes:

$$F_\sigma = F_E + F_C = 0 \qquad F_\sigma = F_E + F_V = 0. \tag{5}$$

Solving and substituting for F_E, we have $F_C = F_V$ at the timestep that the virtual joint is created. If $F_C \neq F_V$ at a future timestep, then the external force F_E has changed and the original stationary criteria $F_\sigma = F_E + F_C = 0$ is no longer satisfied. The actual plugin uses a threshold on $\|F_C - F_V\|$ rather than a strict inequality, but behaves equivalently.

This plugin offers an improvement over previous dynamics-disabling features found in Gazebo's primary physics engine, which only applied to absolutely stationary objects [5]. It is also fairly physics engine-agnostic and lightweight, provided the physics engine supports measuring constraint forces and dynamically spawning joints. The complete pseudocode is given in Algorithms 1 and 2.

```

a2 ← GetWorldFrameAccel(c2)
if $\|v1 - v2\| < e1$ & $\|a1 - a2\| < e2$ then
    CF ← Msg.NetForce
    V ← GazeboCreateNewJoint(c1, c2)
    GazeboDisableContact(c1, c2)
end
```

Algorithm 1: Virtual Joint Creation Callback

5 EXPERIMENTS

In this section, we measure the performance of our two proposed improvements. To do this, we design several scenarios that target the behavior of each improvement in isolation. Each scenario and metric is designed such that the performance of the real system is known to be trivially simple. For example, we know that once a real robot successfully grasps an object, the object will remain completely stationary relative to the gripper during any of the robot's motions (due to the large force exerted by the pneumatic gripper). Now, the objective is to measure whether the simulation violates this "relatively stationary" condition that is known to hold for the real system. Using this approach, we can verify the physical accuracy of our improvements without needing to take any measurements on the real system.

```
Data: Virtual Joint V, ContactForce CF,
ErrorThreshold e
Executed on each simulation physics step
if $\|CF - V.Force\| > e$ then
    GazeboEnableContact(V.Collision1,
      V.Collision2)
    GazeboRemoveJoint(V)
end
```

Algorithm 2: Virtual Joint Deletion Callback

We tested our scenarios primarily with Gazebo's variant of ODE using default simulation parameters. This configuration was mainly used due to technical limitations in Gazebo's support for other physics engines, and because this ODE configuration is fairly common in other work [1].

Parallel Gripper Control

The gripper controller experiments are motivated primarily by the "relatively stationary" condition described above. We consider a grasp more stable and physically accurate if it maintains a constant displacement between the object and the gripper during a motion. Mathematically, we measure this using the Euclidean distance between an initial position and subsequent positions:

$$\delta_t = \|p_t - p_0\|_2 . \tag{6}$$

Here, p is a 3-dimensional relative position and t is a simulation time-step. This metric is similar to Measure C used in [18].

We would also like to incorporate angular displacement into our analysis. To do this, we record the quaternions q_0 and q_t corresponding to initial and subsequent relative orientations between the gripper and grasped object. Thus, we can compute angular displacement as:

$$\theta_t = \arccos\left(2\langle q_t, q_0\rangle^2 - 1\right). \tag{7}$$

We report this value along with δ_t (ideally both should be close to 0 if the simulation is physically accurate). These metrics are computed for our gripper controller along with two baselines:

	Standard	Plugin
Cumulative δ_t	$1.3 \cdot 10^{-2}$ m	$1.0 \cdot 10^{-3}$ m
Real-Time Factor	0.43	0.98

TABLE 1: Multi-object contact simplification experiment

- Constant opposing forces to both joints
- The preexisting mimic joint plugin from [26] with constant force on the mimicked joint

Each controller is attached to a floating gripper (not experiencing any forces). Using each of the three controllers, the floating gripper grasps a conveniently placed APRS gear. Once the gripper is closed, the floating gripper is subjected to a range of accelerations defined in Cartesian world coordinates (emulating the motion of robots performing pick-and-place operations). During these trajectories, the positional and angular displacement metrics are computed and reported using a combination of ROS and Gazebo telemetry.

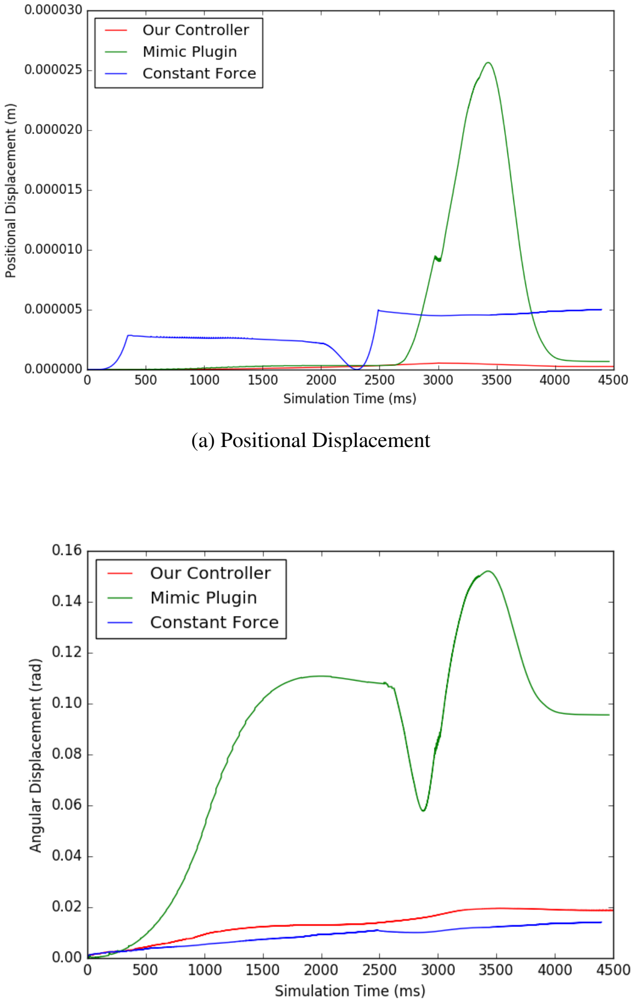
Our results, summarized in Figure 3, show that our proposed parallel gripper controller outperforms both baselines in minimizing positional displacement during Cartesian trajectories. The controller also matches the constant force control scheme in angular displacement. We also note that positional displacement was the largest contributor to objects falling out of the gripper, and that both baselines would drop their objects from much smaller impulses as compared to our proposed controller.

Contact Simplification

Like our previous test, the experiment for our contact simplification improvement uses another “relatively stationary” condition. This time, we know that gears placed inside trays must be stationary relative to the tray (based on their coefficient of friction and the tray design shown in [8]). Therefore, we can reuse the metrics given by Equations 6 and 7, this time computing the relative displacement from gear to tray (rather than gear to gripper).

The scenario that we used consists of a conveyor carrying multiple trays. Each tray is loaded with gears, reminiscent of a typical kitting task. We choose this particular configuration to highlight the benefits of our improvement to both accuracy and run speed for simulations with scaling complexity.

We summarize our results in Table 1. This data was collected based on a simulation of 10 trays carrying 40 gears, which we believe adequately demonstrates the effect of the plugin on both accuracy and simulation speed. We record the relative displacement δ_t between a gear and the tray at $t = 4$ s. We then sum the δ_t values from all 40 gears to compute a cumulative δ_t value for the scenario. We also record the real-time factor of the simulation.



(a) Positional Displacement

(b) Angular Displacement

FIGURE 3: Relative displacement along a Cartesian trajectory using various controllers

As expected, once the contact simplification plugin creates a virtual joint, the displacement of the gear relative to its tray is fixed. This gives the plugin a slight edge over the standard approach by limiting the effect of any unstable simulation behaviour (like jittering contacts).

The plugin also has a pronounced effect on the simulator’s compute speed. On average, every collision between objects in our simulation had about 10 contact points that needed to be processed per time step. The plugin effectively reduced this to one contact point per collision.

6 CONCLUSION

We have presented a physics-based simulation of the APRS Laboratory along with several techniques that enabled it to reach good physical accuracy (as measured by the degree to which the simulation violates static friction conditions). We have demonstrated how our simulation integrates into the overall APRS architecture, and how its design leverages open-source software to include additional industrial components, such as conveyors, grippers, and light curtains.

Given that the APRS Laboratory simulation now achieves good physical accuracy on kitting-related tasks, it can now be extended to simulating entire kitting scenarios currently being developed for the physical APRS Laboratory. To do this, future work will involve improving the software tools needed to create these scenarios, extending the robot agility measures used by the physical lab to the virtual environment, and disseminating the virtual environment to external collaborators. The virtual environment also opens new areas of data-intensive research that are too costly to run on actual hardware, such as controlling robots using reinforcement learning agents or testing the viability of new sensor configurations for computer vision tasks.

Disclaimer

Certain commercial/open source software, hardware, and tools are identified in this paper in order to explain our research. Such identification does not imply recommendation or endorsement by the authors or NIST, nor does it imply that the software tools identified are necessarily the best available for the purpose.

ABSTRACT

Tremendous effort has been dedicated to computational models and simulations of Additive Manufacturing (AM) processes to better understand process complexities and better realize high-quality parts. However, understanding whether a model is an acceptable representation for a given scenario is a difficult proposition. With metals, the laser powder bed fusion (L-PBF) process involves complex physical phenomena such as powder packing, heat transfer, phase transformation, and fluid flow. Models based on these phenomena will possess different degrees of fidelity as they often rely on assumptions that may neglect or simplify process physics, resulting in uncertainty in their prediction accuracy. Predictive uncertainty and its characterization can vary greatly between models. This paper characterizes sources of L-PBF model uncertainty, including those due to modeling assumptions (model form uncertainty), numerical approximation (numerical uncertainty), and model input parameters (input parameter uncertainty) for low and high-fidelity models. The characterization of input uncertainty in terms of probability density function (PDF) and its propagation through L-PBF models, is discussed in detail. The systematic representation of such uncertainty sources is achieved by leveraging the Web Ontology Language (OWL) to capture relevant knowledge used for interoperability and reusability. The topology and mapping of the uncertainty sources establish fundamental requirements for measuring model fidelity and guiding the selection of a model suitable for its intended purpose.

Keywords: Additive Manufacturing, laser powder bed fusion, uncertainty, ontology

1. INTRODUCTION

Additive manufacturing (AM) produces parts by depositing material layer-by-layer without the requirement of specific tooling based on a 3D model [1]. The laser powder bed fusion (L-PBF) process is the most prominent AM technology capable of producing metallic parts with complex geometry and internal structures [2]. It offers the ability to manipulate the chemical compositions and tune part properties by locally controlling the microstructure and mechanical properties to produce finished parts [3]. The process involves different physical activities such as powder layer formation, laser-powder particles interaction, melt pool formation, and solidification. The fundamental physical phenomena that govern the L-PBF process are powder packing, heat transfer, fluid flow, grain growth, and residual stress formation. Due to the complexity of the physical phenomena and process variabilities, the fusion of powder particles affects mechanical properties, surface finish, and fatigue life of the final parts [4].

There are various parameters in the L-PBF process that potentially affect the quality of the part, as well as the energy and material consumption. Some of these parameters include powder size, powder shape, powder size distribution, laser power, spot size, beam profile, layer thickness, scan speed, hatch distance, build orientation, and pre-heat temperature [5]. To insure part quality and ultimately realize the full potential of the L-PBF process, it is crucial to (a) understand the process complexities, (b) identify the sources of process variability, (c) investigate the effect of process parameters, and (d) determine the optimal process parameters. To achieve these goals, intensive experiment-based studies can be time consuming and costly. Thus, efforts have been devoted to computational models and simulations to investigate the parameter-process-structure-property-performance relationships that lead to part quality improvement [6,7]. Although computational models and simulations are beginning to provide a vast resource for predictive models on which design and process decisions can be made, understanding whether or not a model is an acceptable representation for a given scenario is a difficult proposition.

Paper presented at International Mechanical Engineering Congress and Exposition (IMECE2019), Salt Lake City, UT, US. November 11, 2019 - November 14, 2019.

Models based on different physical phenomena of the L-PBF process will possess different degrees of fidelity as they often rely on assumptions that may neglect or simplify process physics, resulting in uncertainty in their prediction accuracy. Predictive uncertainty and its characterization can vary greatly between models. For instance, depending on the (a) type of model, such as a physics-based model or an empirical model, or (b) different measurement techniques, such as optical measurements or thermal measurements. Despite these differences, each source of uncertainty can be related back to the fundamental characteristics of the process. Therefore, it is important to investigate and characterize the potential sources of uncertainty in L-PBF models.

Previous work investigated model fidelity, explored assumptions and approximations of various models, and how this information may be captured [5]. Further work investigated specific sources of uncertainty in L-PBF processes, including a thorough review [8]. In this paper, we build on and harmonize the previous works. We characterize sources of L-PBF model uncertainty, including those due to modeling assumptions (*model form uncertainty*), numerical approximation (*numerical uncertainty*), and model input parameters (*parameter uncertainty*) for low and high-fidelity models. First, the L-PBF models are characterized based on their assumptions by capturing the considered and neglected phenomena and input parameters and output quantities of interest (QoIs). These models include the Rosenthal-based thermal models, the finite element method (FEM)-based continuum thermal models, and the powder-scale thermal-fluid flow models [8]. Following this, characterization of the sources of uncertainty is discussed in detail. Model form uncertainty is characterized based on modeling assumptions by capturing the included and neglected physical phenomena during abstraction and formulation of the model. This uncertainty is commonly quantified using a validation metric by comparing simulation results against measurement data. Numerical uncertainty arises primarily from discretization error and is characterized using code and solution verification. Model input parameter uncertainty comes from the inherent variability present in input parameters or those parameters whose exact values are not known and cannot be directly measured. Then, the characterization of models and uncertainty sources is represented using an ontology to capture relevant knowledge that can be used for interpretability and reusability.

The organization of the paper is as follows. We first briefly present the state-of-the-art on uncertainty related studies for L-PBF process in Section 2. We then discuss the characterization of L-PBF models focusing on their assumptions by capturing the considered and neglected phenomena in Section 3. Then, in Section 4, we present the investigation and characterization of L-PBF uncertainty sources. The systematic representation of models and uncertainty sources is described in Section 5. We view this work to be an essential step to establish fundamental requirements for measuring model fidelity, and for guiding the selection of a model suitable for its intended purpose.

2. BACKGROUND

It has been highlighted that computational models and simulations play significant roles in understanding the AM process phenomena and predicting optimum process parameters and hence are important contributing factors to achieving desired part performance and reducing the numbers of faulty parts [4,9]. There has been tremendous effort to develop computational thermal models to understand the thermal history and predict melt pool geometries in L-PBF process. These models can be broadly categorized into three groups: the Rosenthal-based thermal models, the FEM-based thermal models, and the powder-scale thermal-fluid flow models. The Rosenthal-based thermal models analytically solve the heat conduction equation for a moving heat source [10]. The only heat transfer mechanism considered in these models is thermal conduction; those due to convection and radiation are neglected. The models provide low fidelity predictive results, but they are computationally efficient. However, the heat transfer phenomena and phase transformations that exist in the L-PBF process are complex and hence the governing heat transfer equations and boundary conditions that capture these phenomena are difficult to solve analytically. Thus, to understand the thermal history in detail and accurately predict the temperature fields and melt pool characteristics, various numerical models have been developed [8].

The FEM-based thermal models solve the heat transfer governing equations by discretizing the spatial domain into a finite number of elements and the temporal transient phenomena into time steps regardless of geometrical complexity. In these models, the powder bed is considered as a continuum block of material with effective thermo-physical properties, and the heat transfer mechanisms and distribution of absorbed energy are accounted for. However, the phenomena related to melt pool flow are neglected. To understand the fluid flow of the molten pool, more realistic numerical models based on powder-scale, thermal-fluid flow have been developed [11]. These models represent the L-PBF process more realistically by directly accounting for the phenomena related to powder packing (powder size, shape, and size distribution) and melt pool flow (surface tension, shrinkage, recoil pressure, and others). In addition to the common process signatures (temperature fields and melt pool geometries), these models can be used to investigate the formation of different defects such as balling, porosity, and delamination between layers and substrate. The critical challenge of these models is that they are computationally expensive and thus infeasible to use for full part-scale simulations and studying parameter optimizations as these problems require a large number of simulations.

Though experimental-based uncertainty analysis can provide the actual variabilities present in AM processes [12,13], this approach is time consuming and costly. To deploy computational models for design and process decision making and ultimately for part qualification, their degree of fidelity needs to be known first. Thus, understanding the sources of uncertainty is necessary to determine the degree of model fidelity and conduct uncertainty management to identify the main sources of error.

The uncertainty related studies in L-PBF models are relatively new and have started receiving increasing attention in recent years in the AM community [8,14–16]. Some of these studies are reviewed as follows. Moser et al [17] and Ma et al [18] identified the critical input parameters that largely influence the predictive accuracy of the FEM-based thermal model by assigning a probability density function (PDF) to account for parameter variability using a stochastic collocation approach and fractional factorial design of experiment (DOE), respectively. Nath et al [19] conducted uncertainty analysis on the FEM-based thermal model by constructing a statistical surrogate model using a Gaussian process to replace the computationally expensive physics-based thermal model. They also extended the uncertainty analysis to a solidification model to quantify the uncertainty in grain size distribution of microstructure. Kamath [20] conducted uncertainty analysis on the Eagar-Tsai Rosenthal-based thermal model [21] that considers Gaussian-distributed heat source and powder-based thermal model that was developed by Verhaeghe et al [22] using a regression tree and Gaussian process surrogate models. Tapia et al. [23] used polynomial chaos expansions for uncertainty propagation analysis in the Eagar-Tsai Rosenthal-based thermal model and the FEM-based thermal model. Tapia et al. [24] used a Gaussian process surrogate model for the powder-scale thermal-fluid flow model which was developed by Khairallah et al. [25]. Yang et al. [26] investigated different surrogate modeling techniques and discussed the implementation of adaptive sampling method to manage the sources of uncertainty in AM predictive models. There are some research efforts that use deep learning for classification of melt pool size [27] and machine learning for a data-driven continuous construction of AM knowledge [28]. A thorough literature review on machine learning applications in AM can be found in Razvi et al. [29].

The stated previous works are primarily focused on uncertainty analysis related to input parameters to identify the most critical parameters that influence the output QoIs. However, to fully understand the fidelity of a model and perform uncertainty analysis, it is important to investigate all sources of uncertainty: those due to modeling assumptions, numerical approximations, input parameters, and uncertainty due to measurement errors for model validation. Lopez et al [16] made an effort to identify these sources of uncertainty for the Rosenthal-based thermal model considering melt pool width as an output QoI. To quantify uncertainty propagation of input parameters, the Monte Carlo simulation was directly imposed on the physics-based model as the model is computationally efficient. Moges et al [15] extended this work to further investigate and quantify all sources of uncertainty for the Rosenthal-based as well as for the FEM-based thermal models to predict melt pool width. A fractional factorial DOE was used to drive a statistical response surface model on which the Monte Carlo simulation was imposed to quantify parameter uncertainty. Other uncertainty related studies for L-PBF models can also be found in Hu and Mahadevan [30], Mahmoudi et al [31], and Ghosh et al [32]. In present study, we characterize these uncertainty sources and represent them in a systematic fashion to capture their effects on predictive accuracy of computational models.

3. THE L-PBF THERMAL MODELS

The investigation and characterization of sources of uncertainty in computational models begin from understanding the assumptions, abstractions, and governing equations on which these models rely and capturing the included and neglected physical phenomena. Thus, it is important to first characterize the existing thermal models based on their assumptions as it also provides conceptual understanding of model fidelity [5]. In this section, the characterization of computational thermal models based on their assumptions, governing equations, and included and neglected physical phenomena along with input parameters and output QoIs is briefly presented.

3.1 The Rosenthal-based thermal models

The conduction mode of heat transfer is the main governing phenomenon in laser-powder interaction in L-PBF process. The heat conduction equation for a moving heat source is expressed in Equation (1) [33].

$$\rho C_p \frac{\partial T}{\partial t} = (\nabla \cdot k \nabla T) + Q, \tag{1}$$

where ρ is density, C_p is specific heat capacity, k is thermal conductivity, and Q is internal heat. Assuming the heat source distribution as a point or Gaussian heat source moving in the x direction on a surface of a semi-infinite space, Rosenthal [10] and Eagar and Tsai [21] determined the temperature T at a given time t, respectively. The Rosenthal-based thermal models can be used as a foundation to build more realistic approaches by considering the different laser beam distributions (line, cylindrical, Gaussian, or ellipsoid) [33]. The characterization of these models in terms of input parameters, outputs, assumptions, and considered and neglected phenomena is summarized in Table 1.

Table 1: Characterization of the Rosenthal-based thermal models

Input parameters	Laser power, scan speed, absorption coefficient, melting temperature, thermal conductivity, density, specific heat capacity, latent heat of fusion, preheat temperature
Outputs QoIs	Temperature fields, cooling rates, and melt pool dimensions (width and length)
Assumptions	Surface energy distribution, heat source distribution (point, cylindrical, ellipsoid, or Gaussian), continuum material
Considered phenomena	Energy absorptivity, absorbed energy distribution (only cross-section), moving heat source (scan speed), thermal conduction, latent heat of fusion
Neglected phenomena	Absorbed energy distribution (penetration), heat convection, surface radiation, latent heat of vaporization, all phenomena related to melt pool flow (surface tension, Marangoni effect), phase transformation, powder particle packing (powder size distribution, powder particle contact forces)

3.2 The FEM-based thermal models

To capture the steep thermal gradients near the laser spot and heat affected zone and transient nature of the heat transfer phenomena, the FEM-based thermal models are commonly used in L-PBF process [34]. In FEM models, the layer of powder particles is assumed as a continuum block of material with effective thermo-physical properties. The continuum powder bed is discretized into finite elements and the governing heat conduction equation is solved locally with initial condition and boundary conditions. To solve Equation (1) numerically, the initial condition assumed a uniform preheat temperature throughout the powder bed at time $t = 0$ and the boundary conditions on the top surface are given using Equation (2) [34].

$$-k\nabla T \cdot \boldsymbol{n} = q + h(T - T_0) + \varepsilon\sigma(T^4 - T_0^4), \tag{2}$$

where $\boldsymbol{n}$ is the vector normal to the surface, q is thermal heat flux, h is convection coefficient, ε is thermal radiation coefficient, T_0 is preheat temperature, and σ is Stefan-Boltzmann constant. The surface heat flux of the laser beam is given using Equation (3) assuming Gaussian heat source distribution [35].

$$q = \frac{2AP}{\pi r_b^2} \exp\left(\frac{-2r^2}{r_b^2}\right), \tag{3}$$

where A is absorption coefficient, P is laser power, r_b is laser spot radius, and r is radial distance.

Similarly, the characterization of the FEM-based thermal models in terms of input parameters, outputs, assumptions, and considered and neglected phenomena is summarized in Table 2.

Table 2: Characterization of the FEM-based thermal models

Input parameters	Laser power, scan speed, absorption coefficient, latent heat of fusion, solidus temperature, liquidus temperature, thermal conductivity, density, specific heat capacity, preheat temperature, layer thickness, beam radius, emissivity, convection coefficient
Outputs QoIs	Temperature field, melt pool dimensions (width, depth, and length), melt pool shape
Assumptions	heat source distribution (line, double ellipsoid, or Gaussian), continuum powder bed
Considered phenomena	Energy absorptivity, moving heat source (scan speed), absorbed energy distribution (cross section and penetration), thermal conduction, heat convection, surface radiation, latent heat of fusion
Neglected phenomena	Latent heat of vaporization, all phenomena related to melt pool flow (surface tension, Marangoni effect, etc.), phase transformation, powder particle packing (powder size distribution, powder particle contact forces)

3.3 The powder-scale thermal-fluid flow models

Further understanding of the L-PBF process can be achieved by accounting for the actual physics of the process. As stated above, these include considering the powder bed as distributed powder particles instead of a continuum block of matter and incorporating the effect of melt pool flow as well as the gas-liquid-solid interactions. Powder-scale thermal-fluid flow models are able to consider these physical phenomena and simulate the L-PBF process. In these models, different physical phenomena that potentially govern the fusion process and part quality can be captured. To simulate these physical phenomena, the 3D transient conservation equations of mass continuity, momentum, and energy are solved numerically. The conservation equations are expressed using Equations (4)-(6) [36].

$$\nabla \cdot (\rho\vec{v}) = 0\,, \tag{4}$$

$$\frac{\partial}{\partial t}(\rho\vec{v}) + \nabla \cdot (\rho\vec{v} \otimes \vec{v}) = \nabla \cdot (\mu\nabla\vec{v}) - \nabla \mathrm{p} + \rho\vec{\mathrm{g}} + F_b, \tag{5}$$

$$\frac{\partial}{\partial t}(\rho h) + \nabla \cdot (\rho\vec{v}h) = q + \nabla \cdot (k\nabla T), \tag{6}$$

where $\vec{v}$ is velocity vector, μ is viscosity, p is pressure, $\vec{\mathrm{g}}$ is gravitational acceleration vector, F_b is buoyancy force, h is enthalpy, and $\otimes$ is the Kronecker product. The position of the free surface in terms of phase fraction (F) at the void-liquid interface as a function of time is tracked using the volume of fluid (VOF) method and it is expressed in Equation (7) [37].

$$\frac{\partial F}{\partial t} + \nabla \cdot (\vec{v}F) = 0, \tag{7}$$

The Equations (4) to (7) are solved together to provide the 3D transient temperature and velocity fields using boundary conditions such as the heat exchange between the top surface and the surroundings and the Marangoni shear stress induced by the special variation of surface tension which are expressed using Equations (8) and (9) [37].

$$-k\nabla T \cdot \boldsymbol{n} = h(T - T_0) + \varepsilon\sigma(T^4 - T_0^4) + q_{evap}, \tag{8}$$

$$\gamma(T) = \gamma_m + \frac{d\gamma}{dT}(T - T_m), \tag{9}$$

where q_{evap} is evaporation heat loss, γ is the surface tension at the surface temperature T, γ_m is the surface tension at the melting temperature, and $\frac{d\gamma}{dT}$ is the temperature coefficient of surface tension.

In addition to the convective and radiative heat loss from the top free surface, under intense laser irradiation, heat loss due to evaporation and recoil pressure need to be considered [37]. To predict the amount of energy absorbed by the powder bed, a 3D volumetric heat source that accounts for multiple reflections of the laser beam inside the powder layers has to be considered [7]. Moreover, the temperature dependent material properties of the powder material significantly affect the accuracy of the L-PBF models. Since the powder bed consists of powder particles as well as shielding gas within the interparticle space, the effective temperature dependent properties, such as density, specific heat, and thermal conductivity of the powder bed depend on properties of the powder material and shielding gas [38]. The packing structure of the powder bed in terms of packing density plays a crucial role in simulating the L-PBF process and needs to be coupled with the thermal-fluid flow models. The choice of powder particles distribution (Gaussian, bimodal, uniform, or mono-sized) significantly influences the packing structure of the powder bed in terms of packing density and porosity. The powder bed models are predominantly characterized by particle

Table 3: Characterization of powder-scale thermal-fluid flow models

Input parameters	Laser power, scan speed, absorption coefficient, latent heat of fusion, solidus temperature, liquidus temperature, boiling temperature, thermal conductivity, density, specific heat capacity, ambient temperature, layer thickness, beam radius, emissivity, convection coefficient, surface tension coefficient, viscosity, latent heat of evaporation
Outputs QoIs	3D transient temperature fields and velocity distributions, melt pool dimensions (width, depth, and length), melt pool shape, surface roughness, geometric dimension, porosity, voids
Assumptions	heat source (Gaussian or double ellipsoid), Newtonian and incompressible molten metal
Considered phenomena	Energy absorptivity, absorbed energy distribution (cross section and penetration), multiple reflections effect, thermal conduction, heat convection, surface radiation, latent heat of fusion and evaporation, melt pool flow (surface tension, Marangoni effect, buoyancy, gravity, recoil pressure, mass change due to evaporation and condensation), phase transformation (melting, solidification, vaporization, condensation), powder particle packing (powder size distribution, powder particle contact forces: collision, friction, adhesion)
Neglected phenomena	Mass change due to chemical reaction (oxidation), solid-state phase transformation, gas flow and interaction with solid and liquid, chemical element diffusion and chemical reaction.

shape and size, particle size distribution, packing density, layer thickness, and re-coater velocity and geometry [8]. The heat transfer-fluid flow models can also be coupled with the solidification and residual stress and distortion models to determine microstructure and solidification parameters and mechanical properties of the fabricated parts [39]. The characterization of the powder-scale thermal-fluid flow models in terms of input parameters, outputs, assumptions, and considered and neglected phenomena is summarized in Table 3.

4. CHARACTERIZING L-PBF UNCERTAINTY SOURCES

The beginning of verification, validation, and uncertainty quantification (V&V UQ) for any scientific computing is to identify and characterize the sources of uncertainty [40]. The flow of uncertainty sources and the verification and validation and UQ adapted from Assouroko et al [5], Lopez et al [16], and ASME V&V-20 Standard [41] for L-PBF computational models is depicted in Figure 1. Using the basic principles of physical laws, such as conservation of mass, momentum, and energy, mathematical models are abstracted and formulated based on assumptions to represent the L-PBF physical process. Such assumptions during mathematical model development cause model form uncertainty that results in inaccurate prediction of output QoIs. To solve the partial differential equations and simulate the L-PBF physical phenomena, computational models use numerical approximations. Such approximations cause numerical uncertainty that undermines the predictive accuracy of the models. The V&V UQ process involves verification that verifies whether the computational model accurately solves the mathematical equations and quantifies the numerical uncertainty due to discretization errors. The validation process evaluates how accurately the computational model represents the L-PBF physical process and estimates the model bias and model form uncertainty by comparing measurement results along with associated uncertainty against simulation results along with numerical and parameter uncertainties. The parameter uncertainty of an output QoI is estimated by propagating uncertainties of input parameters through computational model or surrogate model (if the model is computationally expensive). This section discusses the characterization of these sources of uncertainty through V&V UQ approaches.

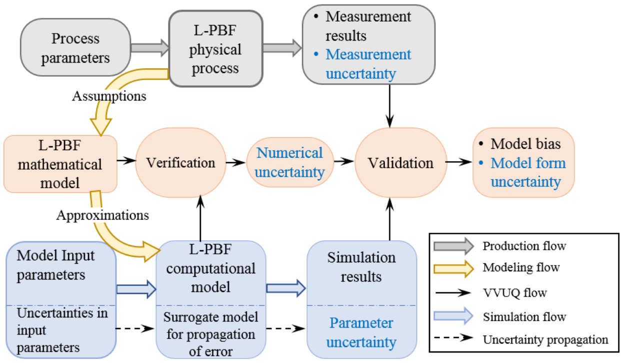

FIGURE 1: UNCERTAINTY SOURCES AND V&V UQ IN L-PBF COMPUTATIONAL MODELS

4.1 Model form uncertainty

The mathematical models only capture certain physical phenomena of the L-PBF process as they are abstracted and formulated based on assumptions and simplifications, and hence they cannot exactly represent the physical mechanisms of the process. As discussed in Section 3, there is a wide range of L-PBF thermal models ranging from low to high fidelity and models within the same level of fidelity. The predictive accuracy of these models potentially depends on the assumptions, considered, and neglected process physics (Tables 1-3). Model form uncertainty arises due to assumptions associated with physical phenomena that neglect or simplify some physics of the process. The predictive accuracy of models across different fidelity or within the same level of fidelity is different due to model form uncertainty. For instance, the assumptions and simplifications of physical phenomena associated with boundary conditions and temperature dependent properties in modeling of heat transfer and phase transformations can lead to inaccurate prediction of temperature gradient and melt pool geometry [8]. The assumptions associated with the distribution of heat source as a point, line, or double ellipsoid heat source significantly conflict with the measured power density distribution. Moreover, ignoring the convective heat transfer, which is one of the main mechanism of heat transfer within the melt pool, can lead to highly inaccurate temperature fields and cooling rates [7].

Model form uncertainty is commonly characterized using a validation approach that evaluates the predictive accuracy of a model by comparing simulation results against measurement results collected under the same condition [42]. Since uncertainties associated with model input parameters propagate through the model and potentially affect the accuracy of simulation results, the values of these parameters need to be first measured and their uncertainties need be characterized. Second, the measurement results along with their uncertainties need to be obtained to perform an effective validation process and estimate model form uncertainty. The ASME V&V 20 Standard for Verification and Validation in Computational Fluid Dynamics and Heat Transfer [41] discussed the verification and validation activities, along with quantifying sources of uncertainty, in heat transfer and computational fluid dynamics. Since L-PBF process involves heat transfer and melt pool flow phenomena, this standard can be suitable for characterizing sources of uncertainty in L-PBF models. The interval within which model bias falls is characterized by validation metrics and expressed using the following expression (10).

$$\delta_{model} \in [E - u_{val}, E + u_{val}], \tag{10}$$

where E is the comparison error between simulation result and measurement result and u_{val} is validation uncertainty. The validation uncertainty that accounts for the sources of uncertainty due to model input parameters (u_{input}), numerical approximations (u_{num}), and measurement errors (u_D) is evaluated using Equation (11). Therefore, all sources of uncertainty need to be characterized for proper assessment of predictive accuracy of L-PBF models.

$$u_{val} = \sqrt{u_{num}^2 + u_{input}^2 + u_D^2}, \tag{11}$$

4.2 Numerical uncertainty

The governing mathematical equations that capture the complex L-PBF physical phenomena are difficult to solve analytically. Thus, numerical methods are often used to solve these equations based on simplification and approximation to obtain approximate solutions. This approximation introduces numerical uncertainty into the predicted QoIs. There are different sources of uncertainty associated with numerical approximations in any computational simulations, such as truncation error, discretization error, error due to computer programming mistakes, iteration error, and round-off error [43]. Among these sources of uncertainty, discretization error is often considered as the main source of uncertainty due to its large magnitude and it is the center of attention in most verification related studies [43]. The verification process insures that a numerical model accurately represents the underlying mathematical equations and estimates numerical uncertainty due to discretization errors. Thus, numerical uncertainty associated with numerical approximations is characterized by the model verification process. To address this matter, verification is divided into two fundamental parts: code and solution verifications [44].

Code verification makes sure that an algorithm or a computer code is free of mistakes or bugs. This is achieved using software quality assurance (SQA) techniques or the method of manufactured solutions (MMS) by comparing predictive outputs with analytical solutions or manufactured solutions if analytical solutions are difficult to compute [43]. In L-PBF models, different simulation codes have been used to numerically estimate the output QoIs. These include discrete element method (DEM) codes to determine powder packing density, OpenFOAM, Flow-3D, or ALE3D code to simulate heat transfer and fluid flow as well as other commercial codes and softwares like ANSYS and ABAQUS to predict the QoIs in heat transfer and residual stress analyses [8]. The Rosenthal-based analytical solution of temperature field is commonly utilized to conduct code verification for L-PBF thermal models. Hence, code verification needs to be conducted to make sure that these codes have satisfied the order of accuracy test.

Solution verification estimates the sources of uncertainty associated with numerical approximations. The governing partial differential equations are solved by discretizing the spatial domain of interest into a finite number of elements and the time advancement into a finite time step. This approach is common in L-PBF models that use different numerical methods, such as FEM, FDM, FVM, DEM, LBM, and CFD [8]. This discretization causes numerical uncertainty in computational simulations. There are different techniques to quantify this source of uncertainty, such as Richardson extrapolation, Roache's grid convergence index, and others [43]. Discretization error is commonly estimated by comparing predictive outputs determined at different grids with course, medium and fine mesh sizes. Roache [45] used grid convergence index (GCI) to convert the discretization error determined from Richardson extrapolation into uncertainty, and the equations used to compute numerical uncertainty are given in Equations (12)-(14). A detailed explanation and formulation on code and solution verifications taking heat transfer and computational fluid dynamics models as a case study can be found in ASME V&V 20 Standard [41] and Roy and Oberkampf [43]. Since numerical-based L-PBF models are computationally expensive, statistically-driven surrogate models are commonly developed to overcome this issue. This introduces surrogate model uncertainty due to the limited number of training and testing data.

$$GCI = F_s \frac{\epsilon_{ext}}{r_{21}^p - 1}, \tag{12}$$

$$\epsilon_{ext} = \left|\frac{f_{\text{ext}} - f_1}{f_{\text{ext}}}\right|, f_{\text{ext}} = \frac{r_{21}^p f_1 - f_2}{r_{21}^p - 1}, p = \frac{\ln(|f_3 - f_2| / |f_2 - f_1|) + q(p)}{ln r_{21}}, \tag{13}$$

$$\begin{gathered} q(p) = ln\left[\left(r_{21}^p - s\right)/\left(r_{32}^p - s\right)\right], \\ s = sign[(f_3 - f_2)/(f_2 - f_1)], \end{gathered} \tag{14}$$

where GCI is grid convergence index, F_s is factor of safety, f_1, f_2, and f_3 are simulation results at course h_1, medium h_2, and fine h_3 mesh sizes, r_{21} and r_{32} are the mesh refinement ratios, p is order of convergence. For a constant mesh refinement ratio, $q(p) = 0$. Otherwise, the order of convergence is computed recursively with initial guess $q(p) = 0$. A numerical

Paper presented at International Mechanical Engineering Congress and Exposition (IMECE2019), Salt Lake City, UT, US. November 11, 2019 - November 14, 2019.

uncertainty is computed by multiplying the GCI with a simulation result.

4.3 Parameter uncertainty

Computational models utilize different input parameters to simulate the behavior of physical phenomena existing in L-PBF process. There is inherent variation in process parameters and in some cases, precise values of some parameters are not known due to imprecise measurement methods or inaccurate estimation of physical properties as the L-PBF process exhibits phase transformation at a small length scale within a very short period of time. Thus, the sources of parameter uncertainty come from natural variability existing in process parameters and/or due to parameters whose exact values are not known or cannot be directly measured. For instance, temperature dependent material properties possess uncertainty due to (a) difficulty in accurately measuring their values especially at high temperature, (b) availability and usage of different measuring techniques, or (c) different values reported in the literature [8]. As a result, any uncertainty associated with input parameters propagates into simulation outputs QoIs through computational models and results in reduction of predictive accuracy. Depending on the amount of information known regarding the distributions of parameter uncertainty, the model input parameter uncertainty can be commonly classified into two categories: aleatory and epistemic uncertainty [14].

Aleatory uncertainty is described as the uncertainty that arises due to natural variation or randomness in a system. There are a significant number of sources of parameter uncertainty in L-PBF process that fall under this category. These include uncertainty sources due to variation in powder size, shape, and size distribution, fluctuations and inherent drift in laser system and galvanometer, vibration in motion and position of built platform and re-coater arm that alter layer thickness, and others. The uncertainty sources that cause variation in process parameters, temperature dependent properties, and absorption coefficient are discussed in Moges et al [8]. This type of uncertainty is characterized by a distribution function, either a probability density function (PDF) or a cumulative distribution function (CDF) to represent the frequency of occurrence [42]. To define the distribution of parameter uncertainty, enough data/knowledge is required.

Epistemic uncertainty is a type of uncertainty that arises due to lack of knowledge and thus it can be reduced by introducing additional information. If a distribution function is assumed for input parameter uncertainty without having enough information, it introduces additional uncertainty into output QoIs. Such an assumption is common in L-PBF input parameters due to the limited number of samples to precisely define the form and parameters of the distribution function. For example, there is limited and sparse data of absorption coefficient and coefficient of friction parameters to accurately define the type and parameters of distribution functions. This uncertainty is commonly characterized by a distribution function to represent the degree of belief [42].

There are different approaches to propagate sources of parameter uncertainty through a model and quantify uncertainty of output QoIs. These include Monte Carlo sampling, response surface methods, stochastic collocation method, polynomial chaos expansion, Gaussian process model, support vector machines, and others [42,46]. For instance, Monte Carlo sampling randomly select a number between zero and one and applies a distribution function to obtain the corresponding parameter sample. This method requires a large number of simulations and hence is only applicable for models that are computationally efficient. For intensive simulation models, the common approach for propagating input parameter uncertainty sources is through surrogate models, such as polynomial chaos expansion, Gaussian process, and others. For example, polynomial chaos expansion expresses output QoI in terms of model input parameters along with their uncertainties using orthogonal basis functions and coefficients and the general expression is given by Equation (15) [14,23].

$$y(\mathbf{x}) = \sum_{j=0}^{N_b} a_j \psi_j(\mathbf{x}), \tag{15}$$

where $\mathbf{x}$ is set of input variables, $y(\mathbf{x})$ is output response, a_j is coefficient of basis function, $\psi_j(\mathbf{x})$ is orthogonal basis function, and N_b is number of basis functions.

4.4 Measurement uncertainty

To accurately compare simulation results with experimental data and perform a validation process to estimate model form uncertainty, measurement results need to be provided along with associated uncertainty of the output QoIs. Measurement uncertainty originates from imprecise measurement methods and error in equipment calibration. Different measurement techniques, such as optical measurements or thermal measurements to conduct in-process monitoring, result in different uncertainty in surface temperature due to the difference in measurement methods [47]. Measurement uncertainty is mainly characterized by different components, such as mean, standard deviation, and probability distribution. These components can be evaluated using statistical method by utilizing the results from a series of measurements. The standard way to evaluate measurement uncertainty from experimental data is described in the “Guide to the Expression of Uncertainty in Measurement (GUM)” [48]. The confident interval of the measurement uncertainty is derived from the standard deviation of a sample population which is evaluated using Equation (16).

$$s = \left[\frac{1}{n-1}\sum_{i=1}^{n}(y_i - \bar{y})^2\right]^{1/2}, \tag{16}$$

where s is standard deviation, n is number of measurements, y_i is measured QoI, and $\bar{y}$ is mean value of all measurement results.

5. CASE STUDY: CHARACTERIZING UNCERTAINTY SOURCES IN L-PBF THERMAL MODEL

In this case study, a Rosenthal-based semi-analytical melt pool model is selected to demonstrate the concept presented in section 4. This semi-analytical melt pool model solves the heat conduction equation for a moving heat source (Equation 1) using a set of ordinary differential equations that describes the motion of isotherms on the surface of the powder bed. By assigning one of the isotherms to the melting temperature, the model can be used to predict the melt pool width. This model is first developed for laser cladding using isotherm migration method [49] and adjusted for use in L-PBF process [16]. The method extends the Rosenthal's solution for moving heat source to consider the temperature-dependent material properties. This model is highly simplified thermal model that neglects multiple physical phenomena of the L-PBF (Table 1), it is suitable for quick prediction of melt pool dimensions.

All sources of uncertainty described in section 4 exist in this semi-analytical melt pool model. Due to the assumptions in terms of point heat source distribution, continuum powder bed, and ignoring melt pool flow phenomena (see Table 1), the model comprises of model form uncertainty associated with these assumptions. The temperature increment used to assign the isotherms on the powder bed surface induces discretization error that causes numerical uncertainty. The uncertainty associated with input parameters propagates through the model and causes uncertainty on the predicted melt pool width. Measurement uncertainty associated with melt pool width is also plays major role in model validation. The detailed analysis and UQ on this regard is given in Moges at al [15].

As discussed in section 4, estimation of modeling error begins from code and solution verification. It was reported that the code verification for the model used in this case study was conducted using manufactured solution and the method converges to the Rosenthal's analytical solution [16]. The solution verification that estimates numerical uncertainty due to discretization error is conducted using Roache's grid convergence index. The GCI that estimates the 95% convergence is determined using Equation (12) based on the values of melt pool width obtained at course, medium, and fine grid refinements. The estimated melt pool width along with numerical uncertainty at laser power 195 W, scan speed 800 mm/s, and absorption coefficient 0.6 for IN625 material is (127.5 ± 2.3) µm.

The source of uncertainty due to unknown input parameters is quantified using full factorial design of experiment (DOE) analysis assuming normal distribution for the parameters given in Table 4. A statistically-driven surface response that uses to estimate parameter uncertainty of the melt pool width is first derived from DOE analysis. Then Monte Carlo simulation is conducted to determine the probability distribution of melt pool width. The histogram of the melt pool widths for 10,000 samples and fitted normal distribution is shown in Figure 2. The average of the predicted melt pool widths and the parameter uncertainty that represents the 95% confidence interval is obtained to be (138.7 ± 12.8) µm.

Table 4: Input parameters for uncertainty propagation

Input parameters	Nominal value	% variation
Laser power	195 W	2.5%
Scan speed	800 mm/s	1.5%
Absorption Coefficient	0.6	20%
Heat capacity	$c_p(T)\ J/kgK$	3%
Thermal conductivity	$k(T)\ W/mK$	3%

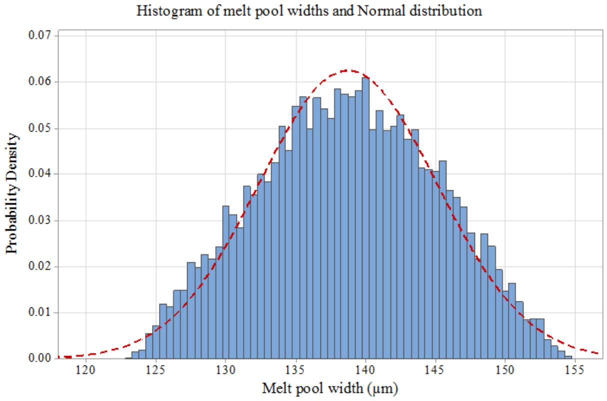

FIGURE 2: PROBABILITY DENSITY OF PREDICTED MELT POOL WIDTHS

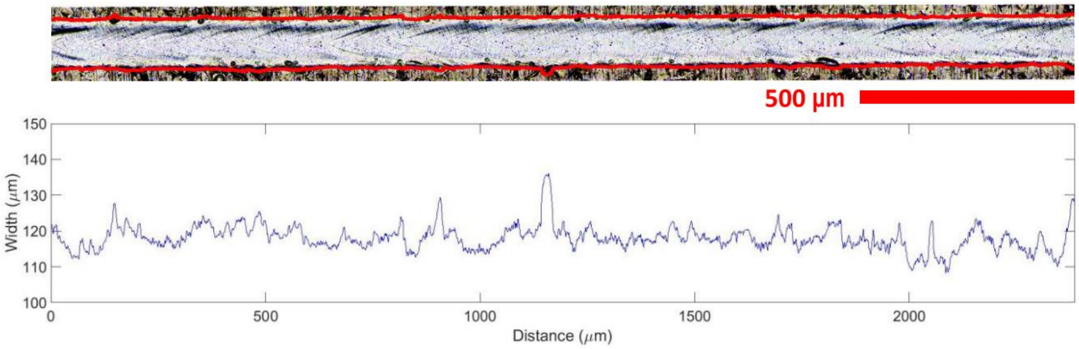

FIGURE 3: MEASUREMENT OF MELT POOL WIDTH FROM OPTICAL IMAGE OF SCAN TRACK. FIGURE ADOPTED FROM FOX ET AL. [50]

To determine measurement uncertainty for model validation and estimate model uncertainty, melt pool width was measured from the image of scan track taken using optical microscope by manually tracing the edges of the scan track and using a software to determine the distance between the traces as shown in Figure 3 [50]. The melt pool average and standard deviation at 195 W laser power and 800 mm/s scan speed are 132.2 μm and 14.1 μm, respectively. Thus, the 95% confidence interval is ± 28.2 μm. In addition, manually tracing the edges of the track induces ± 2 μm uncertainty.

The validation uncertainty, assuming all uncertainty sources are independent, is determined using Equation (11) and is estimated to be (127.5 ± 32.9) μm. The comparison between the predicted and measured melt pool width and the confidence interval obtained from validation uncertainty is depicted in Figure 4.

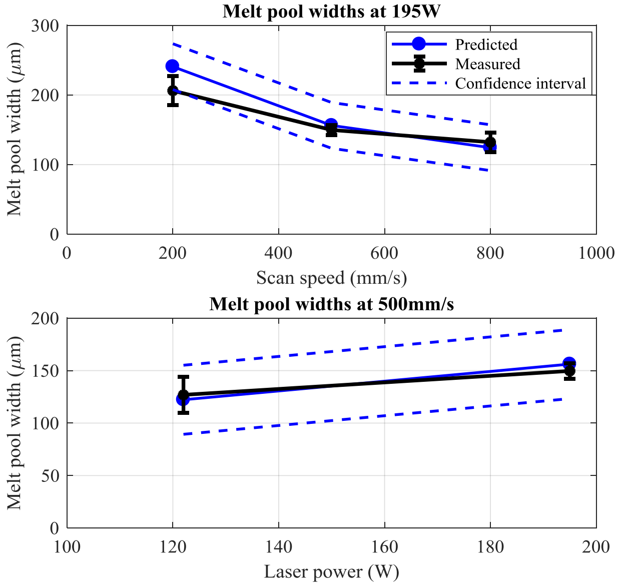

FIGURE 4: PREDICTED AND MEASURED MELT POOL WIDTH AND 95% CONFIDENCE INTERVAL

6. REPRESENTATION OF L-PBF MODELS AND UNCERTAINTY SOURCES

To capture relevant knowledge of the L-PBF models and sources of uncertainty, systematic representation of their characterization is essential. For this purpose, the Web Ontology Language (OWL)-based ontology is leveraged to extract relevant knowledge that can be useful for interoperability and reusability. There are some research efforts that use ontology-based knowledge representation in AM [5,51,52]. This section presents the addition of specific classes and attributes into our previous AM ontology [5] in order to capture knowledge associated to particle-scale thermal-fluid flow models and sources of uncertainty. First, we discuss the representation of the L-PBF models focusing on the powder particle-based models, and then we present the representation of uncertainty sources focusing on their classifications and their relationships with the models.

6.1 Representation of L-PBF models

The proposed ontology in the present study captures the formulations, assumptions, input parameters, output QoIs, and predictive models of the five main physical mechanisms of the L-PBF process: powder layer deposition, heat source-powder interaction, melt pool formation, solidification and grain growth, and the occurrence of residual stress and distortion formation. The main class named *LPBFModel* comprises of the following subclasses: *Formulation*, *Assumption*, *InputParameters*, and *Prediction,* with prefix of *LPBFModel,* as well as *LPBFPredictiveModel*. The *LPBFModelFormulation* subclass involves the mathematical formulations used to capture the aforementioned physical mechanisms of the L-PBF process. For instance, the *MeltPoolModelFormulation* includes the conservation equations of mass, momentum, and energy that capture the heat transfer and fluid flow phenomena in the melt pool. The modeling assumptions and simplifications used while formulating the physical phenomena are captured under the subclass called *LPBFModelAssumption*. For example, this subclass captures the assumptions associated to distribution of heat source: point, cylindrical, ellipsoidal, or Gaussian; powder bed material distribution: continuum or distributed powder particle; powder size distribution: mono-size, bi-modal, uniform, Gaussian, or positively skewed. The subclass that captures the input parameters including process parameters: laser power, scan speed, layer thickness, beam size, etc. and material properties: thermal conductivity, density, heat capacity, melting temperature, etc., is *LPBFModelInputParameter*.

The output QoIs of the L-PBF predictive models are captured by the *LPBFModelPrediction* subclass. This involves the outputs of (a) powder bed model: packing density, coordination number, and radial distribution function; (b) heat source model: absorbed energy, absorbed energy distribution, and effective absorption coefficient; (c) melt pool model: temperature gradient, melt pool dimensions: width, depth, and length, defects: balling, keyhole, and layer delamination, and porosity: gas pores and inter-track voids; (d) solidification model: grain size, grain morphology, and grain orientation; (e) residual stress and distortion model: residual stress and strain distribution, deformation history, fatigue life, and shrinkage. The last subclass under *LPBFModel* is *LPBFPredictiveModel* and this captures the different predictive models in L-PBF process. These models include (1) powder bed models: raindrop method and discrete element method (DEM); (2) heat source model: Beer Lambert, ray tracing, radiation transfer, and surface heat flux; (3) melt pool models: Rosenthal-based model, FEM thermal model, CFD-based model, and lattice Boltzmann method; (4) solidification model: phase field method and cellular automata; (5) residual stress and distortion model: thermomechanical FEM-based model and simplified mathematical model.

6.2 Representation of L-PBF uncertainty sources

The uncertainty related aspects of the L-PBF models, which include sources of uncertainty, uncertainty quantification approaches, and types of uncertainty, are captured in the proposed ontology. The *LPBFUncertainty* class involves subclasses such as *TypeOfUncertainty*, *LPBFUncertaintySource*, and *LPBFUQMethod*. As discussed in previous section, the *TypeOfUncertainty* in any scientific computing can be categorized as *AleatoryUncertainty*, *EpistemicUncertainty*, or *CombinedUncertainty*. As mention in previous section, aleatory uncertainty is due to natural randomness of input quantities or perturbation in a system and cannot be reduced. There are different uncertainty sources that fall under this category. These include variation in measurement results, inherent drift in laser supply system, fluctuation in laser power, scan speed, and beam radius, variation in powder size, shape, and size distribution, friction coefficient, and absorption coefficient of a powder bed. On the other hand, epistemic uncertainty comes from lack of knowledge and can be reduced by introducing more information. The L-PBF uncertainty sources that fall under this category include uncertainty due to modeling assumptions that neglect some physical phenomena (model form uncertainty), uncertainty due to numerical approximation (numerical uncertainty), limited measurement data, error in instrument calibration, imprecise measurement method, and uncertainty in distribution type and parameters due to sparse data.

The *LPBFUQMethod* represents different methods and standard approaches to quantify model form, numerical, parameter, and measurement uncertainties. For instance, measurement uncertainty can be quantified using a standard approach GUM, numerical uncertainty by verification approach, model form uncertainty by validation approach, and parameter uncertainty by sampling methods or surrogate models. The possible sources of uncertainty in L-PBF models including those due to measurement error are identified and captured under the subclass called *LPBFUncertaintySource.* The taxonomy of the uncertainty sources of the top-level entities is depicted in Figure 5.

6.3 Relationships in L-PBF models and uncertainty sources

To capture the interactions between the features of L-PBF phenomena, parameters, and output QoIs at the physical and computational domains, properties that define the relationships are established in the proposed ontology. As described in section 3, the L-PBF models are developed based on assumptions and they do not consider the entire phenomena of the process. Thus, the properties that link these models with their corresponding inputs, outputs, assumptions, and the captured and neglected phenomena are defined in the ontology using *requires*, *predicts*, *assumes*, *considers*, and *neglects*, respectively. Figure 6(a)-(c) shows the relationships in semi-analytical Rosenthal-based thermal model, FEM-based thermal model, and powder-scale thermal-fluid flow model. Similarly, the sources of uncertainty that result in model discrepancy are defined by properties to link different sources with corresponding predictive uncertainties. Those features that cause model form, numerical, parameter, and measurement uncertainties are being captured in the ontology as depicted in Figure 7 and the domains and ranges of properties are clearly defined. For instance, model form uncertainty in (a) powder bed model is caused by assumptions associated with powder bed material distribution and powder size distribution; (b) heat source model is caused by dimensionality of absorbed energy (surface and/or volumetric) and distribution of heat source, and (c) melt pool model is caused by thermal boundary conditions, initial conditions, phase transformation assumptions, and molten metal flow assumptions.

The features that cause variability in some input parameters are captured under parameter uncertainty sources. For example, variability in (a) laser power can be caused by heating of optics, soot on optics and inherent drift in laser delivery system and (b) layer thickness is caused by orientation and positioning errors, vibration in build platform motion, vibration in recoater arm motion, and variation in powder bed density. The main source of numerical uncertainty is discretization errors due to the selection of element size and time steps. Lastly, measurement uncertainty is caused by calibration error, imprecise measurement methods, and variation in measurement results.

7. CONCLUSIONS

This study explored two major aspects of L-PBF additive manufacturing process. First, the L-PBF thermal models were characterized focusing on their input parameters, output QoIs, assumptions, and considered and neglected phenomena. These models include Rosenthal-based thermal models, FEM-based thermal models, and powder-scale thermal-fluid flow models. The characterization of the models is necessary to understand the abstraction and formulations of the models and investigate model elements that can be used as a basis for studying the sources of uncertainty which ultimately leads to understanding the predictive accuracy of the models. Then, characterization of sources of uncertainty of the L-PBF models was conducted. These uncertainty sources include model form, numerical, input parameters, and measurement uncertainties. Model form uncertainty is caused by assumptions and simplifications taken during representation of physical phenomena using governing mathematical equations. A validation approach can be used to characterize this source of uncertainty along with model bias by comparing simulation and measurement results. Discretization error associated with element size and time steps is the major cause of numerical uncertainty and a verification approach can be used to characterize and estimate the value of this uncertainty. The presence of natural variability in input variables and imprecise values cause uncertainty in output QoIs. Parameter uncertainty of a model can be determined by using sampling methods either directly on the model, provided that the model is computationally efficient, or through surrogate models that represent the computationally expensive physics-based models. Finally, measurement uncertainty, which is used in model validation, is caused by calibration error, imprecise measurement method, and variation in measurement results, and a standard approach is used to characterize this uncertainty.

This paper also presented ontological representation of the L-PBF models and uncertainty sources. The ontology based on Protégé captures the relevant knowledge associated to process, model, and uncertainty sources. This ontology represents the characterization of the powder-scale thermal-fluid flow models that better imitate the L-PBF process. The class of the L-PBF process mainly captures the physical characteristics, process parameters, and process signatures. Whereas the model ontology class captures model assumptions, formulations, input parameters, outputs, and predictive methods. The L-PBF uncertainty class captures sources of uncertainty, type of uncertainty, and uncertainty quantification methods and approaches. This work can be further extended by incorporating different models ranging from low to high-fidelity in order to capture more knowledge to assess their predictive capability and compare different models. The topology and mapping of the uncertainty sources presented in this study establish fundamental requirements for measuring model fidelity, and for guiding the selection of a model suitable for its intended purpose.

DISCLAIMER

No approval or endorsement of any commercial product by NIST is intended or implied. Certain commercial equipment, instruments or materials are identified in this report to facilitate better understanding. Such identification does not imply recommendations or endorsement by NIST nor does it imply the materials or equipment identified are necessarily the best available for the purpose.

ABSTRACT

The purpose of this panel is to discuss the state of the art in digital twin for manufacturing research and practice from the perspective of the simulation community. The panelists come from the US, Europe, and Asia representing academia, industry, and government. This paper begins with a short introduction to digital twins and then each panelist provides preliminary thoughts on concept, definitions, challenges, implementations, relevant standard activities, and future directions. Two panelists also report their digital twin projects and lessons learned. The panelists may have different viewpoints and may not totally agree with each other on some of the arguments, but the intention of the panel is not to unify researchers' thinking, but to list the research questions, initiate a deeper discussion, and try to help researchers in the simulation community with their future study topics on digital twins for manufacturing.

1 INTRODUCTION

Recent technology advancement of smart sensors, Internet of Things (IoT), cloud computing, Artificial Intelligence (AI), Cyber-Physical Systems (CPS), and modeling and simulation make it possible to realize the "digital twin" of a manufacturing product, system, and process (Bolton 2016). These technologies enable better real-time data collection, computation, communication, integration, modeling, simulation, optimization, and control that are required by digital twins. "Digital Twin" has become an important

Shao, Guodong; Jain, Sanjay; Laroque, Christoph; Lee, Loo Hay; Lendermann, Peter; Rose, Oliver. "Digital Twin for Smart Manufacturing: the Simulation Aspect." Paper presented at Winter Simulation Conference 2019, National Harbor, MD, US. December 08, 2019 - December 11, 2019.

component in programs and initiatives related to Smart Manufacturing, Digital Manufacturing, Advanced Manufacturing, and Industry 4.0 globally. It is a “hot” topic among researchers, educators, software vendors, and practitioners in these fields, as one panelist indicates that searches of the key word “digital twin” has been growing rapidly since 2016. On Gartner’s 2017 Hype Cycles of Emerging Technologies, digital twin is listed with a time to acceptance of (five to ten) years, i.e., one-half of companies, by 2022, will be using digital twins to achieve more efficient system performance analysis and improved productivity (Panetta 2017). The International Data Corporation (IDC) forecasts that companies investing in digital twins will see improvements of 30% in cycle times of their critical processes in the next five years.

However, manufacturers are not implementing or embracing digital twins as rapidly and efficiently as expected. This may be because digital twins are still in their infancy stage, and there is a lot of confusion about what they actually are, what they should include, and where to start to implement them. The lack of consensus among researchers and practitioners in different communities and different industrial sectors also hinders the acceptance of digital twins by manufacturers. Many companies, especially small- and medium-sized enterprises (SMEs), do not have the expertise and resources required to study and understand the digital twin concept, definitions, and associated challenges; and then effectively implement the digital twin concept for their products and manufacturing operations. They typically have neither sufficient information on the required technologies and standards, nor systematic procedures guiding the implementation of a digital twin. In the simulation community, we thought that we knew digital twins better because we have been performing modeling and simulation for a few decades. However, with the opportunities of new technologies and data and the challenges and requirements of new data-driven and real-time modeling, we, as a community, should equip and update ourselves for this new era of modeling and simulation.

The goal of this panel is to start a discussion regarding the state of the art in digital twins for manufacturing research and development from the perspective of the simulation community. The panelists come from the US (Guodong Shao and Sanjay Jain), Europe (Christoph Laroque and Oliver Rose), and Asia (Loo Hay Lee and Peter Lendermann). Among them are four researchers from academia (Sanjay Jain, Christoph Laroque, Oliver Rose, and Loo Hay Lee), one panelist from the US government (Guodong Shao), and one panelist from a software vendor (Peter Lendermann). Each panelist has provided preliminary thoughts on concept, definitions, challenges, implementations, and future directions. Two panelists also report on their digital twin projects and lessons learned. The panelists may have different viewpoints and may not totally agree with each other on some of the arguments, but the intention of the panel is not to unify researchers’ thinking, but to identify research questions, initiate a deeper discussion, and try to help researchers in the simulation community for their future study topics on digital twin for manufacturing.

The remainder of this paper contains the list of panelists’ statements, which represent their personal thoughts, their research findings, and their implementation results of digital twins.

2 PANELIST STATEMENTS

This section provides initial thoughts of each panelist on the simulation aspect of Digital Twin for Smart Manufacturing.

Guodong Shao

a. What is a digital twin?

The digital twin concept originated by Grieves in 2002 is to create a digital informational construct of a physical system as an entity on its own. This digital information would be a “twin” of the information that was embedded within the physical system and be linked with that physical system through the entire lifecycle of the system (Grieves and Vickers 2016). The digital twin concept allows manufacturers to create models of their production systems and processes using real-time data collected from smart sensors and used for near-real-time analysis and control. The digital twin and the physical system are connected through IoT or smart sensors and actuators. Synchronization between the digital twin and its physical twin, either online or offline, ensures that the production systems are constantly optimized as the digital twin receives real-time performance information from the physical system.

Currently, there are multiple different definitions of the digital twin out there (Ahuett-Garza and Kurfess 2018; Coronado et al. 2018; Garetti et al. 2012; GE 2018; Haag and Anderl 2018; Hughes 2018; Negri et al. 2017; Siemens 2018; Tao et al. 2017). Many of the definitions imply that a digital twin is an identical virtual duplication of a physical entity or an entire system. However, from my perspective, there may be multiple digital twins each representing different focus, aspect, or view of the system, i.e., each digital twin application should have its own focus. A digital twin is context-dependent and could be a partial representation of a physical system, it may consist of only relevant data and models that are specifically designed for their intended purpose (Boschert and Rosen 2018; Shao and Kibira 2018).

b. What are the relationships between digital twins and simulation models?

Many people may think that simulation models are digital twins. The fact is that a digital twin can be a simulation model, but a simulation model may not necessarily be a digital twin. Digital models used in simulations often have the same type of sensor information and controls of a digital twin, but the information may be generated and manipulated within the simulation. The simulation may replicate what could happen in the real world, but not necessarily what is currently happening (Wong 2018). Kritzinger et al. (2018) propose a classification of digital models into three subcategories based on their level of data integration between the physical and digital counterparts: (1) Digital model: a digital representation of an existing or planned physical object without any form of automated data exchange between the physical and digital objects. Most of the current offline simulation models are this kind of digital model; (2) Digital shadow: a digital model with an automated one-way data flow between the physical and digital objects, e.g., a simulation model using real-time sensor data as inputs (Yang et al. 2017); (3) Digital twin: a digital model with bi-directional data flow between the physical and digital objects, e.g., a simulation model that uses real-time sensor data as inputs and updates some of the parameters of a manufacturing process or equipment.

c. Typical digital twin applications for smart manufacturing

Digital twins can be used to ensure information continuity throughout the entire product/system lifecycle; perform real-time monitoring, predict system behavior, provide production control and optimization; view, analyze, and control the state of products or processes; enable preventive maintenance, and realize virtual commissioning. The applications of the digital twin concept help reduce resource downtime, improve product throughput and quality, reduce manufacturing costs, and ensure operation safety. Advanced digital twins may update products in the field and provide service to end-user customer (Hughes 2018).

d. What are the research directions to promote digital twin applications in the simulation community?

Digital twins are gaining more attention but are still in their early stage. There are a lot of challenges that need to be overcome before manufactures can effectively, economically, and correctly implement digital twin technologies. Manufacturers, especially SMEs, need help interpreting the concepts, relevant standards and technology implementations. In the simulation community, we need to help solve issues related to data management including data collection, data processing, and data analytics; real-time model synchronization that guarantees the digital twin reflects the current status of its physical twin; model generation that includes automatic data driven model creation and standard-based model generation; and model verification, validation, uncertainty quantification (VVUQ) (Shao and Kibira 2018; Lugaresi and Matta 2018).

e. Current relevant standardization efforts

Useful standards for digital twin implementation include guidelines for consistently performing credible digital twin modeling and specifications that define the information models and data formats to enable the interoperability of data and models within digital twins. NIST researchers currently participating in the development and testing of multiple such standards. Two of them are listed below:

- ISO 23247 - Digital Twin Manufacturing Framework: is intended to provide a generic manufacturing digital twin development framework that can be instantiated for case-specific digital twin implementation. The standard will have four parts: (1) Overview and general principles, (2) Reference architecture, (3) Digital representation of physical manufacturing elements, and (4) Information exchange. The completed framework standard will provide guidelines, methods, and approaches for the development and implementation of manufacturing digital twins. It will also help facilitate the composability of models and interoperability among modules, provide examples of data collection, modeling and simulation, communication, integration, and applications of relevant standards. The framework will also enable the generation and management of common data and model components that most digital twins need to have to facilitate the reuse of these components. For example, a simulation components library or model template may be useful for composing and reusing components for future models. This standard is currently work-in-progress.
- The American Society of Mechanical Engineers (ASME) Verification and Validation (V&V) standards committee is developing best practices, general guidance, and a common language for verification, validation, and uncertainty quantification for computational modeling and simulation in advanced manufacturing. The guidelines for incorporating VVUQ for data-driven models and throughout model lifecycle are especially applicable to digital twin development. It will allow better traceability, improved verification and validation capability, and better model credibility.

Sanjay Jain

From Virtual Factory to Digital Twin? The panel members' inputs present a range of overlapping perspectives on digital twins in the context of manufacturing. All the perspectives appear to agree on some major aspects. All of us consider digital twins to have simulation models as the key platform and include interfaces to the real system and to analytics applications as part of the concept. Some of us include a few analytics capabilities as part of the digital twin. Some of us explicitly identify the capability to vary level of details and supporting the lifecycle of the manufacturing system. With that overall agreement, the views appear to diverge a bit as we get into some details.

The challenge appears to be in achieving an alignment in our understanding at the deeper level. Considering that all the panel members are long time participants of Winter Simulation Conference (WSC), a practitioner or even a researcher from outside the community may expect us to be quite well aligned. The differences in our perspectives underline the need to work towards a common understanding. If we, being a part of the same community over a long period, differ on the details, it is not surprising that a whole range of diverse viewpoints are found in the larger community of manufacturing practitioners and researchers.

Interestingly the challenge of developing a common understanding of the digital twin concept is rather similar to the challenge with the virtual factory concept. Based on Google Scholar searches the earliest mention of virtual factory appears to be by Fisher (1986) as below:

> "Perhaps the most important benefit that can be derived from the development of an intelligent factory design agent is the ability to create an electronic model of the factory for subsequent use by other KSs (knowledge-based systems) and problem solvers. This virtual factory would benefit, for example, redesign of a factory when a change in product line occurs because only change related information would need to be collected due to the a priori existence of a factory model."

It can be seen that this original idea of virtual factory as an "electronic model" of the real factory that can be updated is quite similar to at least some definitions of digital twins. This is indeed why the challenge of definition of virtual factory has been referred to rather than any of other multitude of concepts that suffer from overuse with varying definitions. We submit that the digital twin in the context of manufacturing is almost the same concept as virtual factory, at least with the definition that we are using now and that is somewhat enhanced version of original idea described in Jain (1995).

Virtual factory was conceptualized as going beyond the simulation of only the material flow and immediately associated resources and activities. The three major enhancements proposed were in taking an integrated view of multiple relevant aspects of the factory, developing the virtual factory in parallel with the development of a real factory through its life cycle, and simulating and analyzing at different resolution levels. The concept was more recently enhanced in Jain and Shao (2014) to include open standard based interfaces with data sources and with analytics capabilities and is shown in Figure 1.

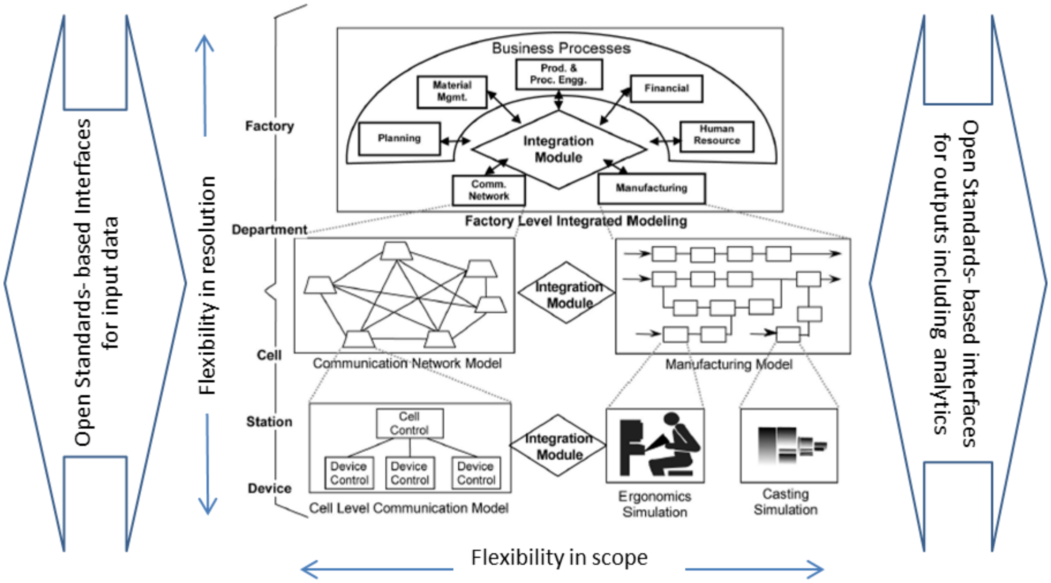

Figure 1: Virtual Factory concept (adapted from Jain and Shao 2014).

It should be apparent that the virtual factory concept largely overlaps with the digital twin concept applied to manufacturing. Digital twin is clearly a more generic concept as it can be applied to other environments such as a port and it appears to be used frequently for products. One would need to use an additional specifier such as the factory's digital twin. Some authors appear to use digital factory largely in the sense of factory's digital twins. It will be beneficial to all to agree on the terminology to avoid potential miscommunications between the providers and users of such capabilities.

It would help define not only one phrase representing the envisaged virtual factory or factory's digital twin capability, but also successively larger subsets that provide a path to start small and build a factory's true digital twin. The coining of digital model, shadow, and twin mentioned elsewhere in this paper is in the right direction and so is the idea of the increasing capabilities defined on four dimensions but perhaps a more comprehensive maturity model approach and/or additional dimensions are needed. Such a set would need to be developed via an international multi-party effort for wider acceptance. The development of the comprehensive model will help with better communication and allow practitioners and researchers to focus on advancing towards smart manufacturing without being lost in definitions.

The multi-resolution capability for the concept in Figure 1 will likely require multiple simulation paradigms for implementation including continuous simulation at for modeling individual manufacturing processes, discrete event simulation for modeling factory flow, and system dynamics for modeling interactions of business processes. Jain et al. (2015) present a virtual factory prototype that employs continuous simulation for modeling the turning process dynamics and kinematics, agent-based modeling for machine level model, and discrete event simulation for job shop level model. While the use of multiple paradigms provides the capability for analysis appropriate to level of detail, it does increase the expertise requirement for the modelers and analysts to carry out the task.

There are multiple challenges beyond definitions of the concept and the high expertise requirement for multiple resolution modeling that are facing manufacturers, particularly SMEs, interested in implementing their factory's digital twins. These include the effort and expertise required to collect and set up data for simulation, build the interfaces, analyze the outputs, and provide timely input to the decision makers. Technology advancements in multiple fields are helping address the challenges. Jain, Narayanan, and Lee (2019) propose a standards-based infrastructure to move towards addressing the challenges.

Christoph Laroque

The Digital Twin for Simulation in Operations – Something new beyond marketing? Data-driven Decision Support such as Simulation, Advanced Data Analytics, and AI are changing how modern manufacturing processes are planned and executed. Within the vision of Industry 4.0 and Cyber-Physical Production Systems, complex problems due to planning, scheduling and control of production, and logistic processes are derived by data-driven decisions in the nearer future. Thus, new processes and interoperable systems must be designed, and existing ones have to be improved, since Industry 4.0 has placed extremely high expectations on production systems to have substantial increase in productivity, resource efficiency, and level of automation. The deliverance of these expectations lies in the ability of manufacturing companies to accurately predict and plan their activities on the machine, the plant, as well as at the supply-chain-level.

Discrete event simulation (DES) is very suitable to model the reality in a manufacturing system with high fidelity. Such models are easy to parameterize and they are able to consider several influences including stochastic behavior. However, simulation models are challenged when it comes to operational decision support in manufacturing as well as logistics. The simulation models are very complex and need huge amount of production data and up to hours for the execution of simulation experiments. A better approach is to integrate the methods and algorithms from (big) data analytics and AI during the implementation of the "digital production twin" for different purposes, e.g., Predictive Maintenance or Workforce Scheduling. The digital twin represents the behavior of the corresponding real object or process and is compared with it at (mostly regular) defined points in time. A large amount of data can be used, the data is generated when implementing the Industry 4.0 concepts during operation as so-called "digital shadows."

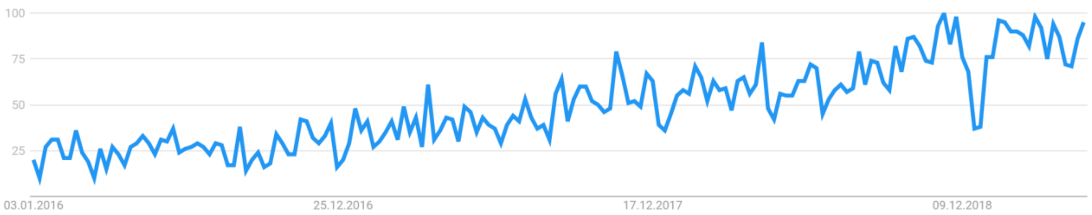

Figure 2: Worldwide Searches for the Term "Digital Twin" (Source: Google Trends).

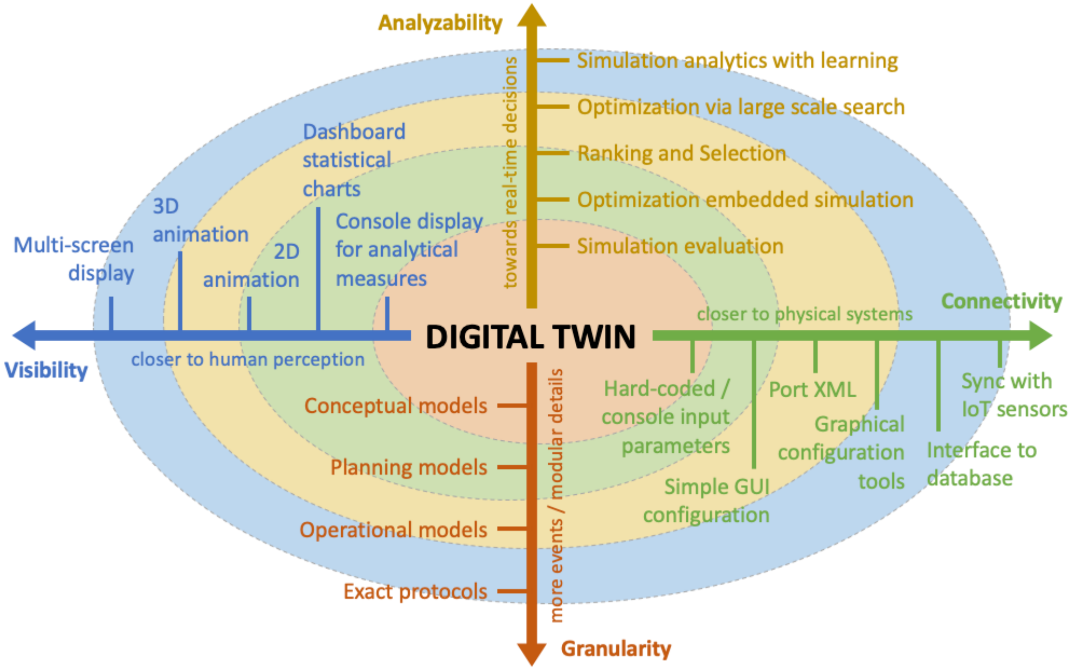
One might say, that the concepts behind the innovative term “digital twin” might be old and known, which seems to be reasonably true from the perspective of a simulation expert. However, with the growing importance of searches for the term from all over the world (Figure2 indicates that searches grow by 400% in the last two years) and within the technological roadmap of the larger consultancies, the “digital twin”’ might lead to a higher visibility in top-management and at the decision-makers desk (at least this panelist thinks so).

But also, from a technological perspective, it might be reasonable to think about innovative combinations of the existing data-driven methods for decision making or decision support with DES, specifically material flow simulation, in order to implement more applications of simulation in daily manufacturing operations to achieve better planning, scheduling, and control results. Especially, approaches from data analytics that perform pre-simulation data aggregation, selection, and analysis might lead to performing successful applications in the manufacturing practice.

Loo Hay Lee

Building Toward the Digital Twin for the Smart System: A digital twin is the manifestation of the physical system in the digital world that can be used for various purposes. It can provide an environment for monitoring, testing, planning, and decision-making without real physical or time constraints. Besides the spatial representation of its physical counterpart, digital twin also needs to include simulation model and analytic methodologies.

The desired capability for the digital twin includes four dimensions as illustrated in Figure 3. Namely, the **Connectivity** that indicates the level of communication with its physical counterpart; the **Visibility** that indicates the ease of perception for human beings; the **Granularity** that indicates the detail level of the model, which can help us to look into the future scenarios in different fidelities; and the **Analyzability** that indicates how it can be used to assist for decision making (e.g., simulation optimization that can help us to find the best decision for the future; an analytics tool that can help us to learn based on the future simulated optimized data).



Analyzability

Granularity

Figure 3: The four dimensions of desired capability for digital twin.

We have developed an O^{2}DES (object-oriented discrete-event simulation) framework as shown in Figure 4 (Zhou et al. 2017). With a rigorously defined Trinary modeling paradigm, the O^{2}DES framework allows developers and researchers to implement algorithmic tools to perform various types of analysis including (1) simulation to handle discrete event model, (2) optimization in simulation that can help to model the operation decision, (3) simulation in optimization (SimOpt approach) that can help to find the best decision under each scenario (Xu et al. 2015; Xu et al. 2016), as well as (4) learning based decision-making, i.e., simulation analytics that can learn the optimal decision function based on future optimized data. We have used this framework to develop digital twin for container terminal (Li et al. 2017; Zhou et al. 2018), aircraft spare part management (Li et al. 2015), warehouse (Pedrielli et al. 2016), and wafer fab plant.

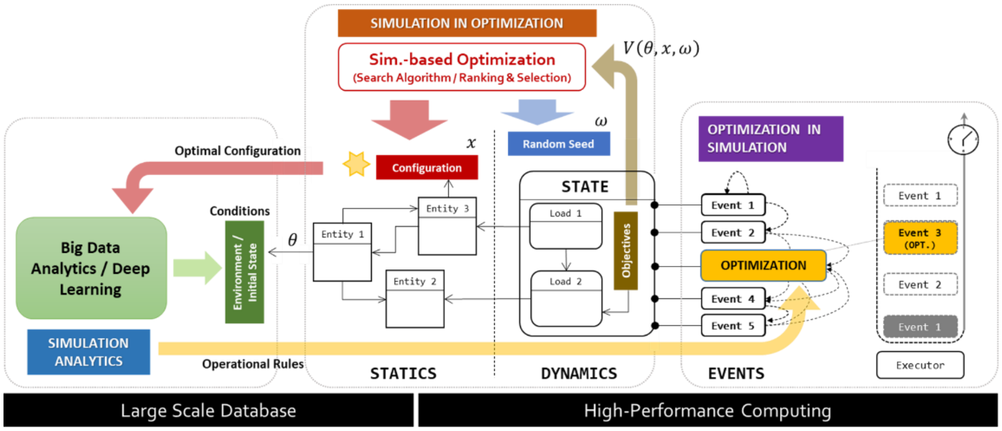

Figure 4: The illustration of O^{2}DES framework with trinary modeling paradigm.

Digital twins are not only the crystal ball to look into future but also the doctors that help provide solution for the future. Digital twins can enable us to actively learn from future, so that we are more prepared for the future, and aim to learn for success.

Peter Lendermann

Challenges with regard to the Usefulness of Digital Twins: The potential of the digital twin concept for the enhancement and continuous re-optimization of manufacturing and logistics operations has generally been recognized and accepted not only by academia but also by industry as it is an important backbone of the Industry 4.0 paradigm.

As mentioned by several co-panelists, simulation is an important enabler for creating a digital twin of a manufacturing and/or logistics system. However, a digital twin will never be able to be an “identical virtual duplication of a physical entity or an entire system” as stated by Shao, main reason being that the behavior of basically all manufacturing and logistics systems also involves human considerations and decision-making which inherently cannot be portrayed a computer simulation model. As such, the digital twin concept appears to be applicable mainly for highly automated systems with little human involvement.

In D-SIMLAB Technologies, the concept of digital twin is currently pursued mainly for semiconductor manufacturing, in particular highly automated 300 mm wafer fabs.

An additional complication in such a manufacturing environment, however, is the high degree of randomness on the production floor, caused by process steps such as quality measurement that, dependent on their outcome, may or may not result in re-work. As such, meaningful deterministic forecasts are only possible for very short time horizons in the order of a few hours at maximum.

Such deterministic forecasts are also the basis for complicated scheduling procedures that nowadays are used to optimize the material flow performance at critical equipment groups in wafer fabs. How this typically looks like in a wafer fab in terms of system architecture is outlined in the upper half of Figure 5.

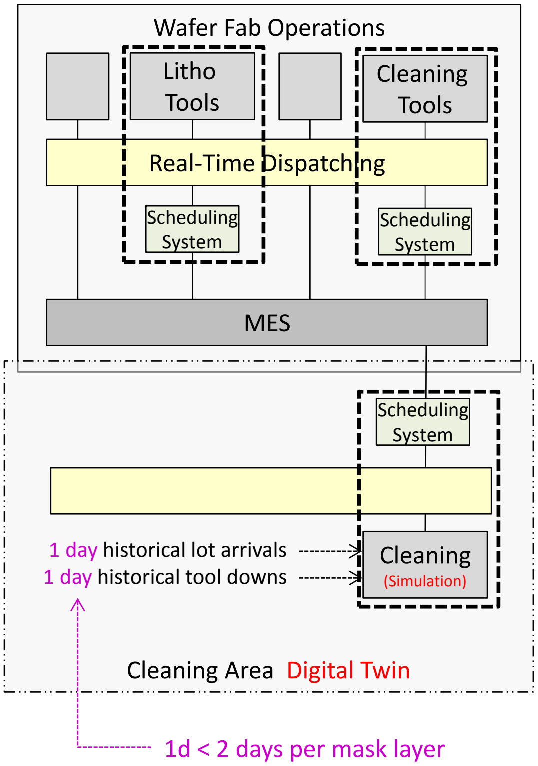

Figure 5: Simplified system architecture for material flow management in a wafer fab (upper half) and Digital Twin representing the cleaning area (lower half).

An important question to be addressed through a digital twin could be, for example whether certain scheduling parameters can be enhanced and better parameter values can be identified consistently. However, in a cleaning area of a large 300 mm fab comprising more than 100 wet benches, furnaces, and metrology tools, for example, commercially available scheduling tools typically run at a frequency of once every 10 min, whereby the scheduling procedure runs most of this time and the remaining time is needed for data input and output. This basically means that the scheduler runs almost continuously and hence also the digital twin, i.e., the simulation model of the cleaning area (in which the scheduler would have to run equally frequently) will inherently not be able to run faster than real-time. Optimization of scheduling parameters, in the sense of what are the best parameter values under which circumstances, will therefore be possible only retrospectively by comparing the (simulated) performance associated with different scheduler settings for different historical down or lot arrival patterns.

As indicated in Figure 6, parallel execution of different scenarios will be required, otherwise a meaningful analysis of scheduling parameters will not be possible. Also, multiple instances of the Scheduling solution will be required, basically equivalent to the number of instances that would be required to compare different scenarios on a cloud infrastructure, posing challenges to the licensing models currently practiced by commercial vendors of scheduling solutions.

Oliver Rose

The term "Digital Twin" was coined as a part of the huge marketing campaign called Industrie/Industry 4.0 to speed up digitalization in production and logistics. Computer simulation models of production and logistics models are in use since the 50s of the last century. A computer model is a digital twin per se. What is more important is the question of what will be achieved with a newly invented digital twin that could not be achieved with computer simulation of manufacturing systems before. In my opinion, the goals are the same, the concepts and methods are the same, and eventually the problems are the same. For high-fidelity trustworthy models we needed and need appropriate data sources that still do not exist in almost all industries, even in high-tech cutting-edge manufacturing facilities, after decades of trying to achieve digital factories, smart factories, and the like. The only difference compared to the approaches of the past is that our computer equipment that is used to analyze the data, build models, and run simulations became much more capable over the years: it is considerably faster and has more memory. This means that we can have more model details, more simulation runs, and improved methods for analyzing data and building models such as machine learning. But this is just an evolution of the same old concept and nothing that is fundamentally new.

SUMMARY

In this panel paper, the panelists' statements are meant to aid researchers and manufacturers to have a better understanding of the concept, definition, challenges, and modeling requirements of digital twins. Two panelists also provided implementation examples to explain the digital twin concept and reported lessons learned. The panelists' statements represent their preliminary thoughts. The panelists may have different viewpoints, but all these viewpoints are worthwhile for further investigation and research.

This panel initiated a discussion on the topic of digital twin for smart manufacturing in the simulation community. The implementations of the digital twin concept have been initiated and better received in the design community for monitoring and improving product design (e.g., jet engine or turbines) and performance throughout the product lifecycle (Grieves 2014). It is mainly because of the characteristics of the problems and the relevant technological advances, i.e., the existence of the formal models of the products (e.g., CAD models) and the capabilities of integrating the system representation models with the system analysis models. These factors facilitate the successful implementation of digital twins for products.

The implementation of the digital twin concept in manufacturing has seen multiple approaches used with varying success as clear from the preceding statements of the panel members. The manufacturing community does not have the benefit of widely accepted formal models of the factory configuration or factory control, though there have been some efforts in this direction. The Core Manufacturing Simulation Data (CMSD) standard (Riddick and Lee 2010) developed under the auspices of Simulation Interoperability Standards Organization (SISO) has been used by multiple researchers in the US and Europe for representing factory configuration data with associated simulation data, such as statistical distributions for processing times. Lin and McGinnis (2017) show the feasibility of developing standard reference models for semantics and syntax of semiconductor manufacturing system models. Continued progress of such efforts will facilitate a more common approach for digital twins in manufacturing.

In the WSC community, most of the manufacturing applications are DES models of the manufacturing systems, processes, and supply chains. Some work does use multiple paradigms as pointed out by one of the panelists. Digital twins of manufacturing systems are anticipated to continue to largely use DES models. The simulation community is invited to help the move towards digital twins of manufacturing systems with efforts in the following tentative areas that are likely to get updated during the panel discussion at the conference:

- Agree on a definition of digital twins in manufacturing perhaps with an associated maturity model that allows clear identification of their capabilities at each stage.
- Agree on standard representations for configurations at each level of manufacturing hierarchy (e.g., machine, cell, line, factory, supply chain). The standards may vary for different manufacturing sectors.
- Develop and agree on standard representation of manufacturing control systems at different hierarchical levels. Again, the standards may vary for different manufacturing sectors.
- Enhance the capabilities of real-time model generation and its validation.
- Develop interfaces for model synchronization with its real manufacturing system counterpart.
- Develop standards for interfaces between models with different simulation paradigms.
- Integrate the digital twins with data analytics applications.
- Integrate digital twins' visualization capabilities (e.g., virtual reality(VR), augmented reality (AR), or mixed reality (MR)) if needed.
- Develop standard infrastructure for digital twins for manufacturing in particular for their implementations by small and medium enterprises.

DISCLAIMER

No approval or endorsement of any commercial product by NIST is intended or implied. Certain commercial software systems are identified in this paper to facilitate understanding. Such identification does not imply that these software systems are necessarily the best available for the purpose.

***Abstract*—Despite significant progress in natural language processing, machine learning models require substantial expert-annotated training data to perform well in tasks such as named entity recognition (NER) and entity relations extraction. Furthermore, NER is often more complicated when working with scientific text. For example, in polymer science, chemical structure may be encoded using nonstandard naming conventions, the same concept can be expressed using many different terms (synonymy), and authors may refer to polymers with ad-hoc labels. These challenges, which are not unique to polymer science, make it difficult to generate training data, as specialized skills are needed to label text correctly. We have previously designed polyNER, a semi-automated system for efficient identification of scientific entities in text. PolyNER applies word embedding models to generate entity-rich corpora for productive expert labeling, and then uses the resulting labeled data to bootstrap a context-based classifier. PolyNER facilitates a labeling process that is otherwise tedious and expensive. Here, we use active learning to efficiently obtain more annotations from experts and improve performance. Our approach requires just five hours of expert time to achieve discrimination capacity comparable to that of a state-of-the-art chemical NER toolkit.**

***Index Terms*—Named Entity Recognition, Machine Learning, Word Embedding, Active Learning, Polymers**

I. Introduction

A wealth of valuable research data is published in unstructured form in millions of scientific articles each year. Reading and extracting pertinent information from those articles has become an unmanageable task for scientists and makes it hard to build on existing results. A major obstacle to scientific fact extraction is the difficulty of identifying scientific entities in text. Despite much progress in natural language processing (NLP), scientific named entity recognition (NER) remains a research challenge. The main reason for this gap between NLP advances and scientific extraction needs is the lack of carefully annotated datasets for specific targets. In standard NER, progress is made possible by, for example, the Conference on Computational Natural Language Learning (CoNLL) dataset, which supports much work that advances the state of the art. But NER systems trained on CoNLL data do not perform well for scientific text, due to the distinctive vocabularies used in different scientific disciplines and subdisciplines.

Science-specific training datasets have been established in biology [1] and, more recently, chemistry [2]. However, the expert effort required to design extraction schema, define clear annotation rules, and generate training data is substantial, and cannot feasibly be performed for every field of science. As a consequence, annotated datasets do not exist in most fields, preventing the application of state-of-the-art NER and fact extraction methods.

This problem is apparent in materials science, where materials informatics seeks to combine large datasets and computational models to replace current trial-and-error materials design processes with targeted materials design, thus reducing time-to-market and development costs of new materials [3]. Unfortunately, the lack of annotated training data has hindered progress, preventing large-scale application of NER methods pioneered in, for example, biomedicine. Those methods, which often use hybrid rule-based, machine learning, and statistical techniques to extract entity names and relations from the literature [4, 5], require much training data. While similar efforts have begun in materials science [6–10], the lack of available training data impedes rapid progress. Instead, each new research project targeting a new type of material, property, or relation must first undertake considerable effort to create a large, carefully annotated training set tailored for this new target, a task that often requires considerable in-depth domain knowledge.

The subfield of polymer science puts these problems in particularly stark relief. Polymers have their own unique nomenclature, as we explain below, and thus annotated datasets created for general chemistry are of little value. Scientists and engineers lack access to a freely available large database of polymers and their properties. To address these challenges, we have previously designed polyNER [11, 12], a system for generating training data for scientific NER using semi-supervised and supervised learning. PolyNER uses NLP to produce sets of candidate entities, which experts approve or reject via a Web interface; the resulting labels are used to train context-based word vector classifiers. PolyNER's labels can also be used to train other machine learning models to leverage other features in addition to context, such as word morphology

Tchoua, Roselyne; Ajith, Aswathy; Hong, Zhi; Ward, Logan; Chard, Kyle; Audus, Debra; Patel, Shrayesh; de Pablo, Juan. "Active Learning Yields Better Training Data for Scientific Named Entity Recognition." Paper presented at 2019 IEEE 15th International Conference on e-Science (e-Science), San Diego, CA, US. September 24, 2019 - September 27, 2019.

to recognize target entities. The goal is to substitute the labor-intensive processes of assembling a large manually annotated corpus (and reduce costs) by using small numbers of carefully selected candidates to be labeled via focused expert input. We aim in our work to slash the expert time and effort required to achieve state-of-the-art NER performance in a new field.

In this paper, we seek to improve polyNER's performance by improving the labeling process and the classification of entity word vectors. Specifically, we address two challenges: (1) lack of (expensive) training data in some fields, including our own polymer science application which lacks free access to large polymer databases; and (2) the need for domain expert curators, which impedes the use of crowdsourcing platforms such as Amazon Mechanical Turk [13] or Figure8 (https://www.figure-eight.com/). In the initial labeling phase, we experiment with different *representative* (commonly used) entities to increase the fraction of target entities in the dataset to be labeled and bootstrap the context-based word vector classifiers. In the subsequent labeling and classification steps, we use active learning with maximum entropy uncertainty sampling and two different pools of unlabeled data to train classifiers, and compare their learning rate after five rounds. Using labels generated via active learning, we train word vector classifiers and achieve NER performance comparable to a modified version of a state-of-the art rule-based chemical entity extraction system, ChemDataExtractor (CDE) [9]. We have previously enhanced CDE with dictionary- and rule-based methods for identifying polymers [14]. Our system, however, took five hours of expert time to achieve this result.

The rest of this paper is as follows. In Section II, we motivate the need for identifying polymer names in text. We review semi-supervised methods for NLP systems in Section III. We describe the design and implementation of our active learning-based approach in Section IV. We evaluate our approach in Section V. We summarize and discuss future work in Section VI.

II. Motivation

Our work is generally motivated by the need to extract previously unmined scientific entities; our initial goal is to enable machine-learned extraction of polymer names. The challenges of polymer science NER are similar to those in biomedicine [2, 15]. Entities can be described with multiple referents (synonymy). Conversely, the same word may refer to different concepts depending on context (polysemy). For example, *polystyrene* is often referred to as *PS*, but *polystyrenes* can also be referred to as *GPPS*, *HIPS*, and *EPS*; combined with other monomers yielding *SBR*, *SBS*, and *ABS*; or used to describe polystyrene derivatives such as *PAMS*, *PMS*, and *PSS*. While standards for naming polymers exist (e.g., International Union of Pure and Applied Chemistry (IUPAC [16]) naming conventions), they are not always followed in practice [17]. Instead, polymer names may be reported as source-based names (based on the monomer name), structure-based names (based on the repeat unit), common names (requiring domain specific knowledge), trade names (based on the manufacturer), and names based on chemical groups within the polymer (requiring context to fully specify the chemistry), generating variability in naming conventions. Typographical variants (e.g., alternative uses of hyphens, brackets, spacing) and alternative component orders cause more variations between polymer names in the literature. The origin of these different naming conventions is linked to the desire for clarity within a journal article, coupled with the often-complicated monomeric structures [18].

In addition to challenges related to the makeup of the scientific entities, the scarcity of entities in scientific literature and the lack of training data also impede the use of machine learning based NER techniques. Considerable time and manual effort are involved in creating and maintaining the balanced CoNLL dataset for standard NER [19]. Example sentences from such corpora include one or more entities per sentence. In our attempt to recognize polymer names in full text documents, we face a very imbalanced dataset where most sentences do not contain a target entity, as there are only a handful of target entities per document. While there has been much interest in machine learned recognition of biochemical entities [7–9, 20], the successes that have been achieved have required much human effort to generate quality training data [2]. Previous work has also found that even state-of-the-art NER systems rarely perform well when applied to different domains [21]. Therefore, the problem of training machine learning models to recognize new scientific entities in a new field, such as polymer science, remains challenging.

III. Related Work

NER and other information extraction tasks rely on a large amount of training data, which are expensive to obtain. Weakly supervised learning methods work with much less training data and aim to address this challenge. They generally fall under two categories: semi-supervised learning and active learning [22]. The key difference between the two is that the former relies on approximately labeled data (as opposed to correctly labeled data for supervised learning) and the latter starts off with unlabeled data. Semi-supervised learning attempts to label data automatically by using prior knowledge and a set of labeled data. For example, it assumes that if x and y are similar, they probably have the same label (first cluster the whole dataset, then label each cluster with labeled data [23]). Active learning assumes there is a source of knowledge, such as a human expert, that can be queried to label a selected batch of unlabeled data.

A. Semi-supervised Approaches

Bootstrapping is a semi-supervised technique, which starts from a small set of seed relation instances and iteratively learns more relation instances and extraction patterns. Snowball [24] which improved the DIPRE system [25], used an intuitive idea to collect new entity relations using a set of seed entity pairs. In the DIPRE system, the intuitive assumption is that, given a few seed entity relations, the text between two known target entities in close proximity of each other describes and constitutes a *pattern* of the relation between the two. Since

Tchoua, Roselyne; Ajith, Aswathy; Hong, Zhi; Ward, Logan; Chard, Kyle; Audus, Debra; Patel, Shrayesh; de Pablo, Juan. "Active Learning Yields Better Training Data for Scientific Named Entity Recognition." Paper presented at 2019 IEEE 15th International Conference on e-Science (e-Science), San Diego, CA, US. September 24, 2019 - September 27, 2019.

that is not the case in practice, the system uses a limited set of regular expressions to limit useful patterns, hence decreasing the number of false positives. A key improvement of Snowball is that its patterns include named entity tags (PERSON, LOCATION, ORGANIZATION, etc.). Given a handful of seed tuples of ORGANIZATION and LOCATION, Snowball attempts to learn the relation *HeadquarteredIn* by assuming that each time the tuples appear in close proximity to each other, the text in between illustrates the desired relation. This text can then be used to discover new tuples, which can in turn be used as seeds for the next discovery round. Of course, organizations may be located but not headquartered in multiple cities; hence it is important to inspect the quality of extraction patterns to reduce noise in the generated output.

Distant supervision maps known entities and relations from a structured knowledge base onto unstructured text [26, 27]. With freely available structured knowledge base such as DBPedia [28] and Freebase [29], it is possible to leverage a large set of known entity pairs to generate training data. Over the past decade, probabilistic approaches have been proposed to allow automatic selection. For example, PaleoDeepDive [26], built upon DeepDive [27], automatically extracts paleontological data from text, tables, and figures in scientific publications. For good performance, such approaches often rely on and extend large databases: for example, PaleoDeepDive uses PaleoDB [30]. The system labels any entity pair that appears in the database as *True*. The user defines features (e.g. if a specific keyword appears between two entities, that pair a certain attribute is labeled *True*, but if the entity pairs are too far apart, another attribute is marked *False*), the system then uses statistical inference to determine the probability that each newly discovered pair of interest is *True*.

Data programming, as used in the Snorkel system [31], has users define *labeling functions* to provide labels for data subsets. Errors due to differences in accuracy and conflicts between labeling functions are addressed by learning and modeling the accuracies of the labeling functions. Under certain conditions, data programming achieves results on par with those of supervised learning methods. While writing concise scripts to define rules may seem to be a more reasonable task for annotators than exhaustively annotating text, it still requires expert guidance. In data programming as in bootstrapping and distant supervision it is important to evaluate the quality of functions and extraction patterns to decrease noisy patterns.

B. Active Learning

Active learning [22] assumes that gold standard labels for unlabeled instances can be obtained by querying an oracle (domain expert or source of knowledge). The goal of active learning is to decrease labeling costs by requesting a limited number of labels from the oracle, that have been deemed most valuable by the learner. Uncertainty sampling approaches define “valuable” data by measuring uncertainty in the predictions. For example, in the case of a single learner, querying predictions with maximum entropy in which the learner assigns all classes with equal probability [32] or predictions closest to the decision boundary in the case of support vector machine classifiers [33]. In the case of multiple learners, query-by-committee requests labels for unlabeled instances on which the learners disagree the most [34]. Uncertainty sampling and query-by-committee are representative approaches based on informativeness, where informativeness measures how well an unlabeled instance helps reduce the uncertainty. Another selection criterion addresses representativeness, which measures how well an instance helps represent the structure of input patterns; in this case selection is made by querying data from unlabeled clusters of data [35, 36].

C. CDE and CDE+

We introduce briefly ChemDataExtractor (CDE), a state-of-the-art chemical NLP tool that combines a dictionary, expert-created rules, and machine learning algorithms. CDE was trained on the CHEMDNER corpus: a collection of 10 000 PubMed abstracts with 84 355 chemical entity mentions labeled manually by expert chemistry literature curators, following annotation guidelines specifically defined for this task [2]. In previous work, we modified CDE with manually defined polymer identification rules [14], creating what we term here CDE+. We compare our methods against both CDE and CDE+ in Section V.

D. Placing polyNER in Context

PolyNER has in common with prior work that it combines semi-supervised and active learning [35, 37]. The initial sampling of unlabeled data is similar to bootstrapping but applied to named entities rather than entity pairs. The initial batch of labels contains strings deemed *similar* to a few seed entities, with similarity determined by using word representations and vector distance measures. As this approach is approximate and is likely to include errors (words that have similar context to entities but are not actual entities), the next phase is expert labeling. Subsequent batches of labels are obtained via active learning and used to train a context-aware word vector classifier in the last phase. PolyNER can be used in a way that complements other scientific NER approaches. For example, it could be used as a scientific entity tagger (i.e., recognizer) to be used with data programming to extract polymer properties.

IV. Design and Implementation

As previously mentioned, our main goal in designing polyNER is to slash labeling costs by reducing the time and effort spent by experts to generate training data. Rather than labeling entire documents and phrases, annotators label proposed candidate entities to be classified. Earlier results show that with two hours of labeling we can achieve precision or recall (but not both) on par with state-of-the-art domain specific software, by selecting an ensemble of classifiers for discrimination [12].

Here, we refine polyNER components and incorporate active learning with different sampling strategies in order to further improve performance. PolyNER uses word representations and minimal domain knowledge (a few seed entities) to produce a small set of candidates for expert labeling; labeled candidates are then used to train named entity word vector classifiers. We integrate an active learning loop into polyNER's architecture to incrementally improve classifier performance.

In order to explore whether the use of word vector coordinates as features can accelerate the learning process, we define and compare three alternative sampling strategies: a random strategy that we use as a baseline, and two NLP-based filtering methods. We also apply these methods against two different candidate pools, one set of unlabeled nouns and another set of approximately labeled nouns deemed *similar* to commonly used known entities from our corpus. We describe our sampling strategies and approximate labeling in more details in this section. The general architecture of polyNER is illustrated in Figure 1. We also describe the labeling process, and the training and testing configuration for our word vector classifiers in Section IV-F

A. Computing Word Embeddings

A word embedding method maps each word in a document to a vector in an n-dimensional real vector space that represents the linguistic context in which the word appears. This mapping may be based, for example, on co-occurrence frequencies of words. We can then determine the similarity between two words by computing the distance between their corresponding vectors in the feature space.

We use Word2Vec, a recent, light-weight and easy-to-use implementation of context-based vector representations [38, 39]. Specifically, we use the Gensim continuous bag-of-words (CBOW) implementation of the Word2Vec algorithm [40] to generate vectors. Prior parameter tuning indicated that window size and vector size did not have a significant impact on the yield of polymers (less than 5%) on initial bootstrapping (see Section IV-C below). Nevertheless, for slightly higher yields, we set the Word2Vec `size` parameter to 100 and the `window_size` to 2; where `size` is the size of the vector, and `window_size` is an adjustable window of surrounding context word used to compute each embedding.

B. NLP-Filtering

The NLP filtering preprocessing step removes strings that are unlikely to be polymer referents. Hypothesizing that names of scientific entities will not, in general, be English vocabulary words, we also remove words found in the SpaCy dictionaries of commonly used English words [41]. We manually remove common polymer names, such as polystyrene and polyethylene, from the dictionaries. We use SpaCy's part-of-speech tagging functionality to remove non-nouns. We also eliminate strings that represent numbers (including numbers followed by common units) and remove extraneous characters from the beginning and end of each candidates to filter out mispellings. Finally, we remove plurals (e.g., polyamides, polynorbornenes), as they can represent polymer family names. Note that these steps are generalizable and applicable to multiple science fields. We refer to the set of words that results when these filtering operations are applied to our corpus as the *NLP-filtered candidates*. This set is the output of step 1 in Figure 1.

C. Initial Bootstrapping and Labeling

NLP filtering reduces the number of entities to be considered, and increases the target vs. non-target entity ratio. However, there still remain a large pool of potential candidates from which entities are to be selected, of which, in our experience, roughly 5% are polymer names. In order to avoid presenting experts with mostly negative examples, hindering meaningful classification, we boost the number of polymer entities in the first batch of candidates to be annotated by selecting strings with low word vector distance (see Section IV-A) from a set of *seed entities*: words that are observed to occur frequently in a subset of publications, or that are suggested by experts. We discuss this distance metric in more detail below. Based on preliminary experiments, we set the size of each batch of strings to be labeled to 200, or about an hour of expert time. We then train the initial classifier on this bootstrap set, using 80% of the data for training and 20% for testing. We subsequently used three different sampling strategies for following classifications.

D. Sampling Strategies

We implement three sampling strategies, which we refer to as *Random*, *Uncertainty-Based Sampling (UBS)* and *Distance Uncertainty-Based Sampling (Distance UBS)*. We apply each of these strategies to our NLP-filtered candidates to determine which candidates to present to experts for labeling.

1) Random: Here, we randomly select 200 of the NLP-filtered candidates.

2) Uncertainty-Based Sampling (UBS): Our second strategy applies maximum entropy sampling to the NLP-filtered candidates. As previously mentioned, maximum entropy selection is an uncertainty sampling method that identifies data points for which a classifier predicts outcomes that lie near the decision boundary between classes. Thus, when predicting whether or not a word vector represents a polymer, maximum entropy arises when the classifier assigns equal probability to the polymer and not-polymer cases. As we have two classes, this equal probability is 0.5. We use the classifier to obtain a probability p for each NLP-filtered candidate. We select the 200 entries for which p is closest to 0.5 as our sample.

3) Uncertainty-Based Sampling with Distance Ranking (Distance UBS): Our third strategy is identical to UBS, except that it works with just a subset of the NLP-filtered candidates, namely the 10 000 that are closest to a set of seed entities. The intuition here is that a candidate is more likely to be a target referent (a name, acronym, synonym, etc.) if it used in a similar context. For example, the polymer name "polystyrene" in a sentence "The melting point of polystyrene is ..." suggests that X may also be a polymer in the sentence "The melting point of X is ...".

We use the word embeddings introduced in Section IV-A to capture this notion of context, and vector distance between word vectors as a measure of similarity. Whether or not this

approach works in practice will depend on whether polymer names are in fact used in consistent contexts as captured by our word embedding vectors.

We can then determine, for each NLP-filtered word, the extent to which it occurs in a similar context to the seed entities, by computing the similarities between the word's vector and those for our seed entities. As we explain in Section V-B, we experiment with one and more seed entities; when dealing with multiple seed entities, we use the lowest distance score for ranking candidates.

E. Bootstrapping

The UBS and Distance UBS sampling methods use a classifier to determine which NLP-filtered entities should be chosen next for expert labeling. This classifier must be trained, and thus we need an initial set of entities to bootstrap this process. We could choose NLP-filtered entities at random for initial labeling, but that choice is unlikely to perform well due to the low proportion of polymers (just 5%) in the NLP-filtered corpus. Instead, therefore, we create an initial bootstrap set comprising the 200 NLP-filtered entities that are closest, in word distance vectors, to a set of seed entities. We then train the initial classifier on this bootstrap set, using 80% of the data for training and 20% for testing.

F. Active Learning Loop

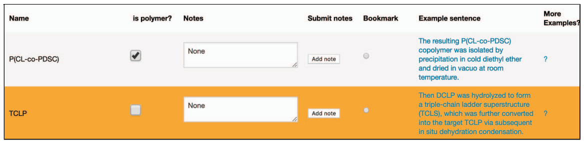
We now discuss our active learning process. As discussed in Section III-B, the basic idea here is that we repeatedly select a set of 200 candidate entities (a "sample") for expert labeling, based on what we have learned from previously labeled entities. We run this process independently with the Random, UBS, and Distance UBS sampling strategies, in order to compare their performance.

1) Use and Evaluation of Classifiers: Not specified in Section IV-D is the nature of the classifier that the UBS and Distance UBS strategies use to estimate the probability of each entity in the NLP-filtered corpus (or, for Distance UBS, the 10 000-entity subset of the NLP-filtered corpus) being a polymer. (The Random strategy does not use a classifier for sampling, as it selects candidates at random.) As we have no prior knowledge of the distribution of target entities in the vector space, we consider seven distinct classifiers in each round of the active learning process: the scikit-Learn [42] implementations of Decision Tree, Gradient Boosting, K-Nearest Neighbor (KNN), Logistic Regression, Linear Support Vector Machine, Naive Bayes, and Random Forest. In each case, we use the word embedding for each string as input features. In each round i, we train these seven classifiers on the sample data gathered in rounds j, $j<i$, and then use the classifier with the highest recall to determine the p scores that UBS and Distance UBS use when assembling their 200-entity sample in that step. (We use recall, or retrieving a maximum of targets, as a measure of performance, because we want to favor extracting a higher number of targets, potentially requiring additional curation, over obtaining fewer correct targets.)

The 200 entities in the new sample are passed to experts for annotation, and the annotated data are added to the set of training data used in the next learning round.

2) Expert (and Non-expert) Labeling: We engage two domain experts to annotate the candidates generated by the *UBS* and *Distance UBS* sampling strategies. Each expert annotates one strategy; we also perform crosschecking for 10% of the first batch of labels, to get a measure of agreement between experts, with results reported in Section V-C. Experts use a web interface (see Figure 2) to approve or reject candidates, a task that is far more efficient than reading and annotating words in text. The interface provides example sentences as context for ambiguous candidates and allows the expert to access the publication(s) in which a particular candidate appears.

We aim to reduce the amount of costly expert time used to obtain labels. Therefore, for our baseline of randomly sampled NLP-filtered nouns, we experiment with a two-phase review process. Tokenization is one of the largest sources of error for scientific entities such as polymers, which contain characters such as ':', '(', '–', ',' etc. Tokenization can also generate incoherent tokens from text, equations, captions, etc. Such obvious non-candidates can be fairly easily detected by non-experts. For example, an untrained human annotator may be able to recognize that '$d\Sigma/d\Omega)(Q$' is not a polymer name, and thus save time for the experts. Hence, we assigned two graduate student labelers to curate the candidates generated by the random sampling strategy, which are less likely to contain



Name	is polymer?	Notes	Submit notes	Bookmark	Example sentence	More Examples?
P(CL-co-PDSC)	☑	None	Add note	○	The resulting P(CL-co-PDSC) copolymer was isolated by precipitation in cold diethyl ether and dried in vacuo at room temperature.	?
TCLP	□	None	Add note	○	Then DCLP was hydrolyzed to form a triple-chain ladder superstructure (TCLS), which was further converted into the target TCLP via subsequent in situ dehydration condensation.	?

Fig. 2: Web interface for expert review of candidates. The expert indicates whether the name (column 1) is a polymer (tickbox in column 2), providing notes if desired (column 3). Clicking on "?" delivers up to 25 more example sentences.

target entities. We asked these untrained labelers to reject obvious non-candidates via the previously mentioned web interface. Our experts then reviewed the remaining candidates, indicating for each whether it is in fact a polymer referent.

V. Evaluation

We first report on a study in which we evaluate the generation of candidate entities using vector distances from representative (frequently used) entities. We then discuss the results of initial classification and subsequent four rounds of active learning using multiple word vector classifiers and our three sampling strategies: random, UBS, and Distance UBS. Finally, we experiment with word representations enhanced with character-level information using FastText [43, 44].

In this work, we evaluate extraction accuracy in terms of precision and recall. *Precision* refers to the fraction of predicted positives that are labeled correctly and *recall* to the fraction of actual positives that are labeled correctly.

A. Dataset

We reuse a corpus of 1690 full-text publications in HTML format from *Macromolecules*, a relevant journal in polymer science [12]. These documents comprise 381 947 sentences and 9 229 417 (253 195 unique) words or "tokens," of which 23 205 pass the NLP filter of Section IV-B. From this corpus, we set aside a test set of 100 documents with 22 664 sentences and 508 391 (36 293 unique) tokens, of which 9656 pass the NLP filter. Six experts identified all one-word polymer names in this test set, a process that produced 467 unique one-word polymer names. We use these 467 names as a gold standard in subsequent subsections; we automatically label all NLP-filtered strings from the 100-document test set using these manually extracted names.

B. Seed Entities

Recall from Section IV-A that polyNER uses the Word2Vec word embedding tool to compute a word vector for each word. In order to maximize the number of actual entities in the dataset—and the ratio of target to non-target entities—in the initial set of labels, we explore how the choice of seed entities impact the number of target entities retrieved. While we cannot expect meaningful classification using only positive examples, given the imbalance in the whole dataset, we aim to select the Word2Vec parameters that yield the highest ratio of polymers in this initial batch of candidates.

In the experiments that follow, we use the 467 gold standard polymer names identified by experts in our 100-document test set to evaluate performance with different seed entities. Specifically, for each choice of seed entities that we want to evaluate, we determine the 10 000 NLP-filtered words with vectors closest to the seed entity vectors, and report what fraction of the 467 gold standard names are included in that 10 000. We use lower-case exact string matching between the gold standard polymer names and the proposed distance candidate strings to determine if a candidate is a polymer.

In previous work using the same corpus [45, 46], we built a dictionary of polymer names by using a rule-based approach and aggregating synonyms across ChemDataExtractor records. (A record consists of all information found about a chemical entity in a document.) Here we use this dictionary to identify the 10 most frequently occurring polymers in our corpus and their acronyms. We assume that frequent polymers provide a large number of sentences that illustrate context in which polymers are commonly used. Hence, we first test the most frequent, the three most frequent, and the ten most frequent polymers as seed entities. We also experiment with including and excluding their acronyms as additional seed entities. (Note that this modest set of 1, 3 and 10 seed entities could also be suggested by an expert.)

Rows 1–6 of Table I shows the results for these experiments. When using *polystyrene* (the most frequently used name) as a seed entity, the candidates contained 33.6% of the 467 gold standard polymers. We note a 2% increase in the fraction of polymers retrieved when using both *polystyrene* and *PS*, when compared to using *polystyrene* alone. The fraction of polymers increases by 10% when we use three representative entities (the three most frequent polymers in our datasets are *polystyrene*, *poly(methyl methacrylate)*, and *polyethylene*), but by less than 1% when using 10 instead of three entities. These results suggest that there is little value to using more than a few seed entities.

TABLE I: Fraction of gold standard polymer names in the 10 000 entities that are closest, by word vector distance, to various sets of seed entities.

#	Seed entities	Fraction of polymers extracted
1	Polystyrene	35.6%
2	Polystyrene, with acronym PS	37.7%
3	Three most frequent polymer names	46.9%
4	Three most frequent polymer names, with acronyms	48.0%
5	10 most frequent polymer names	46.5%
6	10 most frequent polymer names, with acronyms	48.4%
7	χDB polymer names	46.7%
8	crowDB polymer names	36.4%

To further explore whether using larger numbers of seed entities may increase the fraction of polymers retrieved, we conducted a second set of experiments. We have built a small database of polymer properties (χDB) in previous work [45, 46]. Our corpus of 1690 publications included 111 out of 175 χDB polymers. We also scraped CrowDB, which lists some polymers and their properties at http://polymerdatabase.com/

Tchoua, Roselyne; Ajith, Aswathy; Hong, Zhi; Ward, Logan; Chard, Kyle; Audus, Debra; Patel, Shrayesh; de Pablo, Juan. "Active Learning Yields Better Training Data for Scientific Named Entity Recognition." Paper presented at 2019 IEEE 15th International Conference on e-Science (e-Science), San Diego, CA, US. September 24, 2019 - September 27, 2019.

for polymer names; 32 out of 295 scraped polymer names were found in our corpus. We measure how many of our gold standard polymers are identified when these 111 and 32 polymer names are used as seed entities, with results shown in rows seven and eight of Table I. These results confirm that using more entities does not increase the yield of polymers. Thus, in all subsequent experiments, we use the three most frequent polymers and their acronyms as seeds.

C. Labeling

We conduct some experiments to estimate labeling time. We ask two polymer scientists to label 200 candidates from a subset of our corpus. One expert reports 30 minutes, the other 45 minutes. We overestimate the time to label 200 candidates at one hour of expert time. Based on user feedback, we also improve the labeling Web interface after the above mentioned test rounds to further facilitate and speed up labeling. For example, we increase the number of example sentences available to provide context, to decrease the number of occurences in which experts have to look up original publications for candidates. We also increase the size of checkmarks to make it easier to reject erroneous candidates. In the initial labeling round, we perform crosschecking for 10% of the batch of labels. We confirm agreement between labels for all but one of 20: an agreement rate of 95%.

D. The Initial Classifier

Recall from Section IV-E that we use an initial set of 200 NLP-filtered entities that are close to seed entities to bootstrap our labeling process. Once those data are labeled by our experts, we use 80% to train a KNN classifier, validating on the remaining 20%. We then test this *initial classifier* against all 9656 NLP-filtered candidates in the 100-document test set, which as noted in Section V-A contain 467 polymers. Results are shown in Figure 3. Its Receiver Operating Characteristic (ROC) curve shows better-than-random behavior, with an area under curve (AUC) of 0.62. However, in our application, correctly predicting non-polymers is not as important as correctly identifying our targets. Therefore, we also plot in the Precision Recall (PR) curve to show the tradeoff between precision and recall. While the AUC for the initial classifier is above random performance (0.5) its PR curve shows poor precision, regardless of recall. In previous work [12], we found that we could achieve better performance with more labels (897), suggesting that a KNN classifier begins to learn with more data. However, 160 labels (80% of 200) is not yet enough.

E. Comparing Sampling Strategies

After the initial round of labeling, we experiment with the three sampling strategies described in Section IV: Random, UBS, and Distance UBS, performing four rounds of active learning for each. Results, in Table II, show a significant amount of fluctuation and no notable improvement in the first two rounds for any strategy: precision remains under the initial precision of 6.5% for all. However, in the third round, we observe increases in precision, an improvement that is sustained in the fourth round for UBS. Figure 4 shows ROC and PR curves for the three strategies after four rounds. The AUC for UBS is 0.74 and that of Distance UBS is 0.70. The PR curves for both are improved (lifting away from the lower left corner of the graph) over the first round, with active learning performing better with UBS than with Distance UBS. When tested against our gold standard of 467 one-word polymer names, the KNN classifier achieves 18.2% precision and 45.6% recall. We notice that even the random strategy PR curve is improved (away from the initial PR curve and close to the Distance UBS curve), indicating that the NLP-filtering alone is enough to enable the learning process after 1000 labels. We also note that KNN was most-often selected across strategies and iterations; likely due to its inherent nature to optimize locally and our direct focus on finding similarities between observations.

We conclude that while the sampling step helps ensure that the classes are balanced in the initial batch of labels, restricting ourselves to just distance candidates, as is done by Distance UBS, does not yield better results than using active learning with all NLP-filtered candidates (UBS). Intuitively, basic UBS can find *useful* instances (target and non-targets) to be labeled from the entire word embedding space, while examples from Distance UBS are clustered around the seed entities that may be collocated in that space.

TABLE II: Precision and recall relative to the gold standard for the initial classifier (round 0) and the classifiers trained also with the increased data obtained in each of four learning rounds, 1–4.

		Strategy		
Round	**Metric**	**Random**	**UBS**	**Distance UBS**
0	Precision	6.5%		
	Recall	19.1%		
1	Precision	3.8%	3.2%	5.3%
	Recall	0.29%	93.6%	56.8%
2	Precision	1.5%	3.8%	5.4%
	Recall	1.5%	46.4%	10.1%
3	Precision	6.0%	**21.2%**	3.9%
	Recall	44.6%	**40.0%**	84.3%
4	Precision	12.3%	**18.2%**	7.2%
	Recall	33.3%	**45.6%**	51.9%

We selected seed entities based on their frequency in our corpus. This observation suggests that we could also study how the choice of seed entities impact of the performance of the classifier during the active learning process. We revisit this concept of *diversity* of labels in the Section V-G. Note that with limited training data and based solely on context, the classifier retrieves 45.6% (more than one third) of the gold standard polymers with a precision of 18.2%, after five hours of expert labeling. For comparison, an attempt to extract polymer names using the rule: *if the name contains "poly" extract it as a polymer*, gets recall of 41% and precision of 34% on the same dataset. We conclude that with our relatively small and noisy dataset (based on context-only information from entire documents of unstructured and uncurated text), we are able to achieve close to rule-based performance, using active learning and little labeling.

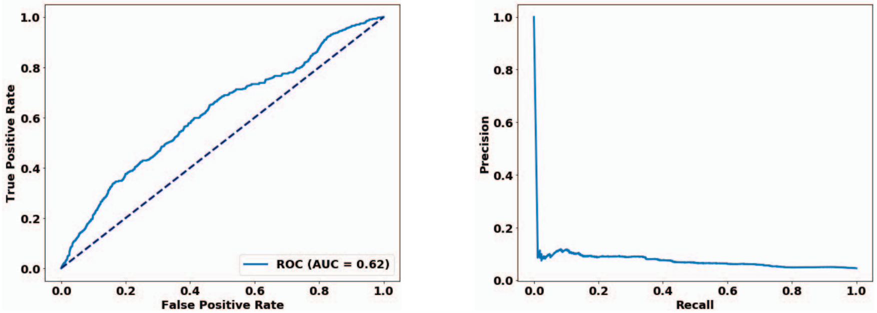


Fig. 3: ROC (left) and PR (right) curves for KNN model for the initial classifier. The PR curve shows that precision is low regardless of recall, indicating that we need more data.

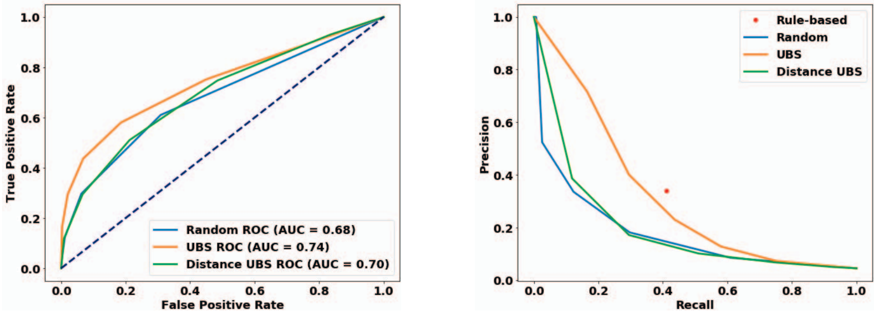

Fig. 4: ROC (left) and PR (right) curves after four rounds. The ROC curves for two active learning strategies, UBS and Distance UBS, show significant improvements, achieving AUCs of 0.74 and 0.70, respectively: significantly better than the 0.62 achieved by the initial classifier in Figure 3. Random achieves an AUC of 0.68. PR curves also show improvements relative to the initial classifier, with all three strategies lifting away from the bottom corner, indicating discriminative capacities. In both types of plots, UBS outperforms Distance UBS and approaches rule-based performance based solely on context information and under five hours of expert input.

F. Active Learning Labels + Character-Level Embeddings

After just 1000 labels, the context-based classifier using active learning applied to NLP-filtered candidates achieved performance comparable to rule-based performance, but not quite as good as the polymer-enhanced CDE+. With the goal of further improving polyNER performance, we experiment with the use of an alternative word embedding model, FastText, which uses word representations enriched with sub-word (character-level) information. Because FastText considers subword information as well as context, it can consider word morphology differences, such as prefixes and suffixes. Subword information is especially useful for words for which context information is lacking, as words can still be compared to morphologically similar existing words. We set the length of the sub-word used for comparison—FastText's `n_gram` parameter—to five characters, based on our intuition that many polymers begin with the prefixes "poly" or "poly(." Therefore, we generate a FastText word embedding model, and generate character-enhanced vectors for our UBS-labeled candidates.

Next, we train a KNN classifier using vectors for the candidates labeled through active learning from the NLP-filtered candidates (the active learning strategy identified as best-performing in Figure 4). We test the classifier against NLP-filtered nouns from our 100-document test set. KNN classifier performance improves when using these word vectors, achieving 29.7% precision and 81.9% recall, comparable to those achieved by CDE (see Section III-C). CDE's recall is high at 74.5%, but its precision for polymers is, as expected, low at 8.7%, as it does not incorporate polymer knowledge. In Figure 5, we show the PR curve for the FastText vector classifier and also results for the polymer-enhanced CDE+, which achieve 42.2% precision and 68.3% recall on the same test set. We achieve higher recall than CDE and CDE+ using labels from UBS and FastText vectors and in-between (higher than CDE and lower than CDE+) precision.

G. Discussion and Future Work

We have previously used seed entities to bootstrap classifiers of context-based word vectors. Using an ensemble of classifiers, polyNER allowed users to tradeoff precision and recall. In this attempt to improve performance, while efficiently using experts' time, we used active learning to obtain more labels. However, we do not observe an increase of precision over the 5% fraction of polymers until the third round of active learning with NLP-filtered words (800 labels). This suggests that our label batch size is lower than the minimum number of labels necessary to start the learning process. More detailed study of performance vs. label batch size will help pinpoint the appropriate number of labels and level of bootstrapping required for learning. We can also ask the following questions: Could we achieve CDE performance classifying only context-based (not character enhanced) representation? If so, how many more iterations would it take? If not, how much do we need to increase the size and/or improve our current corpus of 1690 documents? Corpora for NER tasks are curated and typically include sentences with one or more entities. We could investigate other semi-supervised method to eliminate negative sentences from our corpus (e.g. labeling sentences and classification of sentence vectors for example).

PolyNER achieves CDE performance using labels obtained via active learning (UBS sampling strategy) and FastText vectors. We attribute the increased performance to the character embedding enhancement, which not only recognizes "poly" (and yields more names based on this n-gram comparison), but also filters out more anomalous candidates (preceding or following polymer names) generated during tokenization and missed by the filtering steps, such as "A_mB_n" and "*Mw/Mn=1.36*." In other words, the classifiers of character and (context-based) word embedding vectors perform better than classifiers of only context-based word embedding. Given this result, one may wonder whether the active learning process itself could benefit from using this enhanced vector embedding. To determine whether this is the case, we repeated the active learning experiment using the entire corpus of NLP-filtered candidates and classifying FastText (enhanced) vectors instead of Gensim vectors at each round. However, the performance was worse than random.

These results suggest that character-level information enhances classifier performance only once a certain threshold of context information has been captured by the embedding. We explain this observation as follows. In FastText, the portion of the word embedding vector generated by using context varies depending on how much context is available in the entire corpus. For words deemed to have enough context, vectors do not include any character-level information. At the other extreme, for previously unseen words, the embedding is generated based solely on character n-gram information and comparison to other words in the corpus. During the active learning process, candidates to be labeled by experts are selected by using maximum-entropy-based uncertainty sampling: that is, words for which prediction probability is similar for target and non-target. Such candidates are more likely to lack context and thus have vectors that use mostly character-level information. As a result, the expert is often presented with nearly identical candidates (e.g., PS13k/PMMA12k, PS214k/PMMA12k, PS31.6k/PMMA12k), which hinders the learning process as these candidates are located in close vicinity in terms of the full (character and context) word embedding space. In other words, in this full space, while their uncertainty measure is comparable, these examples are not *diverse*, where diversity is a measure of the distance of the examples to each other or previously labeled instances [47]. One solution to explore in future work would be to impose a diversity constraint on the candidates, for example by using batch active learning [48]. This will be part of broader plan to study the effect of quantity (more documents) and quality (select paragraphs or sentences) of data on the word embedding model and the final results.

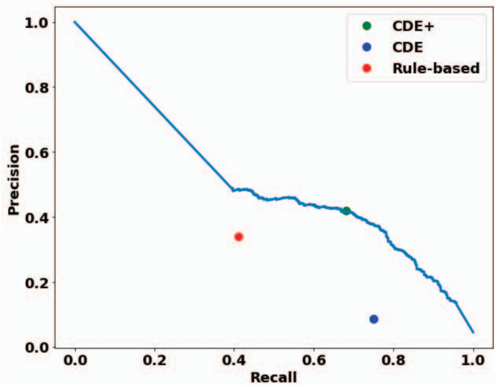

Fig. 5: PR curve for KNN model trained with active learning labels and word representations enriched with character-level information. Results for CDE+ are also shown. Note: PR curves are obtained by varying the threshold of probability that separates classes; straight lines occur when several points have similar probabilities and changing the threshold yields identical precision to recall ratio.

VI. Conclusion

A lack of expert-annotated training data impedes the adoption of machine learning techniques in certain scientific applications. PolyNER overcomes this challenge by using active learning to target expert input so that accurate scientific named entity recognition can be performed at low cost. We show that by using NLP techniques, we can bootstrap a word vector classifier of scientific entities. Using polyNER's labels and a classifier of character-enhanced word embedding vectors, we achieve performance comparable to a best-of-breed hybrid NER model (CDE+) that required much expert development. In contrast, polyNER was trained on data annotated using just five hours of expert time and a little untrained crowd input. Our work highlights the potential for using minimal labeled data and focused expert input to enable machine learning techniques for previously unmined scientific entities. We are currently exploring using polyNER-labeled data to annotate text for other NER approaches, such as bidirectional long short-term memory models. Our code and training dataset will soon be available on DLHub [49] for the public to use for training of machine learning models. Such resources can be used along with other databases and dictionaries such as PPPDB [1] and Khazana [50] for validation purposes. We will also formally explore the hybrid-computer partnership as an optimization problem. In other words, we will work on a more rigorous approach to automatic partitioning and assignment

ABSTRACT

Air leakage through the building envelopes is responsible for a large amount of energy use. The US Department of Energy Windows and Building Envelope Research and Development Roadmap for Emerging Technologies states that, in 2010, air infiltration was responsible for 20% of primary energy consumption attributable to the fenestration and building envelopes of commercial buildings. Despite this fact, improving airtightness is not always recognized by commercial building owners, as they have been slow in acknowledging and diminishing the detrimental effects of air leakage on energy use, comfort, indoor air quality, and building material durability.

The design and construction industry would benefit from a credible, easy-to-use tool that estimates potential energy and financial savings in a standardized manner so designers and contractors can give building owners compelling reasons to invest in reducing air leakage. In 2016–2017, Oak Ridge National Laboratory, the National Institute of Standards and Technology, the Air Barrier Association of America, and the US-China Clean Energy Research Center for Building Energy Efficiency collaborated to develop an online calculator. This user-friendly calculator is free to the public and uses the simulation results of the whole building energy simulation tool EnergyPlus and the airflow simulation tool CONTAM. In 2018–2019, the calculator was expanded to add moisture transfer calculations given that air leakage through the building envelope can have a significant impact on moisture transfer and associated impacts. Four more commercial building types were also added to the existing database of three building types as part of this update. This paper describes the procedure used to calculate moisture transfer due to air leakage and provides examples that demonstrate the moisture transfer for each of the seven commercial building types that are currently part of the calculator.

INTRODUCTION

Envelope air leakage in commercial buildings in the United States accounts for about one quad (1 EJ) of primary energy annually (US Department of Energy [DOE] *Windows and Building Envelope Research and Development Roadmap for Emerging Technologies*), costing approximately $10 billion/year. The roadmap also states that computational tools are critically important for the design of commercial buildings with energy-efficient envelope technologies. As the thermal resistance of commercial building envelopes continues to improve, the relative contribution of air leakage to heating and cooling loads is increasing. As new technologies are developed, models and simulation tools must be updated to account for their performance. One impediment to the broader adoption of continuous air barrier systems into buildings is the lack of a simple, credible tool that can be employed by building architects, designers, and owners to accurately estimate the energy savings that can be expected if building envelope airtightness is improved.

Advances are needed in easy-to-use tools for determining the impact of air leakage to promote more energy-efficient and durable building envelope design. Oak Ridge National Laboratory (ORNL), the National Institute of Standards and Technology (NIST), the Air Barrier Association of America (ABAA),

Shrestha, Som; Desjarlais, Andre; Dalgleish, Laverne; Ng, Lisa; Hun, Diana; Emmerich, Steven; Accawi, Gina. "Moisture Transfer in Commercial Buildings due to the Air Leakage: A New Feature in the Online Airtightness Savings Calculator." and the US-China Clean Energy Research Center for Building Energy Efficiency (CERC BEE) partnered to develop an online energy savings calculator[1], hereinafter referred to as “the calculator” (Shrestha et al. 2016), which calculated the potential energy and costs savings estimates from building envelope air tightening for three building types in 62 cities. The updated calculator now also calculates the reduction in moisture transport from improvements in airtightness, based on pre-and post-retrofit air leakage rates for commercial buildings. The updated calculator also includes four more building types than the original calculator. This article describes the need to add moisture transfer to the calculator, the buildings included in the calculator, the calculator itself, and the procedure used to calculate moisture transfer due to air leakage that is included in the updated calculator.

PREVIOUS STUDIES

Although air leakage through building envelopes has long been recognized as a major contributor to heating and cooling loads, methods that estimate the effects of air leakage on energy consumption vary (Crawley et al. 2008; Goel et al. 2014; Gowri et al. 2009; Ng et al. 2012). Air leakage has also been identified as a significant cause of moisture damage in lightweight constructions as demonstrated by the following studies. Belleudy et al. (2015) state that airtightness has become a considerable challenge over the past few decades in creating low-energy and durable buildings. The study assesses the impact of an airtightness defect on the hygrothermal field in a ceiling section insulated with loose-fill cellulose and separating a heated indoor space from an unheated attic. The experimental and simulation studies were conducted with and without air leakage, and the results show unambiguously that even relatively limited airflow through construction elements has a substantial impact on hygrothermal fields within the building envelope. Janssen and Hens (2003) identify air leakage as a significant cause of condensation problems in lightweight roof systems in cold climates. The study points out a need to incorporate airtightness requirements in building codes and to develop and certify adequate air barrier systems. Tenwolde and Rose (1996) conclude air leakage is one of the primary moisture sources that may increase the risk of moisture problems in wood frame walls. Similarly, Armstrong et al. (2010) identify air leakage as a potential cause of moisture damage in conventional light wood frame walls with exterior insulation that has low water vapor permeability.

PROTOTYPE BUILDING MODELS USED IN THE CALCULATOR

The calculator (described in the next section) uses DOE commercial prototype building models (DOE 2019) developed by DOE in EnergyPlus[2] (Deru et al. 2011) as a standardized baseline for energy savings calculations, and in part to support the development of ANSI/ASHRAE/IES Standard 90.1, *Energy Standard for Buildings except Low-Rise Residential Buildings*. The envelope assembly and heating, ventilating, and air conditioning (HVAC) units for each of the prototypes vary based on geographical location and the version of ASHRAE Standard 90.1 with which the prototype building was modeled to comply. A scorecard of each prototype building model, provided by DOE (DOE 2019), summarizes the building descriptions, thermal zone internal loads, schedules, and other key modeling input information.

The prototype models cover 16 commercial building types that represent about 80% of commercial

[1] https://airleakage-calc.ornl.gov/#/

[2] https://energyplus.net/

buildings in the United States in 17 climate locations defined in ASHRAE/IES Standard 90.1-2013 (ASHRAE 2013). Figure 1 shows the prototype buildings as a percentage of total US commercial building floor space. These are depicted in Figure 1 by a solid green-colored bar and represent over 55% of US commercial floor space. Figure 2 shows the renderings of the seven commercial prototype building models available in the calculator. Table 1 shows the floor area, number of floors, five-sided envelope area (exposed to ambient conditions), and six-sided envelope area of the 16 commercial prototype building models.

The variables defined in these models include building envelope components, HVAC equipment types and efficiency, and occupancy schedules. As ASHRAE Standard 90.1 evolves, Pacific Northwest National Laboratory modifies these models with input from ASHRAE Standing Standard Project Committee 90.1 members and other building industry experts. Features of the building models and a detailed description of their development are provided by Goel et al. (2014) and the Building Energy Codes Program website (DOE 2019).

The selection of the included cities was based on consideration of the major metropolitan areas throughout the United States; therefore, not every state or province is represented. If a specific city of interest does not appear on the list, it is recommended that the user select a city that has similar meteorological conditions (wind, temperature, solar radiation, and rain). This is not always the city geographically closest to the target city. For example, Minneapolis (MN) is in climate zone 6A and commercial prototype building models are not available for Minneapolis; so, the models for Burlington (the representative city for climate zone 6A), along with the weather file for Minneapolis, were used to run simulations for Minneapolis. Models that represent typical commercial buildings in Canada and China are not available in the public domain; therefore, the DOE prototype building models were used in these two countries. US cities where the commercial prototype building models were available, and where the climate matched the five cities in Canada and China, were used to model the buildings in those countries.

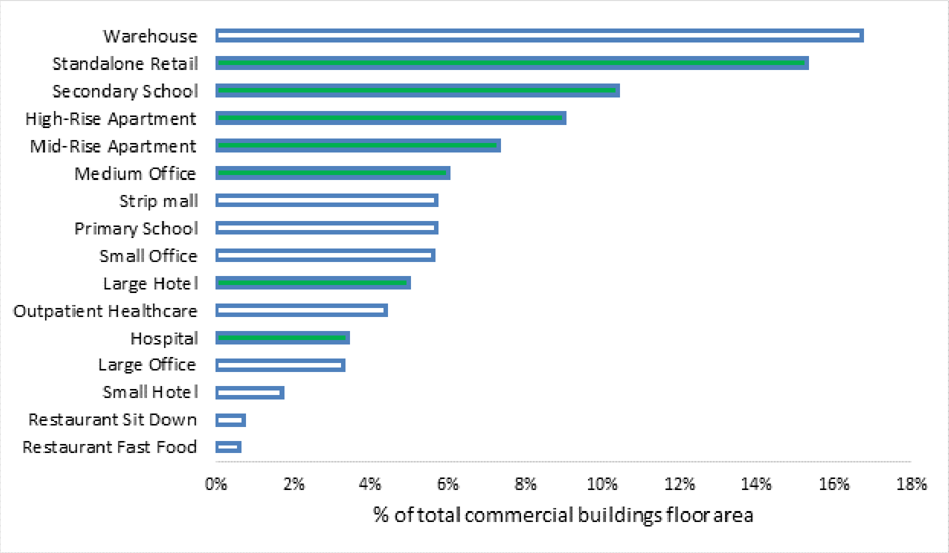

Figure 1. Prototype buildings as a percentage of total US commercial building floor space.

THE CALCULATOR

The calculator uses a database of pre-run simulation results from DOE's whole-building energy simulation software EnergyPlus for the DOE commercial prototype buildings. The main difference between the online calculator and the procedure followed in the DOE prototypes to account for infiltration (or "air leakage") is that the calculator uses CONTAM-calculated air leakage rates as inputs into EnergyPlus, whereas the prototype models make more simplified assumptions regarding air leakage. CONTAM (Dols and Polidoro 2016) is a multizone airflow and contaminant transport analysis software developed at NIST. This software considers multiple factors, such as weather conditions, envelope airtightness, and HVAC system operation, to calculate air leakage rates through building envelopes. The CONTAM-calculated hourly air leakage rates are converted into the format required by EnergyPlus using the CONTAM Results Export Tool (Polidoro 2016). EnergyPlus is then used to calculate the effects of air leakage on energy consumption and moisture transport.

Typical energy simulations tend to simplify their analyses by assuming constant air leakage rates or using simplified algorithms that can lead to less accurate energy usage estimates. Ng et al. 2018 estimate that these simplifications in the EnergyPlus models for the prototype commercial buildings lead to underestimations of average electrical and gas use for heating and cooling. Shrestha et al. 2016 show that the discrepancy in the predicted cost savings could be as high as 40%.

The moisture transport calculation in the calculator (as described below) computes the total amount of moisture that could be transported through the building envelope as a result of air leakage, assuming no loss or gain while traveling through the building envelope. It is a measure of the potential moisture source but does not quantify how much moisture is accumulating in the wall assembly. The hypothesis is that more moisture transported through the wall, the higher the likelihood it will create a durability issue and other moisture-related problems such as mold growth.

Figure 3 shows the input page of the calculator. The user input parameters are location (country, state, city), building type (one of the seven building types from the drop-down menu), floor area, building envelope leakage rate at 75 Pa (0.3-inch water column), "base case", and reduced air leakage after improving envelope airtightness, the "retrofitted building", and unit energy cost (electricity and natural gas). Location can be selected either by using drop-down menus or by using the map. Cities available in the database are highlighted with red flags on the map. Once the building type is selected, the default footprint of the corresponding prototype building is displayed. However, the user can change the floor area to their building footprint. The calculator prorates the energy savings and moisture transport results based on the floor area input by the user. Descriptions of each input variable and recommendations can be obtained by pressing the help button. The calculator allows data input in either SI or imperial units.

Figure 3. Input page for the Energy Savings and Moisture Transfer Calculator.

The output screen is shown in Figure 4. A summary of the user inputs is posted at the top of the page. The calculator determines the equivalent leakage area at 4 Pa (0.3-inch water column) (ELA) for the base case and the retrofitted building. This is calculated using Chapter 16 in the *ASHRAE Handbook—Fundamentals 2017*. When the ELA is calculated, all openings in the building shell are combined into an overall opening area and discharge coefficient for the building. The ELA of a building is, therefore, the area of an orifice with an assumed value of discharge coefficient that would produce the same amount of leakage as the building envelope at the reference pressure. The calculator also calculates the amount of energy saved (electricity and natural gas) and the cost savings in the currency of the country. Finally, the calculator computes the total amount of moisture that could be transported through the wall for both the base and retrofitted cases.

Table 2 compares the moisture transfer at an envelope leakage rate of 7.7 L/(s•m^2) (1.5 cubic feet per minute (CFM)/ft^2) and 1.25 L/(s•m^2) (0.25 CFM/ft^2) at 75 Pa (0.3-inch water column) for the seven building types in Chicago, including the percent reduction in the last column as a result of the increase in building envelope airtightness.

Table 2. Moisture Transfer for all Buildings at Two Different Airtightness levels at Chicago, IL

Building Type	Moisture Transfer, kg/(m^2•year)		Reduction in Moisture Transfer, kg/(m^2•year) (% reduction)
	At 7.7 L/(s•m^2)	At 1.25 L/(s•m^2)	
Standalone Retail	105.7	11.6	94.2 (89)

EXAMPLE CALCULATIONS

This section presents example calculations for the DOE High-Rise Apartment prototype building model using the updated calculator. The relevant characteristics of this prototype model are based on ASHRAE 90.1-2013 and listed in Table 1. The scorecard for High-Rise Apartment building shows that this building was modeled with an air leakage rate of 1 L/(s•m^2) (0.2 CFM/ft^2) of exterior envelope area at 4.47 m/s (880 ft/min) wind speed. In the EnergyPlus model of this building, infiltration is modeled using the "ZoneInfiltration:DesignFlowRate" method that calculates infiltration using Eq. (1).

$$Infiltration = \left(I_{design}\right)\left(F_{Schedule}\right)\left[A + B\left|\left(T_{zone} - T_{odb}\right)\right| + C\left(WindSpeed\right) + D\left(WindSpeed^2\right)\right] , \qquad (1)$$

where

I_{design} = design infiltration volume flow rate normalized by exterior surface area, m^3/(s•m^2)

$F_{schedule}$ = the schedule that modifies the design infiltration volume flow rate

T_{zone}, T_{odb} = the indoor and outdoor air dry-bulb temperatures, °C

The EnergyPlus model of the High-Rise Apartment prototype building uses I_{design} = 0.57 L/(s•m^2) (0.11 CFM/ft^2), $F_{schedule}$ = always 1, coefficients *A, B,* and *D* = 0, and *C* = 0.224. This simplified approach to modeling infiltration in the prototype building models does not consider the effects of indoor-outdoor temperature differences, HVAC operation, or wind direction on air leakage. In contrast, the online calculator uses CONTAM to estimate air leakage rates, which considers all these factors mentioned while accounting for multizone building airflow physics.

Table 3 lists the four levels of air leakage rates that were used in the simulations of the High-Rise Apartment building. These calculations assume the air leakage is equally distributed over all exterior surfaces and include the slab and below-grade envelope area in the normalization of the air leakage rate, which is why they are referred to as 6-sided leakage values. The 6-sided value is used as the requirement in many building codes and standards; however, the CONTAM and EnergyPlus models assume no air leakage through any part of the exterior envelope that is not exposed to ambient air. The baseline value in Table 3 was calculated using the average building envelope airtightness for commercial buildings reported by Emmerich et al. 2005, 9 L/(s•m^2) (1.8 CFM/ft^2) at 75 Pa (0.3-inch water column) for a 5-sided envelope. The baseline of 7.7 L/(s•m^2) (1.5 CFM/ft^2) at 75 Pa (0.3-inch water column) was obtained by multiplying the 5-sided value by the 5-sided-to-6-sided envelope area ratio of the High-Rise Apartment building prototype. Table 3 also lists three target levels for improved airtightness at 75 Pa (0.3-inch water column): 2 L/(s•m^2) (0.4 CFM/ft^2) is the most stringent of three options and is found in the 2015 International Energy Conservation Code (IECC 2015) because it involves a blower door test, whereas the other two options are based on laboratory tests using ASTM E2357 and ASTM E2178. The airtightness required by the US Army Corps of Engineers is 1.25 L/(s•m^2) (0.25 CFM/ft^2) (USACE 2012); and 0.25 L/(s•m^2) (0.05 CFM/ft^2) is used to estimate performance at lower leakage rates. Emmerich and Persily (2014) analyzed the NIST US commercial building air leakage database and found that the 79 buildings categorized as having air barriers had an average 6-sided leakage of 1.39 L/(s•m^2) (0.27 CFM/ft^2) at 75 Pa (0.3-inch water column), which was 70% below the average leakage rate of the 290 buildings without air barriers (i.e., 4.33 L/(s•m^2) (0.85 CFM/ft^2) at 75 Pa (0.3-inch water column)); the former rate is similar to the second target level above. Zhivov (2013) reported the average 6-sided leakage for a set of 285 new and retrofitted military buildings constructed to the USACE specifications to be 0.9 L/(s•m^2) (0.18 CFM/ft^2).

Table 3. Assumed 6-Sided Building Envelope Airtightness Levels for the High-Rise Apartment

Case	Air Leakage Rate at 75 Pa (0.3-inch water column), L/(s•m^2) (CFM/ft^2)	Source
Baseline	7.7 (1.5)	Emmerich et al (2005)
1	2.0 (0.39)	IECC (2015)
2	1.25 (0.25)	USACE (2012)
3	0.25 (0.05)	

The annual total amount of moisture that is transported through the building envelope due to air leakage (M_W) is calculated using Eq. (2).

$$M_W = \sum_{i=1}^{n} \sum_{h=1}^{8760} \dot{m}_{a_{i,h}} W_h \,, \tag{2}$$

where

$\dot{m}_{a_{i,h}}$ = hourly mass flow rate due to air leakage for each zone

W_h = hourly humidity ratio of the outdoor air

i = zone number

h = hour of the year

n = number of zones (e.g., the High-Rise Apartment building model has 90 zones)

Figure 5 shows the annual moisture transfer through the building envelope due to air leakage at four envelope airtightness levels for four cities (Miami, FL; Chicago, IL; Phoenix, AZ; and Winnipeg, Canada) for the High-Rise Apartment building. These cities cover the range in annual moisture transfer for all cities included in the calculator. Figure 5 also shows the quadratic regression equations for each city and the coefficients of determination for the regression equation. Similar equations were derived for each city and used to calculate the moisture transfer as a function of building envelope airtightness for each building type. For the High-Rise Apartment building, the annual moisture transfer at a building envelope leakage rate of 7.7 L/(s•m^2) (1.5 CFM/ft^2) is 546, 367, 288, and 175 metric tons (1.2e+6, 8.1e+5, 6.3e+5, and 3.9e+5 lbs.) (118, 79, 62, and 38 kg/m^2 (24.2, 16.2, 12.7, and 7.8 lbs./ft^2) of exterior envelope area) for Miami, Chicago, Winnipeg, and Albuquerque, respectively.

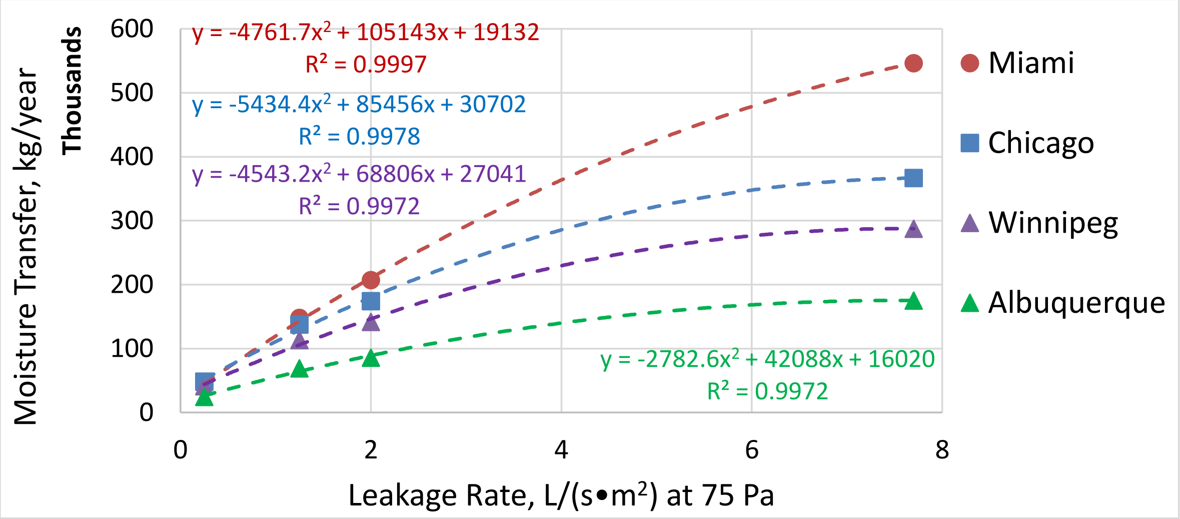

Figure 5. Annual moisture transfer through the building envelope due to air leakage at various envelope airtightness and locations. Note: 1 kg = 2.2 lb., 1 L/(s•m^2) = 0.2 CFM/ft^2, 75 Pa = 0.3-inch water column.

SUMMARY

In 2016–2017, ORNL, NIST, the ABAA, and the CERC BEE collaborated to develop an online calculator that uses the simulation results of the whole building energy simulation tool EnergyPlus and the multizone airflow simulation tool CONTAM. In 2018–2019, the calculator was expanded to add moisture transfer calculations because air leakage through the building envelope can have a significant impact on the amount of moisture transfer. Four more commercial building types were also added to the existing database of three building types. This paper describes the procedure used to calculate moisture transfer due to air leakage. This paper supplements Shrestha et al. 2016, which describes the calculation of energy savings due to the increase in envelope airtightness.

The procedure used in the online energy savings and moisture transfer calculator is different from other methods commonly used in energy analysis in that it uses hourly air leakage rates that are estimated by considering key variables such as building leakage rate, weather conditions, and HVAC operation. The calculator provides energy and costs savings and reduction in moisture transfer as a function of building envelope airtightness for the DOE commercial prototype buildings in 52 cities in the United States, five cities in Canada, and five cities in China. To demonstrate the moisture transfer calculations, the paper presents an example of how annual moisture transfer at an envelope leakage rate of 7.7 L/(s•m^2) (1.5 CFM/ft^2) at 75 Pa (0.3-inch water column) could be reduced by between 47% and 90% if the envelope leakage rate were reduced to 1.25 L/(s•m^2) (0.25 CFM/ft^2) at 75 Pa (0.3-inch water column) in the seven building types in Chicago.

The calculator is a powerful, credible, and easy-to-use tool that designers and contractors can utilize to estimate the benefits of reducing air leakage. These benefits include energy and cost savings in addition to a reduction in moisture transfer through the building envelope, as well as indoor air quality benefits not analyzed in this paper.

ABSTRACT

Multi-resolution simulation models of manufacturing system, such as the virtual factory, coupled with analytics offer exciting opportunities to manufacturers to exploit the increasing availability of data from their corresponding real factory at different hierarchical levels. A virtual factory model can be maintained as a live representation of the real factory and used to highly accelerate learning from data using analytics applications. These applications may range from machine level to manufacturing operations management level. While large corporations are already embarking on model based analytics initiatives, small and medium enterprises (SMEs) may find it challenging to set up a virtual factory model and analytics applications due to barriers of expertise and investments in hardware and software. This paper proposes a shared infrastructure for virtual factory model based analytics that can be employed by SMEs. A demonstration prototype of the proposed shared infrastructure is presented.

1 INTRODUCTION

Multiple trends are coming together to create exciting opportunities across all aspects of human lives. These trends include increasing computing power with accompanying reduction in its cost, increasing connectivity and speed across internet, increasing capabilities for data collection through sensors, and increasing access to data and applications via cloud and fog computing technologies. These trends have largely relaxed the constraints of computing power and data availability and enabled rapid growth in application and further development of technologies such as Internet of Things (IoT), artificial intelligence (AI) and analytics. The application of simulations and mathematical optimization techniques are rapidly growing too, taking advantage of the same trends. A number of these technologies have been around for years but were constrained in their applications due to lack of infrastructure of computing power, data access, and connectivity. For example, artificial intelligence attracted a lot of attention in 1980s building on special purpose languages such as PROLOG and LISP, special purpose hardware such as Texas Instruments Explorer workstation, and deployment of expert system applications for such varied fields as medical advice (Shortliffe 1986) and manufacturing scheduling (Jain et al. 1989). However, such developments plateaued with their growth constrained by the infrastructure limitations.

Jain, Sanjay; Narayanan, Anantha Narayanan; Lee, Yung-Tsun. "Infrastructure for Model Based Analytics for Manufacturing." Paper presented at 2019 Winter Simulation Conference, National Harbor, MD, US. December 08, 2019 - December 11, 2019.

The ongoing rapid growth in infrastructure has not only provided an opportunity for development of earlier developed technologies, it has also spurred further developments across most of them. AI in particular has gained from a shift from mimicking human intelligence and rule based approaches of 1980s to now building on machine learning based analytics. Analytics applications employ increasingly rigorous and advanced applications involving large amount of computations. For example, Neural Networks are getting stacked for deep learning applications. Mathematical optimization and simulation applications have seen new developments based on the advancements in infrastructure. Simulations software today allow quick executions of large models that integrate multiple paradigms such as system dynamics and discrete event representations, compared to a couple of decades ago where applications of even single paradigm models were limited in size due to execution speed limitations.

There are multitude of efforts for developing and deploying standalone applications based on the four technologies listed above, namely AI, analytics, mathematical optimization, and simulation. Efforts are also beginning to be reported that synergistically employ these technologies together. This paper proposes an infrastructure for an application that brings together simulation and analytics technologies for supporting manufacturing operations management and machine level decisions. Majority of recent and under development analytics applications analyze real data to identify patterns and develop insights to support decision making. However, the knowledgebase of such applications is restricted to analyzing scenarios that occur in real life and thus their predictions are credible within that envelope only. Simulation applications on the other hand can generate credible outputs for a range of what if scenarios. Using the simulation as a data-generator for a range of scenarios and using that data to train analytics application can increase the prediction envelope of the analytics application by several fold. Such use of simulation models to generate data, which is then analyzed by data driven analytics applications, has been referred to as model based analytics.

This paper reports on the next step in bringing model based analytics closer to actual implementation. The progression of the work has been reported in successive years at this conference. Jain et al. (2017) presented initial work for model based analytics by linking a virtual factory prototype to a Neural Network (NN) for developing a meta model for manufacturing order promising. Jain et al. (2018) took the model based analytics further by linking virtual factory prototype to a Gaussian Process Regression (GPR) application and using the capability to compare NN and GPR for the order promising function. This paper proposes infrastructure for deploying the model based analytics capability to facilitate its eventual application by small and medium enterprises (SMEs). The emphasis is on SMEs since they generally lack the resources to develop and implement advanced technologies.

The next section briefly reviews recent literature for similar efforts. Section 3 presents a modeling and analysis framework that has been developed with a focus on machine learning based analytics applications for manufacturing. The framework is enhanced in Section 4 to include simulation models and to link them with analytics applications to enable (simulation) model based analytics. A prototype implementation of the proposed infrastructure is described in Section 5. Section 6 concludes the paper with discussion of future directions.

2 RELATED WORK

2.1 Virtual Factory

This paper uses the definition of a virtual factory as a multi-resolution simulation model of a manufacturing system capable of supporting analysis at different levels of hierarchy with interfaces to real factory and analytics applications. The definition largely overlaps with those of digital twin of factory, shop floor digital twin, and digital factory used by some authors (for example, see Garetti et al. 2012). Reported work over the last 2 years relevant to this definition of virtual factory are briefly reviewed in this section. The work focusing on virtual reality aspects or collaboration across manufacturers to make a “virtual factory” is not included here. Readers are referred to Jain et al. (2017) for relevant literature prior to 2017.

A number of efforts report development and implementation of virtual factory models with increasingly diverse applications and identify challenges. Hwang et al. (2017) use a virtual factory model to demonstrate and validate the use of an IoT based performance measurement system. Brenner and Hummel (2017) describe a prototype implementation of a digital twin in a learning factory setting. Modoni et al. (2018) present the digital twin of a factory as a digital factory and also as a virtual factory and highlight its benefits and technical challenges including the lack of interoperability of supporting software systems. Caggiano and Teti (2018) present a digital factory model that allows machine level modeling using a 3D simulation and cell level flow using a discrete event simulation. These efforts indicate continued development of the virtual factory concept with varied applications.

2.2 Model Based Analytics for Manufacturing

There appears to be little work reported that employs model based analytics for manufacturing applications. Giri et al. (2012) propose use of model based analytics for management of power grid and point to its capability for what-if analysis and coming up with corrective actions as a major benefit over measurement based analytics. Kajmakovic et al. (2018) propose to use model based analytics for predictive fail safe systems in industrial operations. Some authors identify the approach as simulation based analytics. Biller et al. (2017) modified simulation models of Silicon Carbide manufacturing operations and analyzed the outputs to address the challenge of limited data from a real facility. Ji and AbouRizk (2018) utilize simulation based analytics for decision support for pipe welding quality management in industrial construction. The opportunities offered by combination of simulation and data driven analytics models are being recognized and its increasing use is anticipated.

2.3 Model Based Analytics Infrastructure

The infrastructure for model based analytics and virtual factory has recently drawn attention of researchers. Chen and Lin (2017) support use of Factory Simulation as a Cloud Service (FSaaCS) for SMEs and identify two major issues, the need to convert models for different simulation systems available on different clouds and estimating the simulation time. They focus on load balancing approaches for FSaaCS. Coronado et al. (2018) describe a Manufacturing Execution System (MES) based on MTConnect protocol and cloud based technologies suitable for SMEs that can be used to develop a shop floor digital twin, an overlapping concept to virtual factory discussed above. The proposed MES could be one building block that SMEs can employ for developing the model. Further development can bring in analytical tools for model based analytics.

A few efforts have been reported outside the manufacturing domain. Lee et al. (2013) present a model based analytics service available via cloud for building energy consumption. He et al. (2018) describe a multi-tier fog computing structure for model based analytics of large scale IoT for smart cities. Gausemeier et al. (2011) discuss integration of manufacturing with control engineering and information services and describe a general procedure model for integrative development of mechatronic products. Lee et al. (2014) propose a framework for self-aware and self-maintained machines for Industry 4.0, which includes cyber physical systems and decision support systems, and address the trends of manufacturing service transformation in big data environment. To our knowledge, there is no framework that integrates simulation into the design and analytics aspects, thus expanding the data driven capabilities beyond the status quo.

Overall, this brief review indicates that there is recognition that the advancements in simulation and data analytics are offering exciting potential for their combined application as model based analytics. Integration frameworks need to be developed or extended to incorporate such combinations. There is also recognition of an emerging need to facilitate the application of model based analytics through development of infrastructure particularly for SMEs.

3 FRAMEWORK FOR DATA DRIVEN MODELS

Data analytics (DA) allows identifying performance improvements across multiple levels of manufacturing system functionality. DA techniques have been applied in manufacturing for many years (Harding et al.

Jain, Sanjay; Narayanan, Anantha Narayanan; Lee, Yung-Tsun. "Infrastructure for Model Based Analytics for Manufacturing." Paper presented at 2019 Winter Simulation Conference, National Harbor, MD, US. December 08, 2019 - December 11, 2019.

2006). Most of these DA applications, however, are addressed to very specific issues under specific conditions (Sharp et al. 2018). Furthermore, DA applications are prohibitively complex and expensive, especially to SMEs. This is because DA techniques often require expertise in data collection, data analysis, machine learning, and decision optimization. A typical SME cannot afford to have a DA expert on staff. Thus, manufacturers need an enhanced decision-support facility so that analysis results at the process level can be elevated and used to influence enterprise-level decision making faster and better. The manufacturing industry can benefit greatly if such facility can 1) represent a wide range of manufacturing problems, 2) connect them to appropriate DA solutions, and 3) translate DA results into decisions that impact manufacturing operations across different levels of hierarchy. To address the need, a model-based analytics framework for manufacturing has been developed (Narayanan and Lee 2018) and is shown in Figure 1.

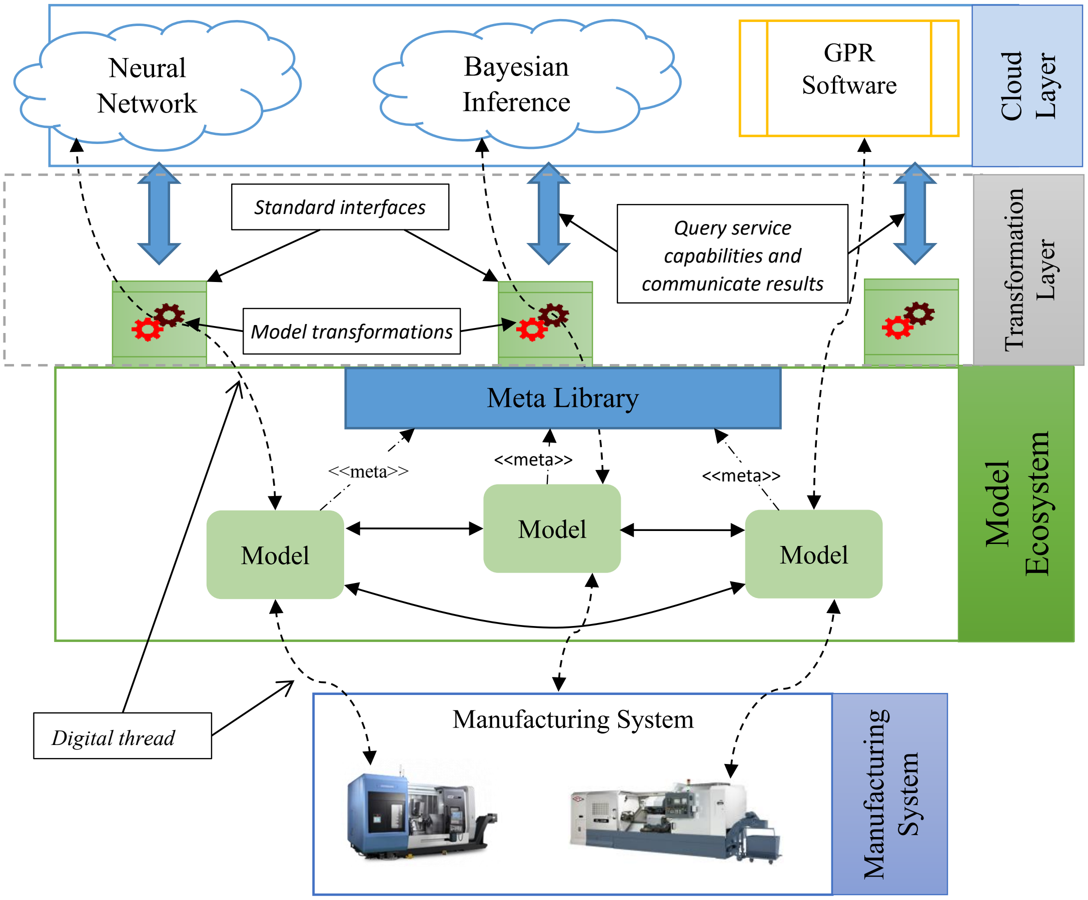

Figure 1: Model-based analytics framework for manufacturing.

The framework consists of a set of software to connect independent cloud and third-party DA applications or services to core manufacturing models. The framework supports both model integration and service integration across the entire hierarchy. The goal of the framework is to help the manufacturing industry to match their requirements to appropriate analysis services. The framework consists of four major layers described below.

- The manufacturing system layer, representing the physical system, includes the physical factory, physical sensors, and other data generators. The physical system may be composed of multiple subsystems organized as different lines, departments, cells, etc. At lower levels of the hierarchy, various machine tools and equipment are used to performs steps in the process plan for different products.
- The model ecosystem layer includes two major components: the domain-specific modeling environment and the library of meta-models. This layer provides the technical foundations for connecting a variety of analysis tools and services. The modeling environment will simplify system specification for manufacturing operations across different levels of hierarchy. It takes the domain-specific modeling approach to model abstracts in digital representations for manufacturing systems. The digital, manufacturing-domain models are then converted into analytical-domain models using model transformation to facilitate DA applications. Meta models are used to describe various aspects of manufacturing systems, based on the essential elements and rules of the domain of the individual physical systems; they are presented in a standardized way to facilitate model exchange and integration (OMG 2016).
- The transformation layer includes a set of model transformations or software tools that transfer system models into analysis models. It utilizes mapping algorithms that identify specific entities in the manufacturing-system domain and produce a corresponding entity in the analysis domain. The analysis model will be used to provide a solution to the manufacturing problem. When possible, the analysis model can be generated in a standard format, such as the Predictive Model Markup Language (PMML) (Guazzelli 2019), which can then be used with a variety of off-the-shelf analysis tools.
- The cloud layer includes various third-party services addressing various analytics needs. The third-party services can be standalone or cloud-based applications. The model ecosystem is connected to the cloud layer to allow various third-party tools to be used to perform analyses based on the system models.

To support the interaction among the layers, the framework provides additional components such as model library, standard interfaces, digital thread, and analysis discovery services. The model library includes pre-built system models to accelerate system specification, analysis models for various analysis objectives, reference data sets for specific scenarios, and possibly, extensions based on custom scenarios and data by individual organizations. Standard interfaces, based on standardized protocols and guidelines, are provided to make it easier for manufacturers to use available analytics services on their system models. The framework uses digital thread (Society of Manufacturing Engineers 2011) mechanism to connect digital representations and their corresponding physical entities. The digital thread allows manufacturers to trace analysis results back to actual physical components of the system. This traceability is necessary and plays a key role in decision making. The analytics discovery service guides manufacturers to the appropriate analysis services based on their needs. The discovery service is a very important component of the framework since the manufacturing users often are not experts in analytics. The service discovery interface will make it easy for manufacturers to find implementations that will provide the analytics service appropriate for solving the relevant analysis problem. The implementation of such service will require a high level of expertise in both the manufacturing and the analytics domains.

The core parts of the framework are the modeling techniques and the communication interface. Advanced modeling techniques are used to define intuitive and robust abstractions and interfaces for system specification and problem formulation. The framework is being developed using a service-oriented approach. The core modeling abstractions are being developed in a standardized way, e.g., the Core Manufacturing Simulation Model standard (Lee et al. 2011) has been used to facilitate the specification of complex manufacturing systems. Standard interfaces, e.g., PMML, are provided to communicate with third-party services for various analysis tasks. The analysis services are being built relying on the accurate transfer of relevant information through the standard interfaces. In the initial implementation, the framework is envisaged to carry only the basic items in each component. It is expected more component items will be developed through a collaborative effort by the community of researchers and practitioners.

4 PROPOSED INFRASTRUCTURE

In this section, we propose enhancements to the framework described in Section 3 to include simulation models in the framework and have their results be analyzed by data driven models.

4.1 Enhanced Framework for Model Based Analytics

Section 3 described the framework for data driven models for advanced manufacturing. Two of the essential components of the framework are the model ecosystem, which holds the digital representations of the manufacturing system, and the transformation layer, which enables the creation of data driven models from the digital representations. We extend these components to support simulation models. We extend the transformation layer to be able to automatically generate simulation models from the system representations in the model ecosystem. The implementation details are described in Section 5. Figure 2 shows the extended framework to support simulation models.

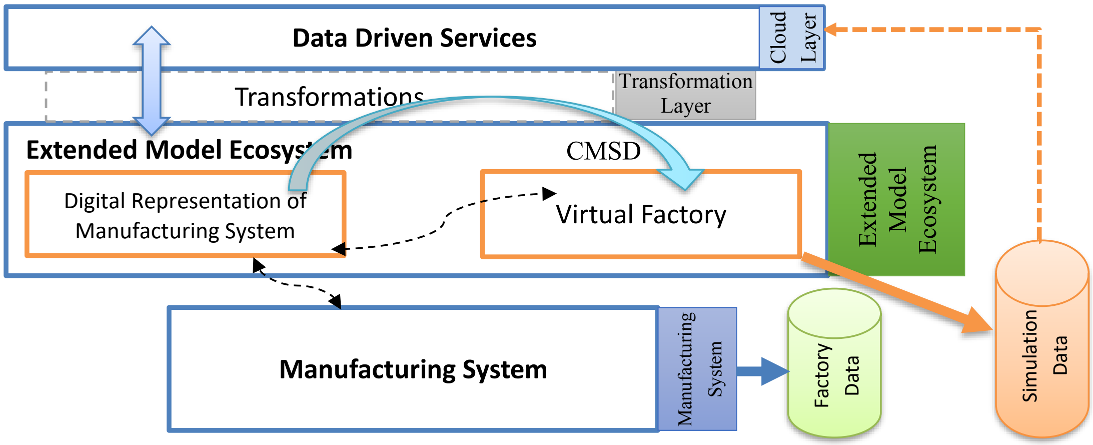

Figure 2: Extended framework for simulation model based analytics.

The goal of the extended framework is to provide the ability to easily configure simulations of a manufacturing system. The extended framework will allow users to make arbitrary changes to the digital representation of the system to easily create new configurations of the system. A model transformation component will automatically generate a simulation model from the digital representation in a standard CMSD (Riddick and Lee 2010) format. This allows users to rapidly generate multiple simulation models for various configurations. The standard simulation model may then be imported into a variety of simulation tools to run simulations. These simulations can be used for various purposes, such as generating synthetic data for new data driven models, or for performing other types of optimizations. In the subsections below, we discuss these applications in more detail.

4.2 Virtual Factory Model

The “model” employed for model based analytics is a virtual factory in the context of manufacturing. The virtual factory is envisaged as a multi-resolution model that allows representation and analysis of the corresponding real factory at different levels of hierarchy. In a real factory, the performance can be analyzed at various levels such as machines, cells, departments, and the entire factory including their interactions with supporting system using the data streams from various sensors and data collection systems. The virtual factory would allow analysis at the desired level of resolution similar to the real factory except it would have the advantage to create and analyze a range of future potential scenarios. The virtual factory will need to be closely linked to the real factory to be its high fidelity representation. The virtual factory will also need to be interfaced with data analytics applications similar to the real factory for this purpose. The virtual factory is proposed to reside in the extended model ecosystem to gain from defined interfaces to the real manufacturing system and the data driven models in the framework.

The virtual factory will have a synergistic relationship with data driven applications. The primary intent is of course to have the virtual factory generate data for model based analysis. However, the analytics applications will help the virtual factory in return by improving the data used for simulations. For example, the data for machine failures can be continuously tracked and periodically analyzed to improve the distributions used to represent them in the virtual factory.

4.3 Support for Model Development

The framework provides an intuitive domain specific modeling environment that makes it easy for practitioners to develop digital models that closely and accurately represent their manufacturing systems. The modeling environment enforces rules that ensure that the models are sound, and allows for error checking. Digital threads trace relationships between model elements and the physical component that they represent. This allows us to develop rule based transformations that can automatically create other types of models from these models. One example of such a model transformation allowed us to generate neural networks for predicting energy consumption from milling machine models (Lechevalier et al. 2014).

In the extended framework, we implemented such a model transformation to generate a CMSD file as a standard representation of a simulation model. This transformation is completely automated, and allows users to make changes in the factory model and quickly generate simulation models. The CMSD file may be imported into a simulation tool such as AnyLogic to execute the simulation. More details of the implementation are presented in Section 5.

4.4 Support for Analytics

As stated before, the transformation layer of the framework implements various model transformations to generate analytic models from the system model. Data from the factory is used to train the analytic models. However, in many cases data from the factory is not available. For example, if the factory is newly set up, there may not be sufficient historic data. Also, the user may want to experiment with various factory configurations, and data may not be available for all of these new configurations. In such cases, it is beneficial to have this data generated synthetically through simulations. Figure 2 shows how simulations can be executed to generate simulated data, which can then be used to train the analytic models.

5 INFRASTRUCTURE PROTOTYPE

In this section, we present our preliminary implementation of the framework, and describe its use through an example.

5.1 Implemented User Modeling Environment

The model ecosystem shown in Figures 1 and 2 was implemented using the Generic Modeling Environment (GME) (Ledezci et. al. 2001). GME is an open source tool for creating configurable modeling environments. We developed a meta-model (abstract model) in GME that describes the main concepts and modeling rules of the model ecosystem. The meta-model defines the rules based on which models can be built. The concepts and relationships in the meta-model are "instantiated" to build models. The models represent actual items in the physical systems in that domain. Figure 3 shows a screenshot of the domain specific modeling environment in GME. It shows an instantiated model of a manufacturing process, showing the process parameters, metrics and variables. The tree structure on the right of Figure 3 represents the hierarchical structure of the entire system model. The environment we implemented for this framework allows the user to model the factory layout, parts manufactured, the process plans, and the resources used.

We implemented a model transformation that takes the factory representation shown in Figure 3, and generates a CMSD file. The CMSD file is an XML file that represents all the elements of the factory model necessary to create a simulation of the factory. We implemented a plug-in for the AnyLogic simulation tool, to read the standard CMSD file and generate an AnyLogic simulation model. We executed the simulation in AnyLogic, and generated data from the simulation. The generated data was then used to train machine learning models for cycle time predictions for the purpose of order promising. We generated a Neural Network (NN) and a Gaussian Process Regression (GPR) model. These models are described in Section 5.3.

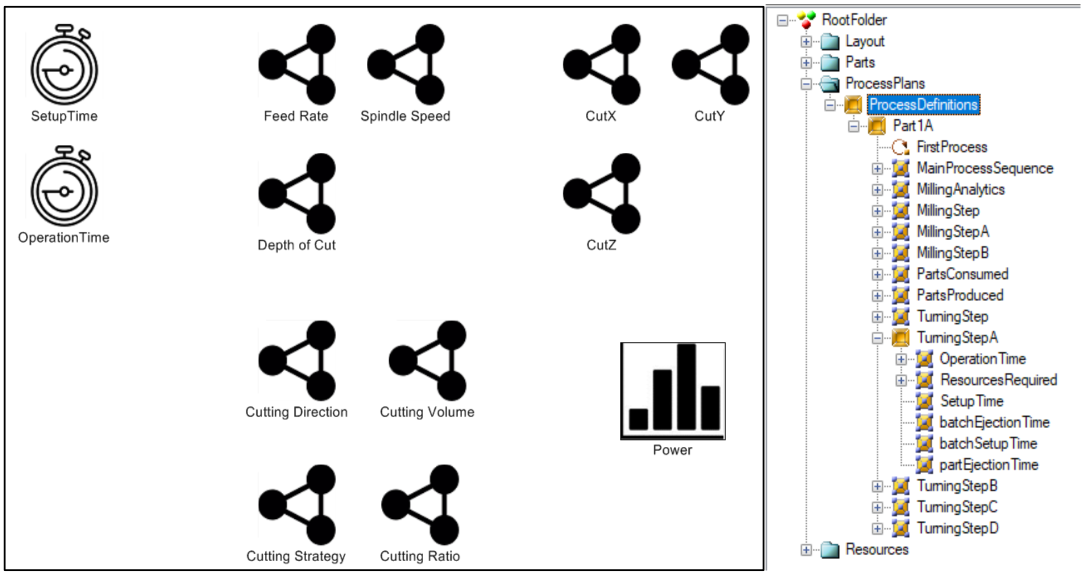

Figure 3: Model representation of a manufacturing process.

5.2 Implemented Virtual Factory Model

The virtual factory model is based on the scenario described in Jain et al. (2017) and Jain et al. (2018). The use case is based on order promising for a small job shop and hence the corresponding model may be referred to as a virtual job shop. The job shop produces parts from three different material types. The goal is to predict a shipment date at the time of the order, based on the material type chosen for the part, and the current load on the shop.

The job shop model was built in GME, in the domain specific modeling environment (DSME) described above. The DSME allows us to visually construct a hierarchical model of the job shop, and specify all the machine parameters within the model itself. The job shop model consists of a turning cell with four turning machines, and a milling cell with two milling machines. A process model is built in the DSME to describe the process flow. The model elements can be seen in the tree hierarchy on the right side of Figure 3. MillingStep and TurningStep specify the machine cells, and MainProcessSequence specifies the overall process sequence.

We implemented a translator tool that automatically generates a standard CMSD file from the shop floor model specified in the DSME. This CMSD file was then imported into the AnyLogic simulation tool (using another plugin that we implemented), to execute the simulation. The virtual factory prototype does have the capability to utilize multi-resolution models with the most detailed level capable of modeling machine dynamics. However, with the focus on analyzing job shop cycle times for this study, only the discrete event model of material flow across the shop was used. We generated synthetic data for the scenario from the simulation, which was then used to train a prediction model for order promising.

The advantage of building the model in the DSME and generating the simulation model, as opposed to building the simulation model directly in the simulation tool, is twofold. First, The DSME is designed to be used by a manufacturing domain expert, and uses concepts and visual representations that are easy to understand for a domain user. This can greatly accelerate model development, reduce model errors, and ease maintenance of models. Second, The DSME allows us to implement many different algorithms for various tasks in a more powerful and elegant way than does a simulation tool (which is restricted to simulation tasks). In particular, we can implement several model translators to generate other types of models from the specification in the DSME. For example, we implemented a Neural Network (NN) generator that can automatically generate a NN for a machine from its specification in the DSME (Lechevalier et al. 2014). This neural network can then be trained on data (real or synthetic) for that machine. Thus, from a single model in the DSME, we are able to generate and run a simulation, generate an NN model, and use the data from the simulation to train the NN. Figure 4 provides an overview of the infrastructure prototype.

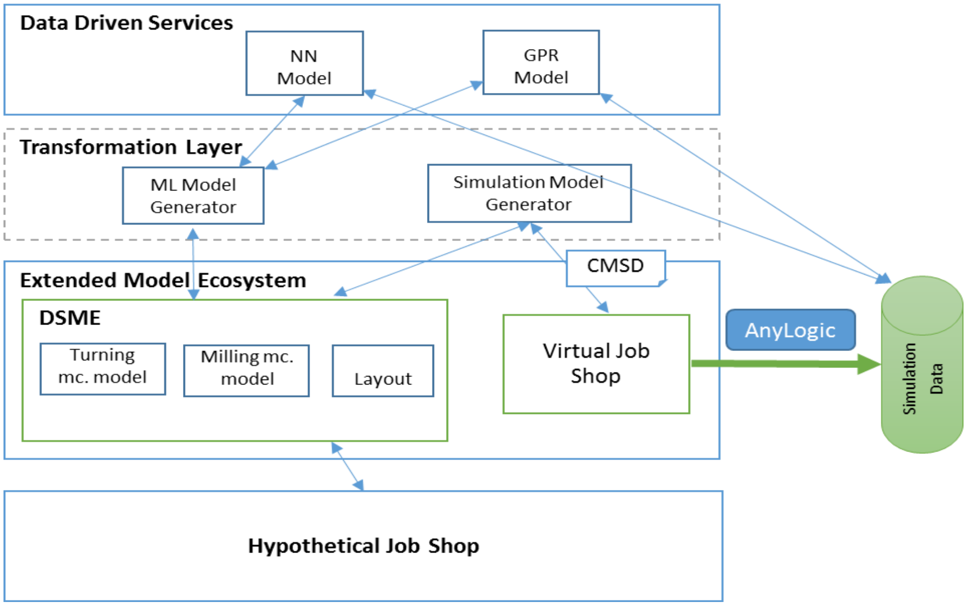

Figure 4. Overview of the implemented infrastructure prototype.

5.3 Implemented Analytics Applications

Based on the simulation model described above, we implemented two different machine learning models to predict throughput. We first trained a Neural Network (NN) model (Jain et al. 2017) for throughput prediction. We then generated a Gaussian Process Regression (GPR) model (Jain et al. 2018) for the same purpose, and compared it to the prediction accuracy of the NN model. We summarize these models here. For theoretical background on NNs and GPR, we refer the reader to Haykin (2004) and Rasmussen (2004).

The NN model takes a set of input variables and makes a prediction on a desired target variable. In our case, the target was “cycle time”, which was needed to estimate the expected time for order completion. The input variables included the material type, the number of parts in the order, and the current load on the system. The material type is one of aluminum, steel or titanium, and is represented using one-hot encoding, i.e., it is represented by three variables (one for each material), with a zero or one depending on the material chosen. The load on the system is modeled by a triplet (n_A, n_S, n_T), which denotes the parts of material type aluminum, steel, and titanium currently being processed in the system. For a new job shop, there is not sufficient real data to train a reliable model for predicting duration under many varying conditions. Our simulation model described previously overcomes this problem, by generating simulated data for a variety of shop conditions. The data generated by the simulation model is then used to train the NN model. The resulting NN model is capable of predicting an estimated duration for new orders, and can be used to give an estimated ship date when the shop is operational.

We also created a Gaussian Process Regression (GPR) model for duration prediction from the same simulated data. GPR is a probabilistic method of interpolation to determine the target value from the inputs. GPR produces a distribution of the expected target value, allowing us to account for uncertainty in the prediction. The GPR model uses the same inputs and outputs but provides a prediction window for the target based on the uncertainty. In input regions where sufficient training data was available to provide a reliable prediction, the uncertainty is small. Figure 5 shows a comparison of the NN and GPR models on simulated test data. The grey color bands around the GPR predictions represent the confidence bounds generated by GPR. More details of the comparison between these prediction models can be found in Jain et al. (2018).

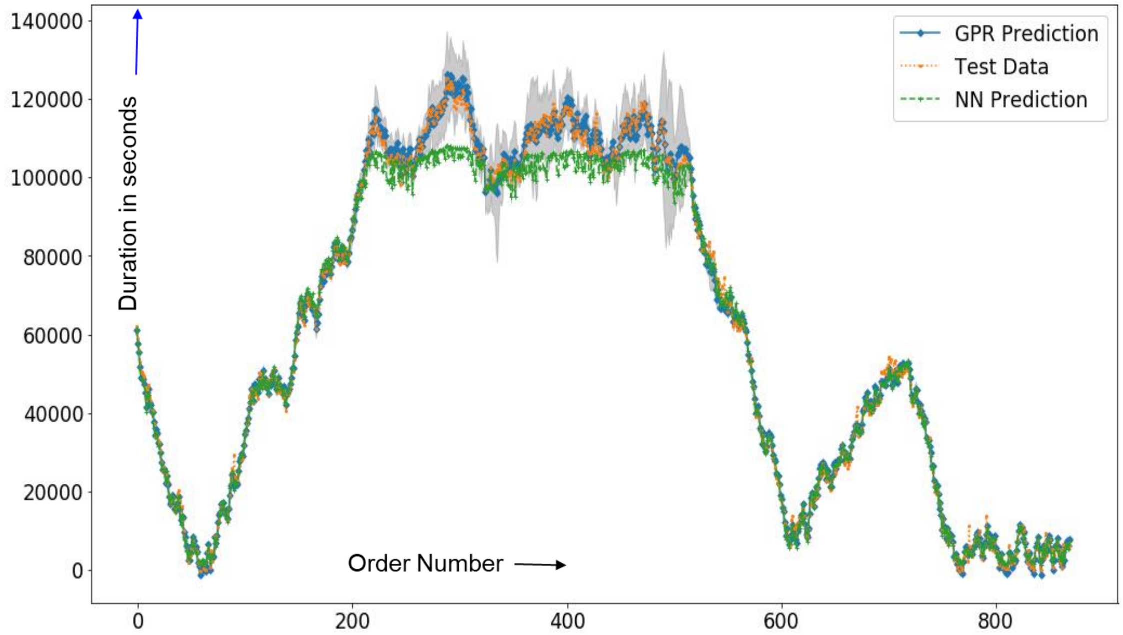

Figure 5: Comparing NN and GPR for cycle time predictions (Jain et al. 2018).

6 CONCLUSION

This paper proposed an infrastructure for model based analytics with emphasis on orienting the capability for SMEs. A prototype implementation for the infrastructure has been described that uses a small virtual factory to generate cycle time performance data that is then analyzed by NN and GPR applications to develop a predictive model for order promising. The next proposed step is to use data from a larger real manufacturing system to set up the model based analytics capability and exercise it for addressing issues of interest to the decision makers. Future work may focus on successive iterations of enhancements in all the components of the framework including the interactions with manufacturing personnel, increasingly automated generations of virtual factory models, interfaces of virtual factory with real factory data systems, and interfaces of virtual factory for guided analytics driven by decision makers.

Effect of Federal Incumbent Activity on CBRS Commercial Service

{souryal, thao.t.nguyen}@nist.gov

***Abstract*—Federal Communications Commission rules for the 3.5 GHz citizens broadband radio service (CBRS) permit commercial systems to share 150 MHz of bandwidth with federal and other incumbents. To protect the federal incumbents, a spectrum coordinator—the spectrum access system (SAS)—uses a standardized algorithm to suspend some commercial transmissions when a nearby incumbent (e.g., a shipborne radar) becomes active. Using propagation models based on those employed by the SAS for interference management, this paper quantifies the impact of federal incumbent activity on commercial service, in terms of both the numbers of transmissions affected and their service area. These metrics are also used to examine the tradeoff between commercial coverage and immunity to incumbent activity as a function of commercial base station antenna height. We find that, in some cases, the reduction in coverage from lowering antenna heights is more than offset by the gain in immunity to incumbent activity.**

I. Introduction

Regulatory rules for the citizens broadband radio service (CBRS) in the U.S. [1] define three tiers of access to the radio frequency (RF) spectrum from 3550 MHz to 3700 MHz (3.5 GHz band). The top tier, or highest priority users, are the incumbents; they include certain military operations, existing fixed satellite service earth stations, and grandfathered wireless broadband licensees. The second tier consists of new entrants to the band that have a priority access license but must not cause harmful RF interference to the top tier (incumbent) users. The third tier is for general authorized access not requiring a license; they must not cause interference to and must accept interference from the top two tiers.

The rules require that second and third tier access to the band be dynamically managed by a spectrum access system (SAS). CBRS devices (CBSDs)—the tier 2 and tier 3 devices that access the band (i.e., base stations and access points)—must receive authorization from the SAS prior to transmitting. Such authorizations include the maximum RF power at which the CBSD can transmit and the specific channel in the CBRS band on which to transmit.

The federal incumbents include both ground-based and shipborne military radars which may or may not be active at a given time. When informed of federal incumbent activity in a certain geographic area, a SAS must dynamically manage the aggregate interference of CBSDs so as not to exceed a predefined protection threshold anywhere in the protected area. To accomplish this interference management, the SAS may need to temporarily suspend certain commercial transmissions on the affected channel.

This paper is a study of the impact of federal incumbent activity on commercial use of the CBRS band. Employing some of the same propagation models mandated by CBRS standards for use by the SAS in managing access to the band, we quantify the impact of incumbent activity in terms of not only the numbers of affected CBSDs as in previous studies (e.g., [2]), but also in terms of their service area. Such an analysis enables the examination of various tradeoffs, such as increasing commercial service coverage with higher power transmissions or higher antennas versus lowering the impact of federal incumbent activity on commercial service.

Sections II and III describe the propagation models and commercial deployment model, respectively, used in this study. Section IV presents a quantitative analysis of the impact of incumbent activity on commercial service and examines the tradeoff in service coverage of antenna height. Finally, section V summarizes the results and draws conclusions.

II. Propagation Models

CBRS standards [3] specify the propagation models that a SAS must use to perform its functions, such as calculating a CBSD's coverage area and managing the aggregate interference of lower tier users to higher tiers.

A. CBSD Coverage

As part of its protection of tier-two users, a SAS is required to calculate a contour around each tier-two CBSD at which the received signal strength from that CBSD is equal to -96 dB relative to 1 mW (dBm) in a 10 MHz channel. To perform this calculation, the SAS uses a propagation model that is a hybrid of the irregular terrain model (ITM) (also known as Longley-Rice model) [4] and the extended Hata (eHata) model described in [5]. The eHata model is an extension of Hata's empirical formulae in both distance and frequency ranges and includes a number of site-specific corrections to the median attenuation, the details of which are provided in [5]. The hybrid model selects the appropriate loss model based on the distance between the transmitter and receiver. For distances less than 1 km, either free space path loss or an interpolation between free space and eHata is used. For longer distances, the loss is generally determined as the larger

Souryal, Michael; Nguyen, Thao T. "Effect of Federal Incumbent Activity on CBRS Commercial Service." Paper presented at IEEE International Symposium on Dynamic Spectrum Access Networks, Newark, NJ, US. November 11, 2019 - November 14, 2019.

of the ITM and eHata losses. However, if the transmitter has an effective height above 200 m or if it is deployed in a rural area, the loss is equal to the ITM loss, regardless of distance. Furthermore, if the CBSD is located indoors, 15 dB is added to the loss to account for building attenuation. Details of the CBRS hybrid model are provided in [3, R2-SGN-04]. An open-source reference implementation of the hybrid model is available [6], as are the terrain and other data used by the model [7].

B. *Federal Incumbent Protection*

While CBRS standards specify the hybrid model described above for the protection of tier two and certain grandfathered incumbents, it currently only specifies the use of ITM for the protection of federal incumbents. However, to better account for clutter and examine the tradeoffs in antenna height, in this study we employ the hybrid model that was used for federal incumbent protection in the 3.5 GHz exclusion zone analysis [5]. This hybrid model differs from that specified in the CBRS standards for tier-two protection and is used solely for calculating the aggregate interference to federal incumbents.

For the purposes of this study, we adapted the hybrid model of [5] in two important respects. First, because the exclusion zone analysis only considered rural antenna heights up to 6 m, it included clutter loss on all paths from rural areas. However, in this study, antenna heights in rural areas can be as high as 100 m, well above most clutter. Hence, we apply the antenna height threshold of 18 m used in [5] for urban and suburban areas to rural areas, as well: below 18 m we apply the same random, uniformly distributed rural clutter loss as in [5], and above 18 m we apply no clutter loss. Second, for the ITM portion of the hybrid model, we use the parameters specified in the CBRS standards [3] for consistency.

To illustrate the difference between the hybrid model and the CBRS standard model based on ITM alone, we consider a simulated deployment of CBSDs near a protected federal incumbent in Pensacola, Florida. In this example, all CBSDs have an antenna height of no more than 18 m. Fig. 1 shows histograms of the hybrid median path loss (in red), the CBRS standard's median path loss (in blue), and the difference (dB) between the two (in green). As shown in the figure, the difference ranges from −5 dB to 60 dB. Negative values are observed because indoor losses in the hybrid model can be as little as 10 dB, while the indoor loss in the standard model is fixed at 15 dB.

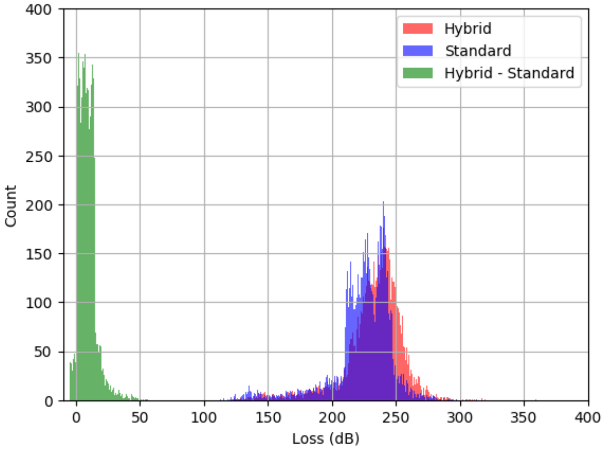

Fig. 1. Histograms of hybrid median path loss, CBRS standard median path loss, and their difference, for CBSDs near Pensacola

III. Commercial Deployment Model

The regulatory rules for the CBRS band specify two categories of CBSDs. Category A CBSDs are lower power devices with a maximum effective isotropic radiated power (EIRP) of 30 dBm/10 MHz and are typically installed indoors. Category B CBSDs are higher power devices (47 dBm/10 MHz maximum EIRP) and are professionally installed outdoors [1].

The simulated deployments used in this study are based on a model that was used by the National Telecommunications and Information Administration (NTIA) to size the coastal areas requiring federal incumbent protection, referred to as "dynamic protection areas" (DPAs) [8], as well as to determine the areas in which commercial service could potentially be affected, referred to in CBRS requirements as the "DPA neighborhood" [3].

The NTIA model, described in [2, Section III-A], generates the locations, antenna heights, and transmission powers of a simulated deployment of CBSDs around a given DPA. The numbers of CBSDs and their locations are a function of population and land classification. For this study, Category A CBSDs were placed as far as 250 km from the DPA boundary, and the higher-power Category B CBSDs were placed as far as 600 km from the boundary. Furthermore, all CBSD antennas were configured to be omnidirectional. Sample deployments generated with the NTIA model can be found at [6].

In addition, we adapted the deployment model to prevent overlap of coverage areas of each category of CBSDs. The rationale for this decision is that, since the deployment is for a given channel in the CBRS band—in other words, all transmissions of a deployment are co-channel—a SAS may try to limit the authorization of CBSD transmissions to avoid their mutual interference [9]. As such, the resulting deployment can be viewed as the effective deployment of CBSDs after SAS authorizations are made.

We apply a simple down-selection of CBSDs to obtain a non-overlapping set. Given a list of CBSDs generated by the NTIA deployment model, we step sequentially through each CBSD in the list and add it to the set if its −96 dBm/10 MHz contour does not intersect with the contour of any CBSD already in the non-overlapping set. We perform this selection separately for Category A CBSDs and for Category B CBSDs, resulting in two sets, each of which contains non-overlapping CBSDs. As such, the coverage of Category A CBSDs, which are considered to be indoors in the NTIA model, can overlap with that of the Category B CBSDs, which are outdoors. The rationale for independent selection of the two sets is that the Category A CBSDs can provide indoor coverage where Category B CBSDs may not.

We observe that our selection of non-overlapping contours does not necessarily maximize overall coverage and depends on the order of the starting list. Nevertheless, as an achievable solution, it provides a lower bound on the coverage of the optimal non-overlapping set.

Fig. 2 depicts the -96 dBm/10 MHz contours of both the original deployment and a non-overlapping deployment of CBSDs near the East 2 DPA (the red polygon in the figure) off the southeastern coast of the U.S. The total area of the union of the contours in the original deployment is $615\,390$ km^2, and the total area of the non-overlapping contours is $259\,623$ km^2.[1]

IV. Analysis

A. Deployment Scenarios

We evaluate the impact on CBRS commercial service of federal incumbent activity for three select DPAs: an offshore DPA off the southeastern coast of the U.S. (East 2), an offshore DPA near a naval base on the West Coast (West 14), and a point DPA on the U.S. Gulf Coast (Pensacola). We quantify the impact in terms of three metrics: (i) the number of authorized CBRS transmissions that are suspended when the DPA becomes active, (ii) the outer distance of the affected transmissions (a measure of the DPA neighborhood), and (iii) the total service area of the remaining active CBRS transmissions.

We compare these metrics under two deployment scenarios, one with unrestricted antenna heights and one with restricted antenna heights. In the latter scenario, we simply clip the height of each outdoor (Category B) CBSD in the original deployment to 18 m, i.e., $h_{\text{new}} = \min(h_{\text{orig}}, 18)$, where h_{orig} is the height of the CBSD in the original deployment in meters. The height restriction has the effect of shrinking the coverage area of a CBSD that has been clipped but, due in part to clutter loss at the lower antenna heights, reduces the likelihood that its transmission is suspended due to incumbent activity.

To illustrate the effect of the height restriction on coverage, Fig. 3 shows the histogram of the coverage area of the Category B CBSDs for each scenario of the East 2 deployment on a logarithmic scale. While the original deployment has CBSD coverage areas as high as 3500 km^2, the height restriction limits coverage areas to around 1000 km^2. In any case, the vast majority of CBSDs in the original deployment have a coverage area below 1000 km^2.

Nevertheless, as a result of the smaller coverage contours of some outdoor CBSDs, the selection of non-overlapping contours from the height-limited deployment yields a somewhat larger number of Category B CBSDs in the non-overlapping set. For the DPAs considered in this analysis, the increase ranges from $2\,\%$ to $16\,\%$ depending on the DPA.

B. Move List Size

CBRS standards refer to the set of authorized transmissions that a SAS must suspend in order to protect a DPA from harmful interference on a given channel as the "move list" (i.e., transmissions that ultimately must be "moved" to a different channel). Because the move list depends on the aggregate interference of all transmissions in the affected area, and because multiple SASs may be managing these transmissions, the standards specify the algorithm all SASs must use to determine which transmissions must be placed on the move list.

We used the Wireless Innovation Forum's reference implementation of the standardized move list algorithm [6] to calculate the move list of each DPA; but in order to assess the tradeoff of limiting the CBSD antenna height, we replaced the ITM propagation model in the reference implementation with the hybrid propagation model for federal incumbent protection described in Section II-B.

An input to the move list algorithm are the sample points in the DPA at which the algorithm will ensure the aggregate interference meets the protection criteria. In this analysis, we used the default setting of the reference implementation, which is approximately 35 points along the edge of the DPA and approximately 15 points interior to the DPA.

Fig. 4 illustrates the number of transmissions on the resulting move list for each DPA with and without the height restriction on a logarithmic scale. The dashed lines above each bar indicate the total number of CBSDs in the deployment. We observe different behavior depending on the DPA. For both West 14 and Pensacola, the move list increases modestly (about $5\,\%$) under the height restriction (despite the fact that the total number of CBSDs increases $16\,\%$ in the Pensacola deployment). However, though the East 2 deployment increases $8\,\%$ with the height restriction, the move list *decreases* by $25\,\%$. This result suggests that, in this case, the negative effect of the height restriction in terms of an increased number of required CBSDs is more than offset by its positive effect in the lower number of transmissions that are suspended in the event of incumbent activity.

C. DPA Neighborhood

The DPA neighborhood is the geographic area a SAS must consider when computing move lists. Any CBSD in the DPA neighborhood must be included in the computation and could potentially end up on the move list. The neighborhood is typically expressed in terms of a distance from the DPA boundary (or point) and is an input to the move list algorithm. The distance is such that transmissions beyond the neighborhood contribute negligible interference to the aggregate.

An estimate of the required neighborhood distance can be found by first computing the move list with artificially large neighborhood distances (in our case, 250 km for Category A CBSDs and 600 km for Category B CBSDs). The move list is composed of the union of component move lists, one for each protection point provided to the algorithm. For each transmission on the move list, we identify the component move

[1] We note that the sum of the areas of the contours in the original deployment is $6\,201\,917$ km^2, an order of magnitude larger than the area of their union, meaning that the original deployment has significant overlap of the -96 dBm/10 MHz contours.

lists it belongs to and their associated protection points. We then find the distance from that transmission to the nearest of these protection points. Finally, from these distances, one per move-list transmission, we estimate the required neighborhood distance to be the largest of these distances.

In NTIA's initial release of DPA protection criteria [10], the East 2 DPA had the largest Category B neighborhood distance of all the DPAs, in excess of 400 km. The results of this analysis are consistent with that, as shown in Fig. 5 which plots the estimated Category B neighborhood distance of each DPA. However, our analysis shows that East 2 also stands to benefit the greatest from a height-restricted deployment when the hybrid propagation model is applied, lowering the neighborhood distance by more than 100 km. The change for the other two DPAs considered here, however, is small.

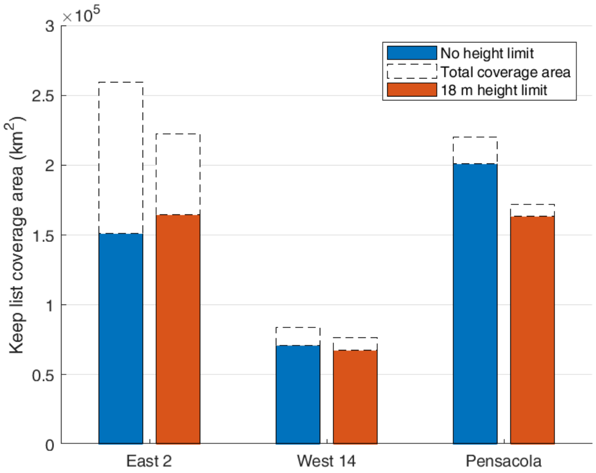

Fig. 6. Coverage area of the keep list.

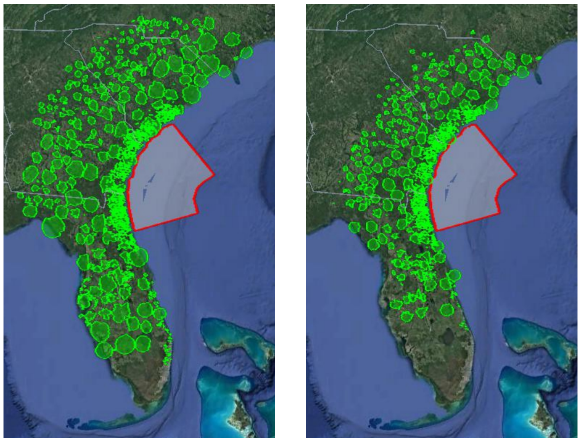

(a) Original Antenna Heights (b) Restricted Antenna Heights

Fig. 7. −96 dBm/10 MHz contours of the East 2 DPA move list (map data: SIO, NOAA, U.S. Navy, NGA, GEBCO; map image: Landsat/Copernicus; copyright 2018 Google, INEGI).

D. Keep-List Coverage

The third and final metric used to evaluate the impact of incumbent activity on commercial usage is coverage area. In particular, we consider the coverage area of commercial service before and after a DPA becomes active.

The complement of the move list is referred to as the “keep list,” the list of transmissions that are not suspended by a SAS when a DPA is active. Fig. 6 shows the coverage area of all transmissions on the keep list for each DPA, with and without the height restriction. The dashed lines above each bar indicate the total coverage area when the DPA is inactive, that is, when no transmissions are suspended.

It is notable that, for East 2, though the total coverage area decreases with the height restriction, the keep-list coverage area actually *increases*, again pointing to the offsetting benefit of using lower CBSD antennas. For the other two DPAs, the keep-list coverage decreases with the height restriction, but not as much as the total area, as a percentage.

Fig. 7 shows the coverage contours of the transmissions on the East 2 move lists. The maps illustrate the smaller area affected by the move list for CBSDs with the height restriction relative to that without the height restriction.

V. Conclusion

The analysis quantified the effects of federal incumbent activity on commercial service in the 3.5 GHz CBRS band in terms of both the number of commercial transmissions that would be suspended as well as the affected service area. It also examined the tradeoff between commercial coverage and immunity to incumbent activity when the antenna heights of commercial base stations are capped.

Based on an analysis of a sample of federal incumbent protection areas, there are situations in which commercial users can benefit from limiting base station antenna heights. To realize this benefit, though, the propagation model used by the SAS for incumbent protection would need to be augmented with height-dependent clutter loss.

Future work can utilize the methodology presented here to examine the tradeoffs when changing other deployment variables, such as base station transmit power.

BowTie - a deep learning feedforward neural network for sentiment analysis[⋆]

Apostol Vassilev

National Institute of Standards and Technology,
100 Bureau Dr., Gaithersburg, MD 20899, USA
apostol.vassilev@nist.gov

Abstract. How to model and encode the semantics of human-written text and select the type of neural network to process it are not settled issues in sentiment analysis. Accuracy and transferability are critical issues in machine learning in general. These properties are closely related to the loss estimates for the trained model. I present a computationally-efficient and accurate feedforward neural network for sentiment prediction capable of maintaining low losses. When coupled with an effective semantics model of the text, it provides highly accurate models with low losses. Experimental results on representative benchmark datasets and comparisons to other methods[1]show the advantages of the new approach.

Keywords: Deep learning · Sentiment analysis · Natural Language Processing.

1 Introduction

When approaching the problem of applying deep learning to sentiment analysis one faces at least five classes of issues to resolve. First, what is the best way to encode the semantics in natural language text so that the resulting digital representation captures well the semantics in their entirety and in a way that can be processed reliably and efficiently by a neural network and result in a highly accurate model? This is a critically important question in machine learning because it directly impacts the viability of the chosen approach. There are multiple ways to encode sentences or text using neural networks, ranging from a simple encoding based on treating words as atomic units represented by their rank in a vocabulary [1], to using word embeddings or distributed representation of words [2], to using sentence embeddings. Each of these encoding types has different complexity and rate of success when applied to a variety of tasks.

Vassilev, Apostol. "BowTie - a deep learning feedforward neural network for sentiment analysis." Paper presented at LOD 2019, Siena, IT. September 10, 2019 - September 13, 2019.

The simple encoding offers simplicity and robustness. The usefulness of word embeddings has been established in several application domains, but it is still an open question how much better it is than the simple encoding in capturing the entire semantics of the text in natural language processing (NLP) to provide higher prediction accuracy in sentiment analysis. Although intuitively one may think that because word embeddings do capture some of the semantics contained in the text this should help, the available empirical test evidence is inconclusive. Attempts to utilize sentence embeddings have been even less successful [3].

Second, given an encoding, what kind of neural network should be used? Some specific areas of applications of machine learning have an established leading network type. For example, convolutional neural networks are preferred in computer vision. However, because of the several different types of word and sentence encoding in natural language processing (NLP), there are multiple choices for neural network architectures, ranging from feedforward to convolutional to recurrent neural networks.

Third, what dataset should be used for training? In all cases the size of the training dataset is very important for the quality of training but the way the dataset is constructed and the amount of meta-data it includes also play a role. The Keras IMDB Movie reviews Dataset [4] (KID) for sentiment classification contains human-written movie reviews. A larger dataset of similar type is the Stanford Large Movie Review Dataset (SLMRD) [5]. I consider KID and SLMRD in Sections 2.3 and 2.4 respectively. Generally, simpler encodings and models trained on large amounts of data tend to outperform complex systems trained on smaller datasets [2].

Fourth, what kind of training procedure should be employed - supervised or unsupervised? Traditionally, NLP systems are trained on large unsupervised corpora and then applied on new data. However, researchers have been able to leverage the advantages of supervised learning and transfer trained models to new data by retaining the transfer accuracy [3].

Fifth, when training a model for transfer to other datasets, what are the model characterizing features that guarantee maintaining high/comparable transfer accuracy on the new dataset? Certainly, training and validation accuracy are important but so are the training and validation losses. Some researchers argue that the gradient descent method has an implicit bias that is not yet fully understood, especially in cases where there are multiple solutions that properly classify a given dataset [6]. Thus, it is important to have a neural network with low loss estimates for a trained model to hope for a good and reliable transfer accuracy.

The primary goal of this paper is to shed light on how to address these issues in practice. To do this, I introduce a new feedforward neural network for sentiment analysis and draw on the experiences from using it with two different types of word encoding: a simple one based on the word ranking in the dataset vocabulary; the other judiciously enhanced with meta-data related to word polarity. The main contribution of this paper is the design of the BowTie neural network in Section 3.

2 Data encoding and datasets

As discussed above, there are many different types of encodings of text with different complexity and degree of effectiveness. Since there is no convincing positive correlation established in the literature between complexity of the encoding and higher prediction accuracy, it is important to investigate the extent to which simple data encodings can be used for sentiment analysis. Simpler encodings have been shown to be robust and efficient [1]. But can they provide high prediction accuracy in sentiment analysis?

I investigate this open question by evaluating the accuracy one may attain using two types of text encoding on representative benchmark datasets.

2.1 Multi-hot encoding

The first encoding is the well-known *multi-hot* encoding of text [7]. The multi-hot encoding represents a very simple model of the semantics in text.

2.2 Polarity-weighted multi-hot encoding

The second encoding I consider is the polarity-weighted multi-hot encoding of text.

Let π be a linguistic type (e.g. morpheme, word) and let Π_D be the set of all such linguistic types in a dataset D. Let $M = |\Pi_D|$ be the cardinality of Π_D. Let ψ be a linguistic text type (e.g., a movie review) and let Ψ_D be the set of all texts in D. Let $N = |\Psi_D|$ be the cardinality of Ψ_D. Let Π_D and Ψ_D be finite sets such that the elements in each set are enumerated by $\{0, ..., M\}$ and $\{0, ..., N\}$ respectively. Let T^{NxM} be a tensor of real numbers of dimensions N by M, whose elements are weighted by the cumulative effect of the polarity of each word present in a given text π, as computed by [8]. Let $c_{\pi,\psi}$ be the number of tokens of the linguistic type π in a text ψ. Let ξ_π be the polarity rating of the token $\pi \in \Pi_D$. Naturally, I assume that if Ξ_D is the set of all polarity ratings for tokens $\pi \in \Pi_D$, then $|\Xi_D| = |\Pi_D|$. Let $\omega_{\xi\pi\psi} = \xi_\pi * c_{\pi,\psi}$ be the cumulative polarity of π in the text ψ. Let $\Omega_D = \{\omega_i\}_{i=0}^{M}$ and $C_D = \{c_i\}_{i=0}^{M}$. Let Θ^{NxM} be a tensor of real numbers of dimensions N by M, whose elements are set as follows:

$$\{\theta_{jk}\} = \begin{cases} \omega_{\xi_k \pi_k \psi_j}, & \text{if } \pi_k \in \psi_j; \\ \\ 0, & \text{otherwise.} \end{cases} \tag{1}$$

The polarity-weighted multi-hot encoding (1) represents a more comprehensive model of the semantics in ψ, $\forall \psi \in \Psi_D$, that captures more information about ψ. I will attempt to investigate if and how much this additional information helps to improve the sentiment predictions in Section 4. An example of a polarity-weighted multi-hot encoded text is shown in Figure 1.

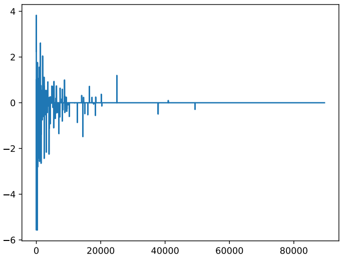

Fig. 1. A polarity-weighted multi-hot encoded text in D, Π_D with $M = 89527$.

2.3 The Keras IMDB Dataset (KID)

The KID [4] contains 50 000 human-written movie reviews that are split in equal subsets of 25 000 for training and testing and further into equal categories labeled as positive or negative. For convenience, the reviews have been pre-processed and each review is encoded as a sequence of integers, representing the ranking of the corresponding word in Π_D with $|\Pi_D| = 88\,587$. Hence, it can be easily encoded by the multi-hot encoding [7].

2.4 The Stanford Large Movie Review Dataset (SLMRD)

SLMRD contains 50 000 movie reviews, 25 000 of them for training and the rest for testing. The dataset comes also with a processed bag of words and a word polarity index [5, 10]. SLMRD contains also 50 000 unlabeled reviews intended for unsupervised learning. It comes with a Π_D, polarity ratings Ω_D, and word counts C_D with $|\Omega_D| = |C_D| = |\Pi_D| = 89\,527$.

3 The BowTie feedforward neural network

The ability of a neural network to provide accurate predictions and maintain low losses is very important for transferability to other datasets with the same or higher prediction accuracy as on the training dataset.

I now introduce a feedforward neural network with that criteria in mind. By way of background [11], logistic regression computes the probability of a binary output $\hat{y}_i$ given an input x_i as follows:

$$P(\hat{\mathbf{y}}|\mathbf{X}, \mathbf{w}) = \prod_{i=1}^{n} \mathbf{Ber}[\hat{y}_i|\mathbf{sigm}(x_i\mathbf{w})], \qquad (2)$$

where $\mathbf{Ber}[\ ]$ is the Bernouli distribution, $\mathbf{sigm}()$ is the sigmoid function, $\mathbf{w}$ is a vector of weights. The cost function to minimize is $\mathbf{C}(\mathbf{w}) = -\log P(\hat{\mathbf{y}}|\mathbf{X}, \mathbf{w})$.

This method is particularly suitable for sentiment prediction. One critical observation is that logistic regression can be seen as a special case of the generalized linear model. Hence, it is analogous to linear regression. In matrix form, linear regression can be written as

$$\hat{\mathbf{y}} = \mathbf{X}\mathbf{w} + \boldsymbol{\epsilon}, \tag{3}$$

where $\hat{\mathbf{y}}$ is a vector of predicted values $\hat{y}_i$ that the model predicts for $\mathbf{y}$, $\mathbf{X}$ is a matrix of row vectors x_i called regressors, $\mathbf{w}$ are the regression weights, and $\boldsymbol{\epsilon}$ is an error that captures all factors that may influence $\hat{\mathbf{y}}$ other than the regressors $\mathbf{X}$.

The gradient descent algorithm used for solving such problems [11] may be written as

$$\mathbf{w}^{(k+1)} = \mathbf{w}^{(k)} - \rho^{(k)}\mathbf{g}^{(k)} + \boldsymbol{\epsilon}^{(k)}, \tag{4}$$

where $\mathbf{g}^{(k)}$ is the gradient of the cost function $\mathbf{C}(\mathbf{w})$, $\rho^{(k)}$ is the learning rate or step size, and $\boldsymbol{\epsilon}^{(k)}$ is the error at step k of the iterative process. One error-introducing factor in particular is the numerical model itself and the errors generated and propagated by the gradient descent iterations with poorly conditioned matrices running on a computer with limited-precision floating-point numbers. Even if regularization is used, the specific parameters used to weigh them in the equation, e.g. the L_2-term weight or the dropout rate, may not be optimal in practice thus leading to potentially higher numerical error. This is why it is important to look for numerical techniques that can reduce the numerical error effectively. This observation inspires searching for techniques similar to multigrid from numerical analysis that are very effective at reducing the numerical error [12].

The neural network design

The feedforward neural network at the bottom of Figure 2 consists of one encoding layer, a cascade of dense linear layers with L_2-regularizers and of appropriate output size ($Z_i@K$, where K is the layer output size) followed by a dropout regularizer and a sigmoid. The encoder takes care of encoding the input data for processing by the neural network. In this paper I experiment with the two encodings defined in Section 2: the simple multi-hot encoding and the polarity-weighted multi-hot encoding.

The sigmoid produces the estimated output probability $P(\hat{\mathbf{y}}^{(i)}|\mathbf{x}^{(i)}, \mathbf{w}^{(i)})$, which may be used to compute the negative log-loss or binary cross-entropy as

$$-\left[\mathbf{y}\log(P(\hat{\mathbf{y}}^{(i)}|\mathbf{x}^{(i)}, \mathbf{w}^{(i)})) + (1-\mathbf{y})\log(1 - P(\hat{\mathbf{y}}^{(i)}|\mathbf{x}^{(i)}, \mathbf{w}^{(i)}))\right]. \tag{5}$$

The binary cross-entropy provides a measure for quality and robustness of the computed model. If the model predicts correct results with higher probability then the binary cross-entropy tends to be lower. If, however, the model predicts correct results with probability close to the discriminator value or predicts an incorrect category, the binary cross-entropy tends to be high. Naturally, it is

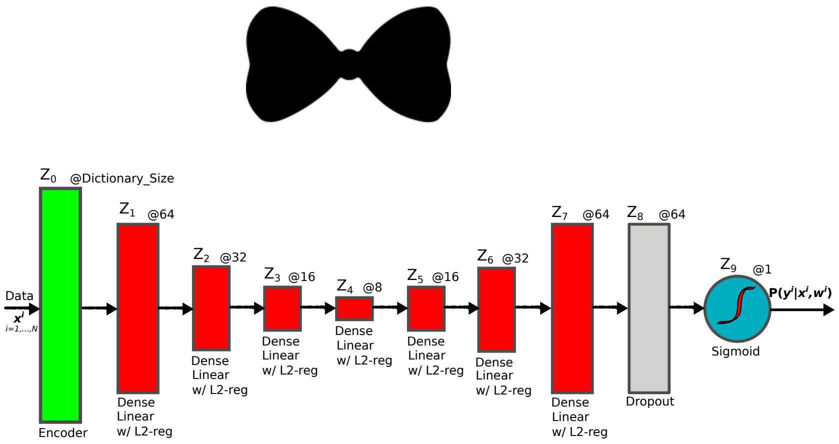

Fig. 2. The BowTie neural network. The classic bow tie (shown on top) originated among Croatian mercenaries during the Thirty Years' War of the 17th century. It was soon adopted by the upper classes in France, then a leader in fashion, and flourished in the 18th and 19th centuries. (Wikipedia). The estimated probability $P(\hat{\mathbf{y}}^{(i)}|\mathbf{x}^{(i)}, \mathbf{w}^{(i)})$ may be fed into a post-processing discriminator component to assign a category (pos/neg) for the input $\mathbf{x}^{(i)}$ with respect to a discriminator value $\delta \in [0, 1]$. All experiments presented in this paper use $\delta = 0.5$.

Table 1. BowTie hyperparameters.

Hyperparameters	
name	**values/range**
L_2-regularization weight	0.01 - 0.02
Dropout rate	0.2 - 0.5
Optimizer	NADAM or RMSProp
Dense Layer Activation	None (Linear network), RELU

desirable to have models that confidently predict correct results. It is also important to have models that maintain low binary cross-entropy for many training epochs because, depending on the training dataset, the iterative process (4) may need several steps to reach a desired validation accuracy. Models that quickly accumulate high cross-entropy estimates tend to overfit the training data and do poorly on the validation data and on new datasets.

Hyperparameters. There are several hyperparameters that influence the behavior of BowTie, see Table 1. For optimal performance the choice of the dense layer activation should be coordinated with the choice for the L_2-regularization weight. This recommendation is based on the computational experience with

BowTie and is in line with the findings in [14] about the impact of the activation layer on the training of neural networks in general. The optimal L_2-regularization weight for the linear network (no dense layer activation) is 0.019 whereas rectified linear unit (RELU) activation favors L_2-regularization weights close to 0.01. The network can tolerate a range of dropout rates but good stability and accuracy is attained with a dropout rate of 0.2. It is interesting to note thatRoot Mean Square Propagation (RMSProp) tends to converge faster to a solution and sometimes with a higher validation accuracy than Nesterov adaptive momentum (NADAM) but the transfer accuracy of the models computed with NADAM tends to be higher than for models computed with RMSPRop. For example, a model trained on SLMRD with validation accuracy of 89.24 %, higher than any of the data in Table 4 below, yielded 91.04 % transfer accuracy over KID, which is lower than the results in Table 4. This experimental finding is consistent over many tests with the two optimizers and needs further investigation in future research to explore the theoretical basis for it.

It may be possible to run BowTie with other optimizers or activation layer choices than those shown in Table 1 but I have not tested their effectiveness.

4 Training and transfer scenarios

This section defines the objectives for the testing of the BowTie neural network shown in Figure 2 in terms of four training and transfer scenarios.

But first it is important to decide on the type of training to employ - supervised or unsupervised. I embark on supervised training based on the findings in [3] about the advantages of supervised training and the availability of corpora of large labeled benchmark datasets [4] and [5]. The scenarios to explore are:

– **Scenario 1 (Train and validate):** Explore the accuracy and robustness of the BowTie neural network with the simple multi-hot encoding by training and validating on KID.
– **Scenario 2 (Train and validate):** Explore the accuracy and robustness of the BowTie neural network with the simple multi-hot encoding by training and validating on SLMRD.
– **Scenario 3 (Train and validate):** Explore the accuracy and robustness of the BowTie neural network with the polarity-weighted multi-hot encoding by training and validating on SLMRD.
– **Scenario 4 (Train, validate, and transfer):** Explore the transfer accuracy of the BowTie neural network with polarity-weighted multi-hot encoding by training on SLMRD and predicting on KID.

The primary goal of this exploration is to establish some baseline ratings of the properties of the BowTie neural network with the different encodings and compare against similar results for other neural networks with other types of encoding. This provides a quantitative criteria for comparative judging.

Results

In this section I report the results from executing Scenarios 1-4 from Section 4 using TensorFlow [7], version 1.12, on a 2017 MacBook Pro, *without* GPU acceleration. The modeling code is written in Python 3. The speed of computation improved on a platform *with* eight Tesla V100-SXM2 GPUs: speedup of nearly a factor of two but in training the acceleration plateaued if more than two GPUs were used.

Scenario 1. In this test, the BowTie neural network is tested with encoding [7]. The results in Table 2 show high accuracy and low binary cross-entropy estimates.

Table 2. Scenario 1 results. Data from experiments with training a model on KID until it attains some validation accuracy grater than 88 %. Note that each time the data is loaded for training, it is shuffled randomly, hence the small variation in computational results.

Training and validating on KID	
validation accuracy (%)	validation binary cross-entropy
88.08	0.2955
88.18	0.2887
88.21	0.2945

To assess the relative computational efficiency of the BowTie neural network, I compared it to the convolutional neural network in [13] with a 10000 word dictionary. The network reached accuracy of 88.92 % at Epoch 4 with binary cross-entropy of 0.2682. However, it took 91 seconds/Epoch, which matched the numbers reported by the authors for the CPU-only computational platform [13]. In addition, after Epoch 4, the binary cross-entropy started to increase steadily while the accuracy started to decline. For example, the binary cross-entropy reached 0.4325 at Epoch 10 with validation accuracy of 87.76 % and 0.5536 and 87.40 % correspondingly at Epoch 15. In comparison, BowTie takes only 3 seconds/Epoch for the same dictionary size and attains accuracy of 88.20 % with binary cross-entropy of 0.2898. The binary cross-entropy stays below 0.38 for a large number of Epochs.

Scenario 2. SLMRD is more challenging than KID for reasons that are visible in the test results for Scenarios 3 and 4, hence the slightly lower validation accuracy attained by BowTie using the simple multihot encoding [7] - it easily meets or exceeds the threshold accuracy of 87.95 % but could not surpass the 88 % level in several experiments.

Table 3. Scenario 2 results. Data from experiments with training a model on KID until it attains validation accuracy of at least 87.95 %. Note that each time the data is loaded for training, it is shuffled randomly, hence the small variation in computational results.

Training and validating on SLMRD	
validation accuracy (%)	validation binary cross-entropy
87.98	0.2959
87.95	0.2996
87.96	0.3001

Scenarios 3 and 4. I combine the reporting for Scenarios 3 and 4 because once the model is trained under Scenario 3 it is then transferred to compute predictions on KID. To perform the transfer testing on KID one needs to reconcile the difference in $|\mathit{\Pi}_{SLMRD}|$ and $|\mathit{\Pi}_{KID}|$. As I noted in Section 2, $|\mathit{\Pi}_{SLMRD}| = 89\,527$ and $|\mathit{\Pi}_{KID}| = 88\,587$. Moreover, $\mathit{\Pi}_{KID} \not\subset \mathit{\Pi}_{SLMRD}$. Let $\mathit{\Pi}_{\Delta} = \mathit{\Pi}_{KID} \setminus (\mathit{\Pi}_{KID} \cap \mathit{\Pi}_{SLMRD})$. It turns out that

$$\mathit{\Pi}_{\Delta} = \left\{ \begin{array}{l} 0s, 1990s, 5, 18th, 80s, 90s, 2006, 2008, \\ 85, 86, 0, 5, 10, tri, 25, 4, 40s, 70s, 1975, \\ 1981, 1984, 1995, 2007, dah, walmington, \\ 19, 40s, 12, 1938, 1998, 2, 1940's, 3, 000, 15, 50. \end{array} \right\}.$$

Clearly, $|\mathit{\Pi}_{\Delta}|$ is small and of the words in $\mathit{\Pi}_{\Delta}$, only 'walmington' looks like a plausible English word. This is the name of a fictional town in a British TV series from the 1970's. As such it has no computable polarity index and is semantically negligible. Based on this, I dropped all these words during the mapping of $\pi \in \mathit{\Pi}_{\Delta}$ into the corresponding $\pi\prime \in \mathit{\Pi}_{SLRMD}$. Note that the mapping $\pi \rightarrow \pi\prime$ enables the encoding of the semantics of the texts in KID according to (1).

Table 4. Scenarios 3 and 4 results. Data from experiments with training a model on SLMRD until it attains validation accuracy grater than 89 % and using that model to predict the category for each labeled review in KID, computing over the entire set of 50 000 reviews in KID.

Training on SLMRD		**Predicting on KID**
validation accuracy (%)	val. binary cross-entropy	Tansfer accuracy (%)
89.02	0.2791	91.56
89.12	0.2815	91.63
89.17	0.2772	91.76

Some simple but revealing statistics about the data. With encoding (1), the elements of the matrix T_{SLMRD} for the training set in SLMRD show cumulative polarity values in the range [-50.072 837, 58.753 546] and the cumulative polarity of the elements of the matrix T_{SLMRD} for the test set is in the range [-48.960 107, 63.346 164]. This suggests that SLMRD is pretty neutral and an excellent dataset for training models. In contrast, the elements of the matrix T_{KID} are in the range [-49.500 000, 197.842 862]. Table 4 contains the results from executing Scenarios 3 and 4. The validation and transfer accuracy results in Table 4 are better than those shown in Tables 2 and 3. This demonstrates the value word polarity brings in capturing the semantics of the text. The transfer accuracy over KID is also higher than the results obtained by using the convolutional neural network [13] on KID. The results in Table 4 are higher than the results reported for sentiment prediction of movie reviews in [3] but in agreement with the reported experience by these authors about consistently improved accuracy from supervised learning on a large representative corpus before transferring the trained model to a corpus of interest.

Note also that the validation accuracy of BowTie with the encoding (1) on SLMRD is higher than the results in [10] for the same dataset. The observation in [10] that even small percentage improvements on a large corpus result in a significant number of correctly classified reviews applies to the data in Table 4: that is, there are between 172 and 210 more correctly classified reviews by BowTie.

5 Discussion and next steps

The experimental results from sentiment prediction presented above show the great potential deep learning has to enable automation in areas previously considered impossible. At the same time, we are witnessing troubling trends of deterioration in cybersecurity that have permeated the business and home environments: people often cannot access the tools they need to work or lose the data that is important to them [15]. Traditionally, governments and industry groups have approached this problem by establishing security testing and validation programs whose purpose is to identify and eliminate security flaws in IT products before adopting them for use. One area of specific concern in cybersecurity is cryptography. Society recognizes cryptography's fundamental role in protecting sensitive information from unauthorized disclosure or modification. The cybersecurity recommendations in [15] list relying on cryptography as a means of data protection as one of the top recommendations to the business community for the past several years. However, the validation programs to this day remain heavily based on human activities involving reading and assessing human-written documents in the form of technical essays. This validation model worked well for the level of the technology available at the time when the programs were created more than two decades ago. As technology has advanced, however, this model no longer satisfies current day industry and government operational needs in the context of increased number and intensity of cybersecurity breaches [15].

There are several factors for this. First, current cybersecurity recommendations [15] require patching promptly, including applying patches to cryptographic modules. Technology products are very complex and the cost of testing them fully to guarantee trouble-free use is prohibitively high. As a result, products contain vulnerabilities that hackers and technology producers are competing to discover first: the companies to fix, the hackers to exploit. Patching products changes the game for hackers and slows down their progress. However, patching changes also the environment in which a cryptographic module runs and may also change the module itself, thus invalidating the previously validated configuration. Users who depend on validated cryptography face a dilemma when frequent updates and patches are important for staying ahead of the attackers, but the existing validation process does not permit rapid implementation of these updates while maintaining a validated status because of the slow human-based validation activities.

The second factor hindering the effectiveness of the traditional validation model is the demand for speed in the context of the cognitive abilities of the human brain. Recent scientific research points out that humans are limited in their ability to process quickly and objectively large amounts of complex data [16].

Going back to the results on sentiment analysis with deep learning from above and in spite of that success, people may always question the ability of machines to replace humans in solving such cognitive and analytical tasks. They will always ask why the accuracy is not one hundred percent? Or, notwithstanding the available scientific evidence [16], say that if a human was reviewing the text she would have never made a mistake.

Changing public opinion may be a slow process. Besides, it seems that cybersecurity and machine learning/artificial intelligence (AI) will always be joined at the hip because the more we rely on machines to solve ever more complex tasks, the higher the risk those machines may be attacked to subvert their operation. Can AI fight back though? The results presented in this paper suggest that computer-based validation of cryptographic test evidence may be the only viable alternative that would allow objective and accurate assessment of large volumes of data at the speed needed to respond to the present day cybersecurity challenge [15]. This paper demonstrates that deep learning neural networks are capable of tackling the core tasks in security validation and thereby automating existing programs [9]. If this effort is indeed successful one may reason that by helping to improve the process of validation and thereby increase cybersecurity, albeit indirectly, AI will in fact be defending itself from cybersecurity threats. Over time, this may lead to societal acceptance of AI into sensitive domains such as the validation of critical components for the IT infrastructure.

Next steps. The importance of incorporating word polarity into the model is illustrated clearly by the results presented in this paper. However, the type of language used in the validation test reports tends to be different than the colloquial English used in movie reviews. The technical jargon in test reports uses many common words whose meaning changes in this context. Moreover, the assessments for the test requirements are written in a way different from movie reviews. Here the author provides arguments that justify her conclusion about compliance. The challenge is to distinguish weak/faulty arguments from solid ones and develop an appropriate polarity model, along with assembling a representative corpus of labeled validation test report data for training and validation.

ABSTRACT

We describe the creation of a new Atomic and Molecular Physics science gateway (AMPGateway). The gateway is designed to bring together a subset of the AMP community to work collectively to make their codes available and easier to use by the partners as well as others. By necessity, a project such as this requires the developers to work on issues of portability, documentation, ease of input, as well as making sure the codes can run on a variety of architectures. Here we outline our efforts to build this AMP gateway and future directions.

1 INTRODUCTION

On May 14-16, 2018, an NSF supported workshop entitled, “Developing Flexible and Robust Software in Computational Atomic and Molecular (A&M) Physics” was organized by Barry Schneider (chair), Robert Forrey (Penn State) and Naduvalath Balakrishnan (UNLV) at the Institute for Theoretical Atomic and Molecular Physics, Harvard-Smithsonian ITAMP [5]. The purpose of the workshop was to bring together a group of internationally known researchers in computational atomic and molecular physics to:

- Identify and prioritize outstanding problems in A&M science, which would benefit from a concerted community effort in developing new software tools and algorithms that would lead to more rapid and productive scientific progress for the entire community.
- Discuss approaches to optimize achieving that goal.
- Produce and disseminate a report of the workshop to the community.

A concerted community effort is underway to develop and maintain these tools in order to ensure continued scientific progress. The group acknowledged that, in contrast to some other communities, A&M physics has lagged behind in developing community software that is robust and can be used, in a relatively straightforward way, by other than the group who developed that software. While there are exceptions, many software packages are poorly documented, poorly written, and only usable by a set of local “experts”. The tools themselves are capable of treating scientific and technologically interesting problems, but they are only accessible to a small group of people. The codes are not always maintained, and the lack of coordination among the developers has led to a lot of “reinventing the wheel”. The group felt strongly that the efforts being expended

Schneider, Barry I.; Bartschat, Klaus; Zatsarinny, Oleg; Bray, Igor; Martin, Fernando; Scrinzi, Armin; Pamidighantam, Sudhakar; Tennyson, Jonathan; Gorfinkiel, Jimena; Klinker, Markus. "A Science Gateway for Atomic and Molecular Physics." Paper presented at Practice and Experience in Advanced Research Computing (PEARC), Chicago, IL, US. July 28, 2019 - August 01, 2019.

in developing these computational tools should be available and usable by future generations of A&M scientists.

The success of the workshop led six of the groups to work together and develop an XSEDE proposal to build and maintain a Science Gateway devoted to the codes developed in these groups. That proposal was supported, and since May of 2018 there has been decent progress. A number of the codes are already ported and running on various XSEDE platforms. Some progress has been made in making them usable by others within the group but not yet the outside world. We are now taking steps to achieve this last goal.

The AMPGateway uses the multi-tenanted Apache Airavata middleware framework [2–4] served by the SciGaP hosting services for sustained operation. In the first stage of our efforts the software suites have been deployed as independent applications with specific input interfaces. Community building has already started and a few additional software suites have been identified for inclusion in phase two. The interoperability of the software suites is very important and will be addressed as a follow-on.

The present manuscript is divided into four major sections. In the Introduction we provide a history of how and why the project got started and our decision to go to XSEDE [1] for support for the gateway. In Section II we present some information on the AMP codes that are already available on the gateway. Section III is devoted to the details of the construction and deployment of the gateway. In Section IV we discuss issues of broadening usage of the gateway and questions of community building.

2 CURRENT CODE STATUS

At present, we have concentrated our major effort on five codes. A brief description of these packages is given below.

2.1 BSR

The *B*-spline *R*-matrix (BSR) method and the accompanying computer code [6] were developed by Oleg Zatsarinny in the group of Klaus Bartschat at Drake University. The program computes transition-matrix elements for electron collisions with atoms and ions as well as photoionization processes. From these, cross sections and other experimentally observable parameters can be obtained. The code can also be run in a mode that provides atomic structure information through energy levels and oscillator strengths.

The BSR approach is a particular variant of the *R*-matrix method to solve the close-coupling equations in coordinate space. In this respect, it is complementary to the convergent close-coupling (CCC) approach described below. BSR is an alternative formulation of the well-known *R*-matrix code developed in Belfast under the long-term leadership of Philip Burke. The Belfast code is somewhat singular in that it is readily available and used by a small group of users. While the last general write-up appeared in 1995 [7], updated versions are available [8]. A comprehensive introduction to *R*-matrix theory for atomic and molecular collisions processes, as well an overview of many applications, can be found in the book by Burke [9].

The published BSR code [6] is a serial version, which was written in the non-relativistic and semi-relativistic (Breit-Pauli) frameworks. Relativistic (DBSR) and MPI-parallelized versions, as well as extensions to treat ionization processes (similar to the CCC method described below) exist and are being used by the developer and a small group of collaborators. Executables of the parallelized codes (currently running on Stampede2) will be uploaded to the Gateway in the near future. The BSR and DBSR packages are a prime example where updated documentation and a wide distribution are urgently needed before critical expertise is lost. Fortunately, the urgency was recently recognized by the NSF and resulted in the funding of a three-year proposal to achieve exactly these goals. We expect the gateway described in the present paper to be one of the vehicles to ensure significant future progress.

A comprehensive overview of the BSR method and its applications at the time was published by Zatsarinny and Bartschat [10]. The most noteworthy features of the code are:

- Use a finite-element (*B*-spline) rather than a finite-difference approach in the calculation of the matrix elements needed to set up the hamiltonian in the inner region.
- Employ non-orthogonal sets of one-electron orbitals to account for the term-dependence of the valence orbitals, in particular for complex, open-shell targets, thereby providing an economical and accurate description of the target states and much flexibility in building the scattering wavefunction as well as pseudostates to further improve the target description and enable the treatment of electron-impact single-ionization as well as photon-driven double ionization processes.

The BSR code has the following major parts:

- Build the $N-$ and $(N+1)-$electron configurations.
- Generate all necessary one-electron and two-electron matrix elements to set up the target and scattering Hamiltonians in the internal region.
- Diagonalize these Hamiltonians.
- Propagate the wavefunction from the *R*-matrix boundary, $r = a$, to "asymptotia" (r_b), where it can be matched to known analytic forms. The propagation requires the solution of a set of coupled differential equations using known long-range potentials and needs to be repeated for each scattering energy. If angle-differential ionization processes with two free electrons in the final state are to be treated as well, the inner region may need to be increased beyond the original criterion.

Even though there is no general way to predict where most of the computational effort is needed, in most cases the generalized eigenvalue problem (diagonalization with *all* eigenvalues needed) of the $(N+1)-$electron Hamiltonian is a very time-consuming step. For complex targets, setting up this Hamiltonian can be expensive as well. For ionic targets, the wealth of resonances may require many thousands of collision energies to be treated, which can result in significant time going into the asymptotic region.

To summarize: The BSR method is closely related to both the Belfast *R*-matrix approach and the CCC method described below. The two *R*-matrix codes were designed to handle complex targets and many energies, while the CCC code can handle more processes but is essentially limited to quasi-one and quasi-two electron targets. Some benchmark comparisons for problems that all three methods should be able to handle have been performed. As expected, the results are numerically equivalent, but one or the other method may be more efficient. The details strongly depend on the complexity of the target and the energies for which results are required.

2.2 CCC

The original implementation of the Convergent Close-Coupling method was designed to produce accurate cross sections for scattering of light projectiles from quasi one- and two-electron targets [14]. It began with electron-hydrogen scattering [15], and was further extended to quasi-one electron targets well-modeled by one valence electron above a frozen Hartree-Fock core [16]. It was then extended to the helium target [17], and quasi two-electron targets such as Be [18]. The main features are:

- Expansion of the target state in a sufficiently complete $\mathscr{L}^2$ basis size N to treat cases where both excitation and ionization of the target are possible, with convergence tested by systematically increasing N.
- Expansion of the scattering wavefunction in the momentum based Lippmann-Schwinger equation.
- Introduction of numerical quadrature to reduce the problem to a very large set of linear algebraic equations.

CCC has been extended to positron scattering, where the positron introduces a second center capable of forming the electron positron bound state known as positronium (Ps) [19]. This is an example of a rearrangement collision and as such introduces even more complexity into the computational procedure. Such calculations can be "time-reversed" to be considered as Ps scattering on (anti)protons to form (anti)hydrogen [20]. A review of the CCC method for positron scattering has been given by Kadyrov and Bray [21].

On the computational side, the CCC codes have been parallelized to use OpenMP on a node and MPI between nodes and have been deployed successfully on Comet and Stampede2. A GPU implementation, currently underway, shows immense promise with up to two orders of magnitude speedup.

2.3 UKRMol(+)

The UK Molecular R-matrix codes were designed to treat low-energy elastic and inelastic electron-molecule collisions using the R-matrix method; they have evolved to also study photoionization and positron-molecule collisions as well as to produce the input required for time-dependent molecular R-matrix with time (RMT) calculations [22]. Similar to BSR they are based on the R-matrix method and the general theory can be found in the book by Burke [9].

The now frozen release version of the (mainly serial) UKRMol suite uses Gaussian Type Orbitals (GTOs) to represent both the target and continuum orbitals. A publication presenting this code by Carr *et al.* [23] followed a project which substantially updated (to Fortran95) and standardized the programming used, particularly in the inner region. A review article by Tennyson [25] from the same period gives a comprehensive overview of theory used and the functionality of the code.

The use of GTOs to represent the continuum leads to constraints on both the size of the inner region that can be used and the free electron energy range. Recently a new suite, known as UKRMol+, has been developed led by Zdeněk Mašín and Jimena Gorfinkiel [23]. The code uses the new GBTOlib integral library to determine all the one- and two-electron integrals needed in the mixed basis of GTOs and B-splines: it offers the choice of using GTOs, B-splines or hybrid GTOs – B-splines to represent the continuum; the bound orbitals are always described by GTOs. The library, that uses object oriented features from the Fortran2003 standard, involves distributed and shared-memory parallelization. UKRMol+ incorporates a number of algorithmic improvements, including a faster configuration state function (CSF) generation and parallization of the construction and diagonalization of the N and $(N+1)$ Hamiltonians [29]. Further parallelization to avoid I/O to disk during the evaulation of transition moments for photoionization and RMT input is currently being tested.

Both suites contain a rich array of outer region functionality including automated resonance detection and fitting, bound state detection, computation of multichannel quantum defects, rotational excitation and evaluation of photoionization cross sections. So far applications of the UKRMol+ suite are limited [26–28], but a full release and associated article will be available shortly [29].

The codes have been available as freeware for more than a decade and are widely used: the software can be downloaded as a tarball and installed (in the case of UKRmol+) using cmake, provided the necessary libraries are available in the system. Neither suite is straightforward to use without training; Quantemol-N [30] is a commercial front end which has led to a significant increase in the user base of the code. A set of perl scripts developed by Karel Houfek that simplify writing the input is also now available, both for electron scattering and photoionization calculations. Further details can be found on the website of the UK Atomic, Molecular and Optical physics R-matrix consortium (https://www.ukamor.com/).

2.4 tRecX

The tRecX code package [31, 32] is a general framework for solving initial value problems of the form

$$\frac{\partial}{\partial t}\Psi = \mathcal{D}[\Psi, t] + \Phi(t) \tag{1}$$

for an arbitrary number of spatial dimensions and a variety of coordinate systems. The main design is for linear $\mathcal{D}$, but non-linear operators can also be used.

2.4.1 Applications. The code has been primarily used for solving the time-dependent Schrödinger equation of atomic and molecular systems in ultra-short pulses and in strong near-IR fields. The most significant results are fully differential spectra for single- and double photo-emission from the He atom at near infrared wave-length [33], strong field ionization rates of noble gases [34] and differential spectra for small di- and tri-atomic molecules [35, 36], cf. Fig. 1.

2.4.2 Methods. The code uses three newly developed key techniques:

(1) irECS — *"Infinite range exterior complex scaling"* [37] as absorbing boundary conditions and for the computation of life-times. irECS is a variant of exterior complex scaling with an infinitely wide boundary for absorption at all wave lengths.

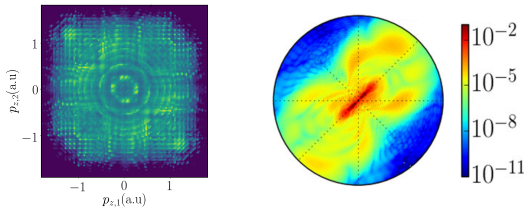

Figure 1: Left: Helium in full dimensions, double emission cross-section $\sigma(p_{z,1}, p_{z,2})$ for a 2-cycle pulse at wavelength 400 nm and $5{\times}10^{14} W/cm^2$ intensity. Anti-correlated emission is favored. Right: haCC calculation for CO_2, photoemission by an 800 nm laser pulse at intensity $10^{14} W/cm^2$ up to energies 2.5 au in the xz-plane at 45° alignment of the molecular axis to polarization direction (from [36].)

(2) tSurff — the *time-dependent surface flux* method [38] for photo-emission spectra. By tSurff, the actual numerical solution remains contained in a small reactive region of typically 20 to 100 atomic units.

(3) haCC — the *"hybrid anti-symmetrized Coupled Channels"* method [39] combines Gaussian-based neutral and ionic CI states with a numerical single-electron basis. The numerical basis extends over the whole system, thus ensuring the proper description of energetic electron-molecule collisions.

Two of these techniques are reflected in the code's name

tRecX = tSurff + irECS

2.4.3 Structure and inputs. An effort was made to keep the code flexible without sacrificing efficiency. Systems with dimensions from one (popular models) to six (He in elliptically polarized fields), as well as multi-channel models (photo-electron spectra for molecules) are treated within the same framework: the degrees of freedom map into a tree hierarchy, inducing a tree-structure for vectors and operators, and producing transparent and efficient code by recursion.

Basis functions are arranged in a tensor-tree with a variety of basis sets, finite-elements, FE-DVR, and grids that can be combined on any number of coordinate axes, with multiple basis sets on the same axis. Discretization and operators can all be input-controlled. For example,

```
#define BOX 20
Axis: name,nCoeff,lower,upper,funcs,order
Phi,5,,,expIm
Eta,3,-1,1, assocLegendre{Phi}
Rn,60, 0,BOX,polynomial,15
Rn,20, BOX,Infty,polExp[0.5]
```

with Eta for $\cos\theta$ defines polar coordinates. The bases $\exp(im\phi)$ and $P_l^{|m|}(\cos\theta)$ combine to the spherical harmonics up to $l = 2$ and the r-coordinate uses 60/15=4 FE-DVR elements on $[0, 20]$ with 15 polynomials on each and 20 exponentially damped polynomials at the end. An example for operator specification is

```
Operator: hamiltonian
0.5(<d_1_d><1>+<1><d_1_d>+<Q*Q><1>+<1><Q*Q>)
```

for $(\overleftarrow{\partial}_x \overrightarrow{\partial}_x + \overleftarrow{\partial}_y \overrightarrow{\partial}_y + x^2 + y^2)/2$. Many standard operators are pre-defined for various coordinate systems.

2.4.4 Software. The code is open source hosted on a Gitlab repository [32]. It is written mostly in C++ and linked with some Fortran-based libraries. Optionally, functionality can be extended by linking FFTW and GSL. Standard compilers are gcc and Intel, ports to Windows and Mac's Clang have been successful but are not actively supported. Compilation is through CMake, and Doxygen documentation is available. Tutorials and further materials are available in the git and from the tRecX website [31].

2.5 XChem

XChem [40, 41] is a solution for an all-electron ab initio calculation of the electronic continuum of molecular systems. XChem combines the tools of quantum chemistry (as implemented, e.g., in MOLCAS [44]) and scattering theory to accurately account for electron correlation in the single-ionization continuum of atoms [41, 43], small and medium-size molecules [42]. At its core lies a close coupling expansion combined with the use of a hybrid Gaussian and B-Spline basis set [40].

This approach yields the scattering states of the molecular system via the eigenstates of the close coupling matrix (CCM). While useful in their own right, the full potential lies in using the close coupling matrix as a starting point for time dependent calculations. In doing so, one may explicitly model the interaction of molecules with ultrashort (attosecond) pulses. The large band widths of such pulses lead to the coherent excitation of multiple ionization channels, whose coupling (accurately described in XChem) gives rise to complex phenomena.

An attractive feature of XChem is that the architecture of the basis functions (Fig. 2) and the use of MOLCAS allow one to describe the electronic continuum of medium-size molecules at the same level of theory as multi-reference CI methods do for the ground and the lowest excited states of such molecules. At present the largest systems treated have of the order of ten atoms.

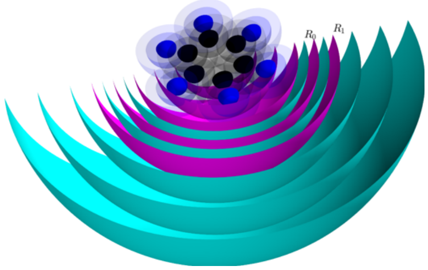

Figure 2: Illustration of the XChem basis architecture in benzene. Cyan: B-splines, mangenta: Gaussians at the center of mass of the molecule, blue and black: Gaussians at the atomic sites not overlapping with B-splines.

2.5.1 What can XChem do? XChem can compute:

- The CCM for a user-defined set of ionization channels (each defined as an ionized molecular state coupled to electrons

of given angular momenta) and including short range states relevant to the problem at hand.
- Scattering states and scattering phases by asymptotic fitting to the analytical solution.
- Total and partial photoionization cross sections within perturbation theory.
- Lifetime and character of resonances embedded in the molecular continuum, either via analysis of the cross section or via inclusion of a complex absorbing potential in the CCM yielding complex eigenenergies.
- The electron dynamics during and after ionization, caused by and probed with ultrashort laser pulses, by solving the time dependent Schrödinger equation using the CCM.
- The angular distribution of photo electrons (in progress).

2.5.2 What can XChem be used for? XChem is a valuable tool for:

- The theoretical study of ultrafast processes in in Attosecond pump-probe experiments, Attosecond Transient Absorption Spectroscopy (ATAS) and Reconstruction of Attosecond Beatings by Interference of Two-Photon Transitions (RABBIT).
- The investigation of photoionization of complex molecules close to threshold, where electron correlation effects are crucial to describe the photoionization cross sections.
- The study of ionization processes intrinsically dependent on electron correlation, like autoionization and Auger decay.
- The computation of potential energy surfaces for the investigation of molecular dynamics during and after fast photoionization events.

2.5.3 Who is using XChem?

- Researchers in (computational) quantum chemistry or molecular physics interested in studying electron dynamics in the ionization continuum of molecules (e.g., photoionization, charge migration, etc).
- Laboratories investigating ultrafast phenomena in many-electron atoms, small and medium-size molecular systems.

2.6 Other Interesting Software

We are also standing up the rather old Many Electron Structure Applications (MESA) code that was developed at Los Alamos in the 1980's and modified to compute electron scattering and photoionization cross sections from polyatomic molecules using the Complex Kohn Method [45]. While this code is old, and in need of significant modernization, it was built to compute electron scattering and photoionization transition matrix elements for general polyatomic molecules, a capability not present in other codes and of interest to many users.

There is also an effort underway to incorporate MOLSCAT [46], a heavy particle collision code for vibrational-rotational scattering in molecules. Table 1 summarizes some of the applications deployed.

3 AMP SCIENCE GATEWAY DEPLOYMENT AND APPLICATION INTEGRATION

The AMP Gateway is deployed using the Apache Airavata Framework. [4] It relies on the Science Gateway Platform as a Service (SciGaP) (https://scigap.org/) hosting services [3] at Indiana University. The SciGaP platform provides gateway services using the multi-tenanted Apache Airavata middleware. The Airavata core enables features such as managing user identity, accounts, authorization provisioning, and the ability to access XSEDE and other high performance computational resources such as XSEDE's Stampede2, Comet and Bridges. These resources are transparently integrated into the AMP gateway and the batch queues are used for scheduling the execution of models using applications and user defined parameters.

3.1 User Accounts, Authentication and Authorization

The AMP gateway user accounts can be created by users by providing a userid and setting a password along with providing email for verification process. In addition to this an automated process using the user institutional login via CI-Logon [47] is also provided which avoids the email verification step. The gateway administrator controls the access to the resources and needs to approve the user for gateway resource access. The users get a "gateway pending role" when they register. The gateway middleware provides authentication and authorization services through the Keycloak [2] identity management system supported by SciGaP. Once the gateway administrator provides approval, the role of the new user will be changed to "gateway-user" which enables access to gateway resources and applications. The gateway additionally provides "admin-read-only" and "admin roles" with their associated permissions for a group to share the admin responsibilities and reporting purposes. A "gateway-user" then, can use gateway services such as creating, monitoring, sharing and cloning experiments (computational simulations). The users can also add their own compute resource allocations using the functions available under "User Settings". The "admin" users have the authorization to control metadata for accessing XSEDE through the gateway "community login", register and deploy applications and their (user) interfaces, manage users, and monitor and access all user experiments. These privileges enable the admin to efficiently troubleshoot any issues relating to the user services. The "admin-read-only" users can view all "admin" related information but not modify any of the settings.

3.2 AMP Application Deployment and User Interface Creation

The AMP gateway started with four specific applications described above: BSR, XChem, CCC and tRecX suites. These applications were compiled and tested on a number of the XSEDE resources. Each of them requires a different set of libraries and in the case of XChem integration with other Open source software such as OpenMolcas [12]. They were independently tested by the collaborating XSEDE ECSS consultant when deployed by the developers or deployed by the consultant to establish the required environments and tweak make/cmake data. The Application deployment in the

Code	Application	Method	Parallel or Serial	Access	Restrictions
BSR	Electron scattering, photoionization, structure	R-matrix/B-spline	S, MPI	BSR (serial)	atoms, atomic ions
CCC	Electron scattering, Positron scattering Photoionization	Close coupling, Fredholm equations in momentum space	OpenMP and MPI		Quasi one- and two-electron atoms and ions
UKRMol(+)	Electron scattering, photoionization	R-matrix, Close coupling Gaussian and B-spline basis	OpenMP and MPI	Public (Zenodo)	Molecules and clusters ($\leq$ 30 atoms)
tRecX	Strong field photo-emission spectra, rates	TDSE (tSurff, haCC): grids, CI-states, FE-DVR, bases	MPI	Public (Git)	Small molecules, two-electron atoms
XChem	Scattering states Photoionization	Close coupling Configuration Interaction Hybrid Gaussian and B-spline basis	OpenMP	Upon request	Small and medium-size molecules
MESA	Electronic structure, scattering, photoionization	SCF, MCSCF, CI, Complex Kohn	S	By request	Small to medium molecules

Table 1: Some characteristics of the software suites deployed in the AMP Gateway.

AMP Gateway consists of defining the application as a "module", an "interface" is defined to user interaction with the application and a resource specific "deployment" description to fully define it on the gateway. The user interfaces are tailored to each application and enable the users to provide input parameters using files or variables that either can be sent as arguments to the application or a wrapping script. Currently, the interface generator, the PHP Airavata client API, provides ways to define file URIs, variables (strings, real/integer/Booleans) for inputs and standard Error/Outputs and file and variables for outputs. Multiple choices for different application sub-modules can be provided to specify and invoke a specific component of the application(for example, Bound/Photonics/LS/JK under software BSR). This can be defined using a simple comma delimited set and can be used in a wrapper to pass it as arguments or specified as input parameters for the application as depicted in figure 3. The interfaces deployed for the four applications will be further enhanced with additional details for input variables and ingesting file sets as archives and whole folders in due course. The job submission interface then enables users to define HPC resource details such as the system/machine ID that is automatically sorted from the list obtained from the deployment description, queue/partition and allocation registered by the administrator or a user, and job specific details such as the number of nodes and processors, time and memory specifications. In additions these experiment specification the Apache Airavata framework provides a sharing mechanism for jobs/experiments and projects (which are collections of experiments) to be shared with collaborators and can be set during the experiment creation (or at any time after). This allows collaborative job submission, monitoring and analysis of the results.

3.3 Monitoring Job Progress

During experiment creation users can provide their email to receive messages at job start and end supplied by the scheduler. Additionally, once the experiment is accepted and launched, an "Experiment Summary" interface is launched and automatically refreshed periodically in order to show the status of the job submitted into the XSEDE resources. Currently the status of the job in the scheduler is reflected in the summary interface shown in figure 4. Gateway users can monitor experiments owned by them or shared with

them by other gateway users. Gateway administrators can monitor all gateway experiments using the "Experiment Statistics" page available in the "Admin Dashboard". The monitoring information is provided by a log processing system that extracts the relevant experiment task level execution logs from the gateway middleware and presents it in the gateway monitoring interfaces as depicted in figure 5.

3.4 Gateway Admin Dashboard

The "Admin Dashboard" is the workspace for the gateway administrator(s) within the gateway. All the admin features discussed above are available through the Admin Dashboard. Apart from what has been discussed, the admin dashboard provides a notification feature and also a way to managing gateway preferences when it comes to individual compute resource and storage resource connectivity and also helps managing credentials for secure compute resource communications. Gateway administrators can create notifications for gateway users and share them with the users with set begin and expiration times. The gateway admin can set and define preferences for the usage of each compute resource with specifications such as community or shared login name, job scratch location for the job data staging and execution, preferred job submission and file transfer protocols, and allocation project number for charging the run time. Similarly, the admin dashboard is used to generate an SSH credential token and key to be used for authentication and authorization at the compute resource and storage resource communications. The admin dashboard also provides job scripts created by the Airavata middleware, the actual path of the job directory on the remote HPC system and detailed task level logs for a specific job to the administrator to check health of the job workflow or troubleshoot in case it is needed.

4 COMMUNITY BUILDING

A proposal has been written to the MOLecular Software Sciences Institute(MOLSSI) [48] to host a series of workshops designed to ;

1. (1) Promote our ideas to a larger more diverse group of scientists than the ITAMP workshop participants both in A&M physics as well as other related fields to help us solidify our ideas.
2. (2) Initially conduct a three day workshop, most likely hosted by NIST sometime this fall.
   - We envision inviting about 30 participants consisting of both A&M scientists and quantum chemists.

- We have requested support from the MOLSSI for the participants and have already been informed that we can expect $15K to support our efforts.
- The NSF Computational Physics program has also promised $10K in support.

(3) The workshop will consist of a number of general sessions discussing the codes and what they can and cannot do. In addition, there will be hands on sessions on how to use the codes on the Science Gateway.

(4) Develop a road-map for other workshops focusing more on a specific code or codes for specialists.

5 ACKNOWLEDGEMENTS

BIS acknowledges the Mathematical Software group of the Applied and Computational Mathematics Division at NIST for supporting this work. This work used the Extreme Science and Engineering Discovery Environment (XSEDE) Stampede2, Comet, and Bridges resources, and an ECSS collaboration grant the through the allocation TG-PHY180023, which is supported by National Science Foundation grant number ACI-1548562. Additional support is provided by the Science Gateways Community Institute, NSF Award 1547611 [49]. The SciGaP.org platform and Apache Airavata are supported by NSF Award 1339774. KB and OZ acknowledge NSF support through grant Nos. PHY-1520970, PHY-1803844, and OAC-1834740. FM and MK acknowledge support by the ERC Proof-of-Concept Grant No. 780284-Imaging XCHEM within the Horizon 2020 Framework Program and by the Spanish MINECO Grant No. FIS2016-77889R. JT and JDG acknowledge support through the UK-AMOR high end computing consortium under EPSRC grant EP/R029342/1.

Performance Study of a GAA-GAA Coexistence Scheme in the CBRS Band

Weichao Gao and Anirudha Sahoo
National Institute of Standards and Technology
Gaithersburg, Maryland, U.S.A.
Email: {weichao.gao anirudha.sahoo}@nist.gov

***Abstract*—The General Authorized Access (GAA) users in the Citizens Broadband Radio Service (CBRS) band are the lowest priority users who not only have to make sure that they do not cause harmful interference to the higher tier users but also must cooperate with each other to minimize potential interference among themselves. Thus, efficient GAA coexistence scheme is essential for operation of GAA users and to obtain high spectrum utilization. Towards this goal, the Wireless Innovation Forum (WInnForum) has recommended three schemes to facilitate coexistence among the GAA users. To the best of our knowledge, there is no performance study on any of these schemes available in the public domain. In this paper, we study performance of one of these schemes (called Approach 1). We choose two actual locations in the USA around which our study is conducted using actual terrain and land cover data of the continental USA. We evaluate performance of the scheme at different deployment densities, using different propagation models and with different mix of CBRS devices (CBSDs) at those two locations. We provide some interesting insights into the bandwidth allocation process and performance of Approach 1 in terms of mutual interference.**

I. Introduction

The Federal Communications Commission (FCC) in the USA has published the rules for commercial use of the spectrum in the 3.5 GHz band known as Citizens Broadband Radio Service (CBRS) band on a sharing basis [1]. The CBRS band has a three tiered access model. Current incumbents will operate in the highest tier followed by the Priority Access License (PAL) users in the middle tier and the General Authorized Access (GAA) users in the lowest tier. The incumbents must be protected from harmful interference caused by tier-2 (PAL) and tier-3 (GAA) users. PAL users should be protected from interference from GAA users. However, a GAA user cannot expect interference protection from higher tier users as well as from other GAA users in the same tier. Access to the spectrum in this band is managed by Spectrum Access Systems (SASs). As per the rule 47 C.F.R. § 96.35 in [1], GAA users must cooperate with each other to minimize the potential interference and to increase spectrum utilization. In the first phase of deployment in the CBRS band, there will be no PAL users. Hence, only GAA users will share the spectrum with the incumbents. Thus, GAA-GAA coexistence is very criticial to the success of this band. The Wireless Innovation Forum (WInnForum), which is involved in developing standards for operation of systems in the CBRS band has published Technical Reports recommending different schemes to faciliate effective GAA-GAA coexistence that should minimize mutual interference and increase spectrum utlization. The WInnForum has recommended three different schemes for GAA-GAA coexistence in three different Technical Reports [2]–[4]. The design and architecture of these schemes are largely based on discussions and experience of various members of the WInnForum. To the best of our knowledge, there is no performance study on any of these schemes available in the public domain. In this paper, we take up one of those schemes, named *Approach 1*, proposed in [2] and study its performance in different configurations. In the CBRS band, there can be two types of CBRS devices (CBSDs). Category A (CatA) CBSDs transmit at lower power than Category B (CatB) and are typically installed indoors. CatB CBSDs are deployed outdoors. We study the effect of propagation model, deployment density and different population of CatA and CatB CBSDs on the performance of the GAA-GAA coexistence. It is envisioned that operators will group their CBSDs into, what are called, Coexistence Groups (CxGs). The CxGs will be responsible for managing interference among their respective CBSDs. Hence, a SAS will only be responsible for allocating bandwidth to the CxGs.

The main contributions of this work are as follows. The WInnforum does not define any performance metric to evaluate its proposed schemes. We have proposed a few performance metrics, which will be useful for operators and SAS administrators to evaluate the schemes as well as to compare different schemes. To the best of our knowledge, there is no such study on the GAA-GAA coexistence schemes available in the public domain. Consequently, our work should provide insight into the performance of the scheme (Approach 1) proposed in [2] in terms of various deployment parameters and propagation models. We use actual deployment location data and use the WInnForum reference implementation of propagation models [5] which uses actual terrain and land cover data of the continental USA. Hence, our simulation results should be close to what one would expect in practice. As explained later in the paper, in one of our experiments, we deviate from the WInnForum scheme and show how more bandwidth (compared to WInnForum scheme) can be allocated at the cost of higher interference. Results from this experiment suggest that a better scheme can be designed to provide more bandwidth to the CBSDs if they agree to tolerate higher

AIPCCG	Average Interference Power per CBSD per Channel per grid

interference up to a certain threshold.

II. Related Work

Coexistence issues in different wireless bands have been studied in the past. Coexistence challenges for heterogeneous cognitive networks in the TV white space have been discussed in [6]. In this study, coexistence between the secondary users and the incumbents as well as among the secondary users is discussed. Coexistence among secondary users which are heterogeneous in their air interface and MAC protocol is also considered. Coexistence of LTE-licensed assisted access (LTE-LAA) and WiFi in the 5 GHz band has been studied in [7]. Coexistence of LTE-LAA and WiFi in the TV white space has been proposed in [8], [9]. Some of the solutions proposed in the literature are to modify LTE MAC protocol to improve coexistence performance. The above coexistence scenarios are addressed with specific air interface or MAC protocol in mind. However, the GAA-GAA coexistence schemes in the CBRS band proposed by the WInnForum do not assume any particular air interface or MAC protocol. As mentioned earlier, the WInnForum has proposed three approaches to solve the GAA-GAA coexistence problem. Approach 1 [2] treats bandwidth as the only resource and hence, allocates bandwidth to the CBSDs such that interfering CBSDs are assigned different channels to the extent possible. It does not manipulate transmit power of the CBSDs for coexistence purpose. If the deployment is too dense and hence, assigning different channels to interfering CBSDs is not possible, then this scheme allows some CBSDs to be assigned the same channel even if they may interfere with each other. Approach 2 [3] deals with bandwidth and transmit power together and treats them as two types of resources. In dense deployment scenarios, if there are not enough channels to allocate different channels to interfering CBSDs, then less transmit power is allocated to a pair of interfering CBSDs so that intereference between them is mitigated and hence, can be allocated the same channel. Approach 3 [4] tries to maximize the amount of bandwidth allocated to individual CxGs by using a recursive algorithm to a cluster of CBSDs. It first identifies the CBSDs which belong to a CxG and are only connected to (i.e., interfere with) CBSDs which belong to the same CxG. These CBSDs are refered to as *cluster of size 1*. These clusters can be allocated $100\,\%$ of the available bandwidth. Next is to identify CBSDs belonging to cluster of size 2. CBSDs in these clusters belong to one of two CxGs. In this case, $50\,\%$ of available bandwidth is allocated to CBSDs belonging to one CxG and the other $50\,\%$ is allocated to CBSDs belonging to the other CxG. This algorithm is then applied recursively until all CBSDs are covered. A study of impact of propagation models on GAA-GAA coexistence and deployment density is presented in [10].

III. Overview of WInnForum Scheme (Approach 1)

The WInnForum has proposed three different schemes as solutions to GAA-GAA coexistence. In this section, we present salient parts of one of these schemes, named Approach 1 [2], which we have used in our study.

A. CBSD Interference Graph

For the purpose of GAA-GAA coexistence, a CBSD Interference Graph (CIG) is constructed in a deployment area. The vertices in the CIG are the CBSDs. An edge is placed between two CBSDs if either one or both of the CBSDs experience interference from the other CBSD above a given threshold. Edge Weight (EW) between all pairs of CBSDs is computed to determine if an edge should exist between the pair. If the computed EW is above a set Edge Threshold (ET), then an edge is established between the two CBSDs.

1) Edge Weight Calculation: For Edge Weight (EW) calculation, an Interference Metric (IM) between two CBSDs is first computed. IM is a measure of mutual interference between two CBSDs. Depending on the deployment scenario, IM may be computed in *area coordination* or in *point coordination* mode. For example, when CBSDs are deployed as LTE e-NodeB, then it needs to have a coverage area which should be protected from interference. Hence, in this case, IM in area coordination mode should be computed. On the other hand, when two CBSDs are deployed for Fixed wireless service, one CBSD is deployed as the Base Transceiver Station (BTS) and the other is deplyed as a Customer Premise Equipment (CPE) CBSD. They communicate in point-to-point mode and hence, interference at those CBSDs needs to be limited. The point coordination mode is appropriate in this case. In this study, we are intereseted in CBSD deployment for LTE coverage and hence, focus on area coordination mode.

In area coordination mode, for a pair of CBSDs, say CBSD-1 and CBSD-2, coverage area of each CBSD is computed. Coverage area of a CBSD, for a given transmit power, is the area around the CBSD such that the received signal strength at any point inside the area is above a set threshold. The WInnforum scheme specifies that this threshold should not be less than -96 dB relative to 1 mW (dBm)/10 MHz. The fraction of coverage area of CBSD-1 that overlaps with the coverage area of CBSD-2 is taken as CBSD-1's interference metric IM_1. Similarly, interference metric IM_2 of CBSD-2 is the overlap area expressed as a fraction of its coverage area. Then the EW between CBSD-1 and CBSD-2 is the maximum

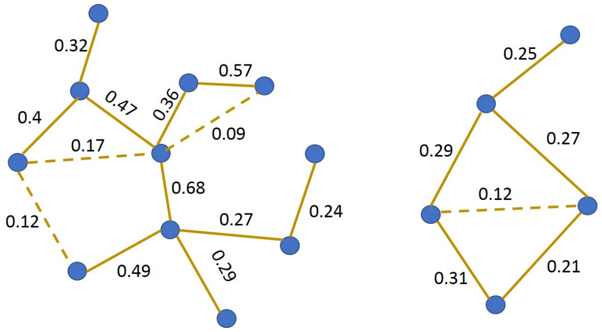

Fig. 1: An Example CBSD deployment with Edge Weights

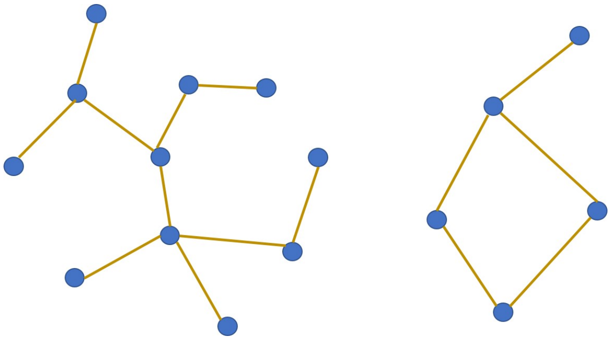

Fig. 2: Example CBSD Interference Graph when ET=0.2

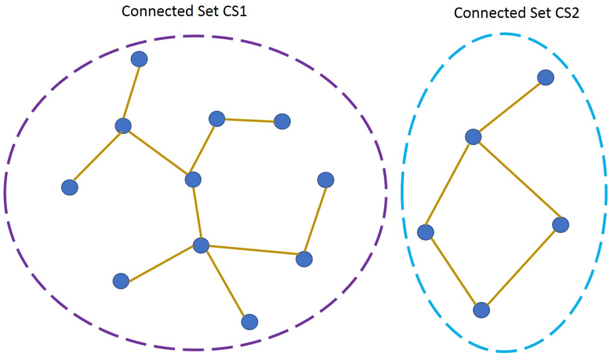

Fig. 3: Example Connected Sets

of IM_1 and IM_2. Note that EW takes a value between 0 to 1. For a given edge threshold (ET), an edge is established between CBSD-1 and CBSD-2 only if the EW is greater than the ET. This procedure is followed for every pair of CBSDs to obtain the CBSD interference graph.

2) Connected Set: Once the CBSD inferference graph is constructed, the next step is to generate *connected set(s)* off of it. A CBSD interference graph may contain one or more connected sets. Any two CBSDs in a connected set are connected directly through an edge or indirectly through other CBSDs in the interference graph. No CBSD within a connected set is connected directly or indirectly to any CBSD outside of the connected set [2].

Fig. 1 shows an example of CBSD Interference Graph when the ET is set to 0.2. In the figure, there is a solid edge between two CBSD if their coverage areas overlap and the EW between them is greater than or equal to the ET. A dashed edge indicates that the coverage areas of the two CBSDs overlap, but the EW is less than the ET. No edge between two CBSDs implies that the coverage area of the two CBSDs do not overlap. After applying edge threshold and removing the dashed edges, we get the CBSD interference graph as shown in Fig. 2. When the conditions of connected set are applied to this interference graph, we get two connected sets CS1 and CS2 as shown in Fig. 3.

3) Coexistence Groups: It is envisioned that operators in this band will create Coexistence Groups (CxGs) to faciliate GAA-GAA coexistence. A CxG consists of a group of CBSDs which will coordinate their own interference within the group. Thus, a SAS is only responsible for the allocation of bandwidth at the CxG level. The operator (or a CxG manager) of a CxG will take the bandwidth allocated to it and assign it to individual CBSDs within the CxG as per its interference management policy. As a result, a connected set will consist of one or more CxGs, i,e., CxGs are subgraphs in a connected set. The CBSDs which do not belong to any CxG are grouped together to form a common CxG (sort of a virtual CxG).

4) Graph Coloring of Connected Sets: The WInnForum scheme proposes a graph coloring approach [11] to allocate GAA bandwidth. The graph coloring starts at the CxG sub graph level. Graph coloring of a CxG involves computing its *chromatic number*. Chromatic number of a CxG is the minimum number of colors required to color the nodes of the CxG such that no two nodes having an edge between them are assigned the same color. Once chromatic number of each CxG inside a connected set is computed, then the *total chromatic number* of the connected set is computed by summing up the chromatic numbers of the CxGs belonging to the connected set. The bandwidth allocation to the CxGs is done as per the following procedure [2].

Let B be the total bandwidth available for the GAA users. Let C_i be the chromatic number of CxG_i. If there are M CxGs in the connected set, then the total chromatic number of the connected set is $C = \sum_{i=1}^{M} C_i$ and the bandwidth allocated to CxG_i is given by

$$BW_i \quad = \quad B \cdot \frac{C_i}{C} \tag{1}$$

Note that the bandwidth allocated to a CBSD is B/C. It is understood that for useful operation, a CBSD should get at least 10 MHz bandwidth. Consequently, if $B/C < 10$ MHz then the ET needs to be increased which will eliminate some edges from the connected set and hence, bring down the value of C. Then the bandwidth allocation process is repeated again. This procedure is repeated until $B/C \geq 10$ MHz.

TABLE II: CBSD Parameters

Area Type	Antenna Height [m] (Above Ground Level)		EIRP [dBm/10MHz]	
	Cat A	Cat B	Cat A	Cat B
Dense Urban	50%: 3 to 15 25%: 18 to 30 25%: 33 to 60	6 to 30	26	40 to 47
Urban	50%: 3 50%: 6 to 18	6 to 30	26	40 to 47
Suburban	70%: 3 30%: 6 to 12	6 to 100	26	47
Rural	80%: 3 20%: 6	6 to 100	26	47

TABLE III: Ratio of CBSD categories deployed in different Areas

Area Type	Cat A	Cat B
Dense Urban	90 %	10 %
Urban	90 %	10 %
Suburban	90 %	10 %
Rural	95 %	5 %

IV. Experiment and Results

A. Deployment Model

We consider a deployment area of $5\,km \times 5\,km$ in size around Virginia Beach (VB) in the east coast (the center at latitude 36.872227 and longitude -76.023389) and around San Diego (SD) in the west coast (the center at latitude 32.723588 and longitude -117.145319) of the USA.

We chose these two cities because the terrain around these two cities are quite different. The terrain around Virginia Beach is somewhat flat, whereas it is hilly around San Diego. Propagation loss is a function of the terrain profile between transmitter and receiver. Hence, the two chosen cities have quite different propagation characteristics. The coverage area of CBSDs are clipped by the above square deployment area. The deployment area is discretized by dividing it into equal sized grids of size $50\,m \times 50\,m$. CBSDs are uniformly placed around this deployment area as per the deployment density used for a given experiment. The parameters of the CBSDs used in our experiments are shown in Table II. All the CBSDs are assumed to have omnidirectional antennae.

In this study, we have assumed that each CBSD is a singleton CBSD and hence, all the CBSDs in the deployment area form one CxG. Since the FCC rule allows up to 70 MHz (out of total of 150 MHz) for PAL users, we assume that the rest 80 MHz is available for GAA users. We have used -96 dBm/10 MHz as the receive power threshold while computing coverage area of a CBSD.

B. Deployment Configurations

We ran our experiments in two deployment configurations as follows.

- *Config A*: In this configuration, all the deployed CBSDs are chosen to be Category A.

TABLE IV: ITM Parameters

Parameter	Value
Polarization	1 (Vertical)
Dielectric constant	25 (good ground)
Conductivity (S/m)	0.02 (good ground)
Mode of Variability (MDVAR)	13 (broadcast point-to-point)
Surface Refractivity (N-units)	ITU-R P.452
Radio Climate	ITU-R P.617
Confidence/Reliability Var. (%)	50/50

- *Config B*: In this configuration, we used a mix of Category A and Category B CBSDs as per Table III.

For each of the above configurations, we ran experiments with different deployment densities and propagation models at the two chosen locations (SD and VB). All the Category A CBSDs in our experiements are considered indoors, whereas all the Category B CBSDs are deployed outdoors.

C. Performance Metrics

The WInnForum does not suggest any performance metrics for evaluating the GAA-GAA coexistence scheme. In this section, we describe the performance metrics used in our evaluations.

- *Signal to Interference Ratio at a Grid (SIRG)*: The signal power at a grid within the coverage area of one or more CBSDs operating on the same channel is the highest received power at the grid from one of these CBSD transmitters. The received power at that grid from all other CBSDs operating on the same channel is considered as interference power. So, the SIRG (for a given channel) is the ratio of signal power to the aggregate Interference power expressed in dB.
- *Average Interference Power per unit Area (AIPA)*: This metric captures the average interference experienced by a receiver while it is inside the coverage area of a CBSD. If there are N_g grids inside the coverage area of a CBSD and I_i is the interference power (in dBm) received at the grid i over a channel assigned to the CBSD, then the AIPA (in dBm) of the CBSD, on that channel is given by

$$AIPA \quad = \quad 10\log_{10}\left(\frac{\sum_{i=1}^{N_g} 10^{I_i/10}}{N_g}\right) \qquad (2)$$

- *Average Interference Power per CBSD per Channel per grid (AIPCCG)*: The AIPCCG is defined as the average interference power (in dBm) per CBSD per channel per grid. Let I_i^j be the interference power (in dBm) received at a grid i on channel j. Let N_g, N_c and N_d be the number of grids, channels and CBSDs in the deployment area respectively. Then AIPCCG is given by

$$AIPCCG \quad = \quad 10\log_{10}\left(\frac{\sum_{j=1}^{N_c}\sum_{i=1}^{N_g} 10^{I_i^j/10}}{N_g \cdot N_c \cdot N_d}\right) \quad (3)$$

D. Propagation Models

We have evaluated performance of the GAA-GAA coexistence scheme using two different propagation models: the Irregular Terrain Model (ITM) (in point to point mode) [12] and the Hybrid model as described in the Requirement R2-SGN-04 in [13]. The ITM model, also known as the Longley-Rice model, is a propagation model based on electromagnetic theory, terrain features and radio measurements. The parameters used in the ITM propagation model are given in Table IV. The Hybrid propagation model is a model proposed by the WInnForum and is a hybrid between the ITM and the extended Hata (eHata) model. The eHata model [14] is an extension of the Hata model [15], which is essentially an empirical model based on a series of land-mobile measurements made by Okumura [16] over varied terrain. While the eHata model accounts for clutter loss, the ITM model does not consider clutter loss. The Hybrid propagation model primarily sets its loss equal to the larger of the ITM loss and the eHata loss in urban and suburban area. In the rural area, the propagation loss using the Hybrid model is equal to the loss using the ITM model. Thus, in general, propagation loss using the Hybrid model is higher than or equal to the ITM model.

E. Bandwidth Allocation

In this section, we analyze bandwidth allocated to the CBSDs using the WInnForum GAA-GAA coexistence scheme (Approach 1). The experiments were run for all combinations of locations (San Diego and Virginia Beach), propagation models (ITM and Hybrid), and deployment densities of 3, 10, 30 and 50 $CBSDs/km^2$ for both the CBSD deployment configurations.

We first analyze the BW allocation in San Diego. Fig. 4 and Fig. 5 show the cumulative distribution function (CDF) of BW allocation for different deployment densities and propagation models for Config A and Config B respectively. For both Config A and B, for the ITM model as deployment density increases we generally see better BW allocation to the CBSDs (more CBSDs get more BW). This is counter intuitive. However, in these cases, as deployment density increases, the interference graph becomes more connected leading to a higher chromatic number. If the chromatic number is too high then the BW allocated to the CBSDs goes below 10 MHz and hence, the algorithm increases the ET which results in a lower chromatic number. In some cases, some edges in a connected set may be eliminated so as to create multiple connected sets due to this. Each connected set has the entire available bandwidth at its disposal for allocation to its CBSDs. Hence, the increase in the ET increases the chance of getting more BW for each individual CBSD. An extreme case is when the algorithm has to raise the ET to 1.0 for some of the connected sets (as is the case for the ITM model at density 50 in Config B). In this case, each CBSD becomes a single-CBSD connected set and is assigned the entire available bandwidth. As we will discuss later, this improvement in BW allocation comes at the cost of incurring higher interference. However, in the case of the Hybrid propagation model, as the density increases, there is no clear trend in BW allocation. The way the BW allocation algorithm is designed, when deployment density increases, as described above, the system parameters such as the ET, the number of connected sets, the chromatic number in connected sets change. With so many parameteric changes in the system, it is hard to predict a trend in the BW allocation when the deployment density increases. Comparing BW allocation using the Hybrid vs the ITM propagation model, again, it is hard to conclude which model produces better performance. In Config A, the Hybrid model produces better performance whereas in Config B, the ITM gives better performance. In general, the Hybrid propagation model produces equal or more loss than the ITM. So, one can generally assume to get better BW allocation than the ITM. However, sometimes the ITM model can result in better BW allocation (see in case of Config B) (at the cost of higher interference as we will see later). Comparing performance between Config A and B, we see that if the Hybrid model is used, Config A gives better performance, but if the ITM model is used, then there is no clear winner. Again, this is because there are many system parameters that change when the deployment density increases.

At Virginia Beach (Fig. 6 and Fig. 7), the BW allocation does not vary that much when the deployment density increases, especially for Config B (in which the interference graph is more connected due to higher transmission power of CatB CBSDs). Because of the flat terrain, propagation loss is less compared to SD. Hence, CBSDs quite far away are connected to each other. As a result, degree of vertices is high for low deployment density. As the deployment density increases, the degree of vertices does not increase significantly. Thus, the chromatic number of connected sets, and consequently BW allocation does not increase significantly. Note that chromatic number of a graph is less than or equal to the (maximum vertex degree +1). When the deployment density increases, we see that the BW allocation remains the same or becomes better for both propagation models and for both Config A and B. The reason is same as we discussed before for SD. For other cases, there is no clear trend.

When we compare BW allocation between SD and VB, generally SD has an equal or a better BW allocation for both configurations. This can be attributed to the hilly terrain around SD which leads to more propagation loss which, in turn, leads to less dense connectivity in the connected sets and hence, results in a lower chromatic number.

For both SD and VB, it is hard to draw a trend in the BW allocation across two configurations. As mentioned before, when the deployment density increases, there are multiple system parameters that change. Hence, when using the WInnforum coexistence scheme it is hard to determine which configuration is better in terms of the BW allocation.

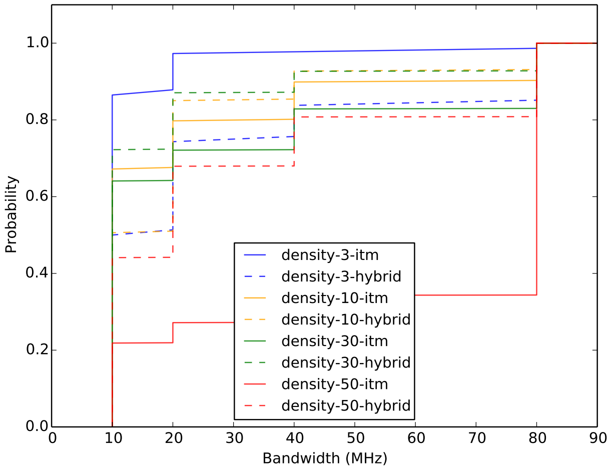

Fig. 4: CDF of Bandwidth Allocated for Config A (San Diego)

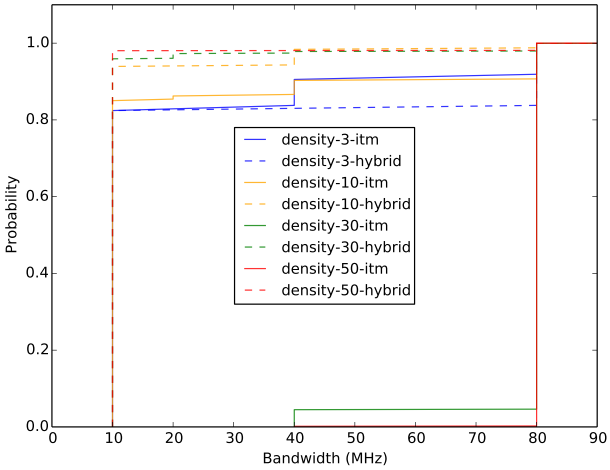

Fig. 5: CDF of Bandwidth Allocated for Config B (San Diego)

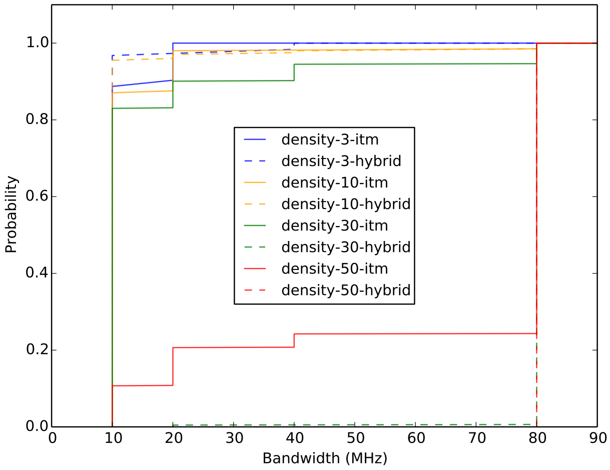

Fig. 6: CDF of Bandwidth Allocated for Config A (Virginia Beach)

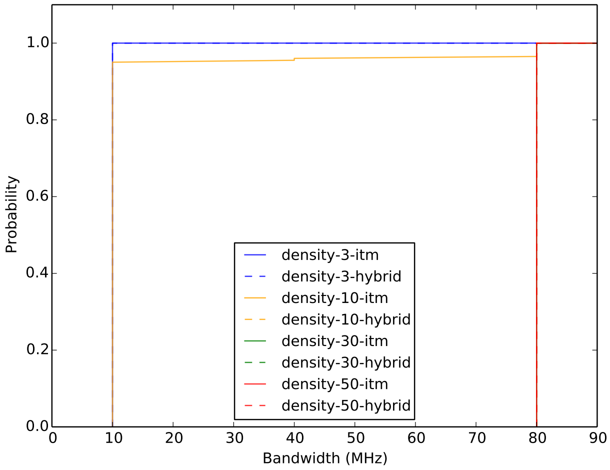

Fig. 7: CDF of Bandwidth Allocated for Config B (Virginia Beach)

F. Performance in terms of AIPA

Fig. 8 and Fig. 9 show the CDF of the AIPA with different propagation models and deployment densities in SD in Config A and Config B respectively for the channel with the worst interference. The corresponding figures for VB are Fig. 10 and Fig. 11. For a given propagation model and a given configuration, as the deployment density increases the AIPA becomes worse for both SD anf VB location. This is quite intuitive. When the deployment density increases, there is more interference due to transmission from higher number of CBSDs which causes the AIPA to increase. Another factor that contributes to the AIPA increase is when the scheme has to increase the ET to allocate a minimum of 10 MHz BW to the CBSDs. As explained in the BW allocation for SD, the ITM model allocates more BW when the deployment density increases, but this is achieved at the cost of increasing the ET which leads to a higher AIPA. We see this increase in the AIPA for the ITM model in SD in Fig. 8 and Fig. 9. In SD, the Hybrid propagation model results in better AIPA than the ITM model in both the configurations. But in VB, the ITM does better than the Hybrid in both the configurations. This is because

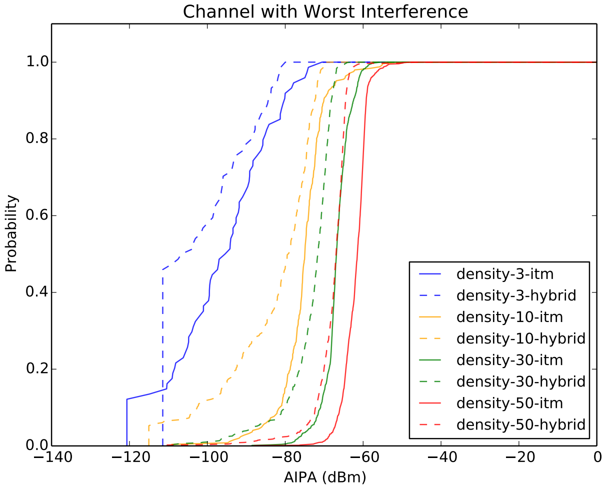

Fig. 8: CDF of AIPA for Config A (San Diego)

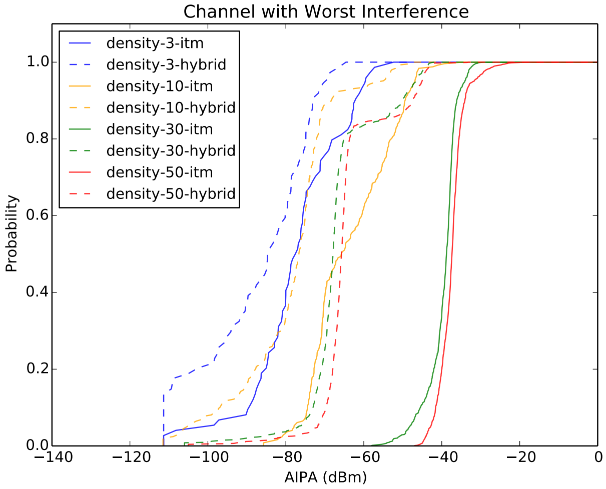

Fig. 9: CDF of AIPA for Config B (San Diego)

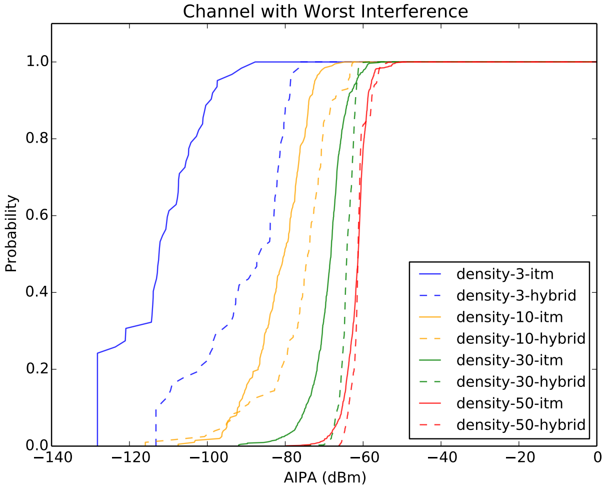

Fig. 10: CDF of AIPA for Config A (Virginia Beach)

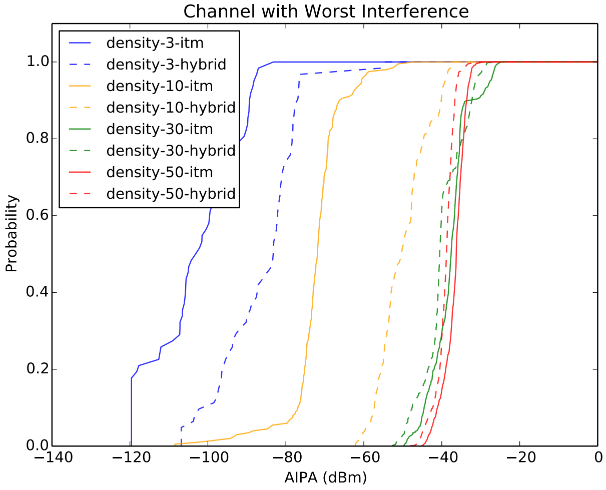

Fig. 11: CDF of AIPA for Config B (Virginia Beach)

of the way the Hybrid model is defined. When the Hybrid model is used in urban and suburban areas, the propagation loss takes on the value provided by the eHata (since its loss is generally more than the ITM in such areas) whereas in rural areas the propagation loss is equal to that provided by the ITM (as per Requirement R2-SGN-04 in [13]). In SD, the majority grids are in urban or suburban area, so that the propagation loss is determined by the eHata model in most cases when the Hybrid model is used, which leads to higher loss. Thus, the AIPA in SD is better for the Hybrid model than when the ITM model is used. In contrast VB has a large rural area. Thus, when the Hybrid model is used, the propagation loss in VB is mostly equal to that calculated by the ITM model. As a result, one would expect the AIPA performance of the ITM and the Hybrid model to be very close to each other. However, as per the implementation of the Hybrid model by the WinnForum (see R2-SGN-04 in [13] and [5]), antenna height of a CBSD cannot be less than 20 m. Due to this requirement, for the CBSDs having height less than 20 m typically its coverage using the ITM would be lower than that using the Hybrid model. Lower coverage area leads to lower interference. Since VB is dominated by rural grids, the ITM provides better AIPA performance than the Hybrid.

For both the locations, the AIPA performance is better for Config A for both the propagation models and for all deployment densities. This is intuitve, since having Cat B

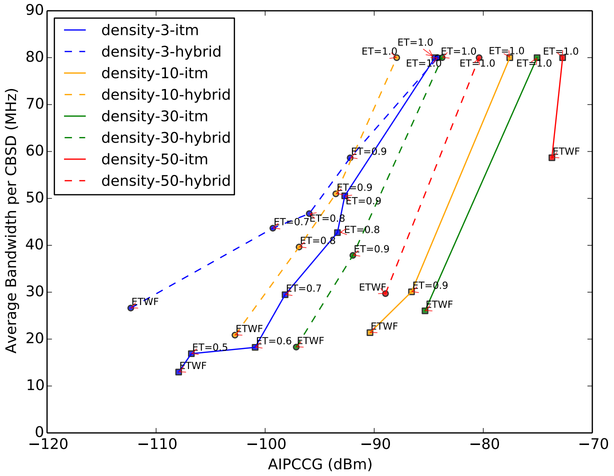

Fig. 12: BW Allocation vs AIPCCG at Different ET in Config A (San Diego)

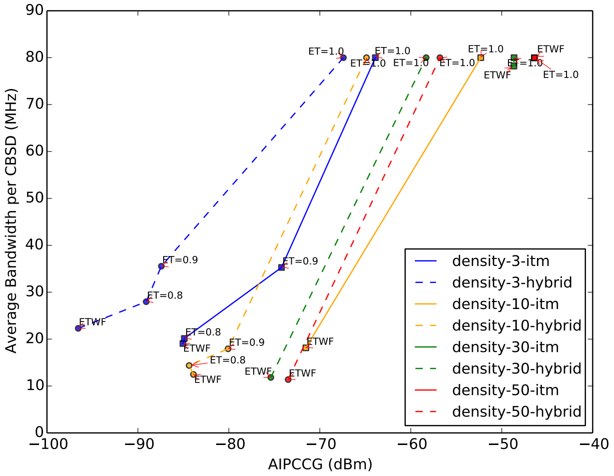

Fig. 13: BW Allocation vs AIPCCG at Different ET in Config B (San Diego)

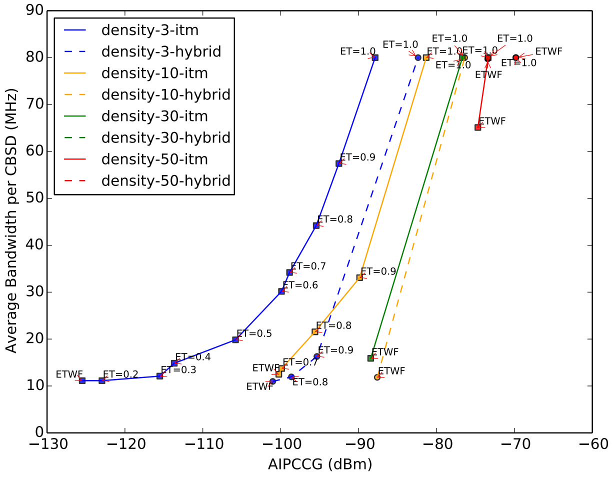

Fig. 14: BW Allocation vs AIPCCG at Different ET in Config A (Virginia Beach)

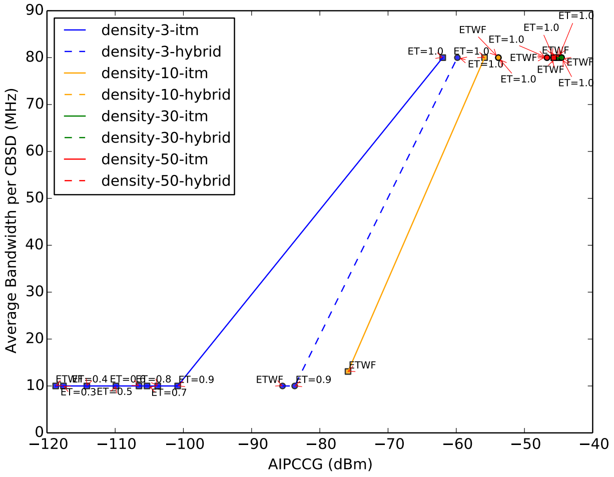

Fig. 15: BW Allocation vs AIPCCG at Different ET in Config B (Virginia Beach)

CBSDs (which have higher transmit power), creates more interference.

G. Performance of BW Allocation vs AIPCCG

For this performance measurement, we deviate from the scheme proposed by the WInnForum. In this experiment, we want to observe the effect of allocating higher BW at the cost of higher interference when we go beyond the ET at which the proposed WInnForum scheme would stop. Note that the proposed WInnForum scheme stops increasing the ET of a connected set once the CBSDs in the connected set get at least 10 MHz bandwidth. Figures 12, 13, 14 and 15 show how increase in the ET results in more average BW allocation per CBSD at the cost of interference for the locations SD (Config A and B) and VB (Config A and B) respectively. Note that in this experiment, the CBSDs are allocated actual BW computed for a given ET, i.e., the final BW allocation is not rounded down to multiples of 10 MHz. The points marked as ETWF (WInnForum ET) represents the operating point of the WInnForum Scheme in terms of average BW and AIPCCG. Note that, in general, there will not be a single ET value at this operating point since there could be multiple connected

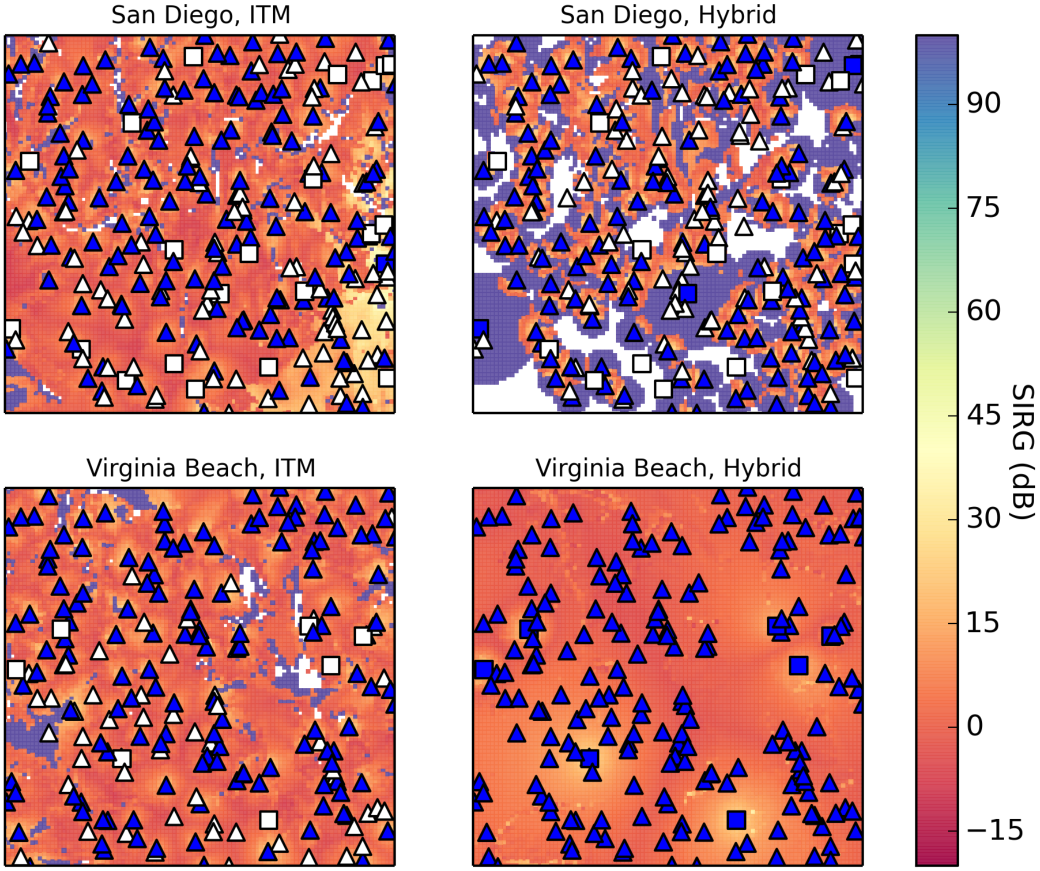

Fig. 16: Heatmap of SIRG of Channel 1, Deployment Density 10, Config B

sets each with its own ET. Hence, we do not provide an ET value at this operating point in the graphs. For a given deployment density, we then continue to increase the ET beyond the corresponding ETWF. The interference metric in this experiment is AIPCCG and its computation is explained in Section IV-C. At both SD and VB location, as expected, when a higher BW is allocated to the CBSDs, the AIPCCG also goes up for all combinations of configurations, propagation models and deployment densities. Also, as the deployment density increases, to get the same BW allocation, the ET needs to be higher and the corresponding AAIPC is also higher. For a given propagation model and a given deployment density, as the ET increases, the CBSDs get more BW at the cost of higher AIPCCG. In SD, the Hybrid propagation model produces a better result than the ITM model for all deployment densities and for both the configurations, i.e., for a given allocated BW, the AIPCCG is lower for the Hybrid model than the ITM model. But in VB, the ITM model produces a better BW allocation than the Hybrid model. This reversal of performance between the two propagation models at the two locations is due to the same reason as explained in the performance in terms of the AIPA.

H. Performance in terms of SIRG

Figure 16 shows the SIRG heatmap in SD and VB for both propagation models in Config B for the most crowded channel (Channel 1). The CBSDs in blue have been allocated channel 1 whereas the CBSDs in white operate on some other channel(s). The color coded scale (in dB) is provided to the right. For both the ITM and the Hybrid propagation models, SD shows better SIRG performance over VB, although the difference is more prominent with the Hybrid model. With the hilly terrain around SD, the Hybrid propagation loss is more in SD than in VB. Hence, there is less interference which leads to a higher SIRG. At SD, using the Hybrid model gives a much better SIRG performance over the ITM. Since SD has lot of urban and suburban areas, the Hybrid model incurs more loss and hence, leads to less interference. At VB, there is no marked difference between the ITM and the Hybrid propagation in terms of SIRG. VB has a vast rural area in which the ITM and the Hybrid model produce almost the same loss. Hence, the SIRG performance using those two models at VB has no significant difference. We have the SIRG performance for other deployment densities and configurations, but we are not able to present them here due to space limitation.

V. Conclusion and Future Work

In this paper, we studied the performance of the proposed WInnForum GAA-GAA coexistence scheme, called Approach 1. Our study looked at the effect of propagation model, deployment density and different mix of CatA and CatB CBSDs on the performance of GAA-GAA coexistence. Our study found that the way WinnForum Approach 1 is designed, performance of the BW allocation is hard to predict. There are multiple system parameters at play while allocating BW (e.g., ET, number of CSs and chromatic number of each CS), which are inter-dependent, making the prediction hard. In terms of the AIPA performance, Config A performs better than Config B. The AIPA performance in SD is better than in VB for the Hybrid model, whereas the ITM model performs better in VB. The way the GAA-GAA coexistence scheme is designed, it is possible to get a better BW allocation at higher deployment densities at the cost of incurring higher interference. The SIRG performance is generally better at locations having hilly terrian (e.g., SD) than at locations having flat land. At a given location, the Hybrid model will generally have a better SIRG performance than the ITM model.

From our study of performance of average BW vs AIPCCG, we feel a better scheme could be to have a target threshold for the SIRG in a deployment area and then allocate the maximum possible BW to CBSDs such that the SIRG does not go below the threshold. We intend to study this scheme further and compare its performance with WInnForum's Approach 1. We would like to analyze the performance of the WInnForum scheme when the CBSD deployment has multiple CxGs to investigate the effect of having CxGs on BW allocation and on interference. We are in the early stage of implementing WInnForum's Approach 3 proposed in [4]. We would like to compare the performance of that scheme with Approach 1.

ABSTRACT

The last decade has seen an influx of digital connectivity, operation automation, and remote sensing and control mechanisms in the railway domain. The management of the railway operations through the use of distributed sensors and controllers and with programmable and remotely controllable railway signals and switches has led to gains in system efficiency as well as operational flexibility. However, the network connectivity has opened up the railway cyber communication networks to cyber-attacks. These are a class of cyber-physical systems (CPS) with interconnected physical, computational, and communication components. The cyber-attacks on these systems could potentially cascade through these interconnection and result into significant damage. These systems are safety-critical owing to their large-scale monetary and, more importantly, human life safety concerns. Therefore, it is better to incorporate security and resilience requirements right from the design time. In this paper, we describe a domain-specific framework for simulations in the railway domain. The framework allows analyzing the resilience of railway operations in the presence of cyber-attacks. In particular, our simulation framework allows modeling the railway network as well as the railway transportation. It provides an online graphical modeling environment that allows multiple users to collaborate, through a web-based interface, over the same model for the railway infrastructure as well as network attacks. The framework also allows the user to configure and run experiments through the web-interface and also to visualize the key operational metrics from the railway domain as the experiment is running. The framework also supports executing large simulations in the cloud. In addition, it supports hardware-in-the-loop (HIL) simulation for incorporating physical effects and network attacks that can only be realized realistically in the hardware. A detailed case study is provided to demonstrate the framework's capabilities.

1 INTRODUCTION

Railway infrastructure is going through a transformation through incorporation of network enabled sensors and actuators that make it possible to control its operations and remotely and in an automated manner. The growth in network connectivity and with programmable and remotely controllable railway signals and switches has made railway operations and management more efficient as well as operationally flexible. At the same time, the open connectivity has made them vulnerable to cyber-attacks. These systems are a class of CPS [14] with interconnected physical, computational, and communication components. These are also safety-critical systems because a large number of transportation and even human life depends on their continual safe operations. As such the railway infrastructure is one of the nationwide critical infrastructure. However, the tight coupling among the communication, computational, and physical components enable cascading failures once one of the component gets compromised and attacked. Thus, even though the integration of vehicle to infrastructure (V2I) and vehicle to vehicle (V2V) enables fine-grained control over the transportation operations, it makes them susceptible for cyber-attacks that can cause significant damage to the systems and can even cause loss of human life. Therefore, analyzing the security and resilience of railway systems is critical for studying the effect of cyber-attacks.

Railway is unique due to the tight integration between legacy standalone devices and modern communication interfaces. As such, many systems which were designed several decades ago, do not take into account the vulnerability space presented by remote

Potteiger, Bradley; Neema, Himanshu; Koutsoukos, Xenofon; Tang, CheeYee; Stouffer, Keith A. "Simulation Testbed for Railway Infrastructure Security and Resilience Evaluation." Paper presented at Hot Topics in the Science of Security (HoTSoS) 2020, Lawrence, KS, US. April 07, 2020 - April 08, 2020.

communication. This fact combined with the rush to market by Internet-of-Things (IoT) manufacturers makes railway susceptible to an increased and diversified attack surface, especially the communication-related vulnerabilities such as memory corruption. As such, the threshold to a successful compromise is significantly lower compared to traditional information technology applications such as servers, websites, and databases. Since in modern railway there is a tight integration between software processes and physical dynamics, vulnerable applications can be exploited for causing physical damage, that could potentially include terrorist attacks by sophisticated adversaries.

One key differentiator between CPS and traditional software applications is the unpredictability in analyzing the impact of cyber-attacks on a live system, particularly the physical actuation of safety-critical components. Additionally, the increased interconnectedness between components increases the potential and impact of attack propagation. As such, it is no longer sufficient to rely on locking down the most critical components, but zero trust architectures must be utilized to take a weakest-link approach to prevent adversaries from gaining entry into critical networks. Finally, the necessity of requiring the stability of physical actuation, makes it important to not only analyze the cyber-attack behavior on the underlying software components, but also the physical operations of systems. As such, in railway applications, a high priority focus should be on system safety, high availability, system and data integrity and predictable operation.

The main problem that this paper addresses is how to leverage simulation and emulation capabilities to create secure and resilient CPS. In addition, we focus on how to provide a systematic methodology for creating cyber-attack experiments to assess their impact, with or without defense mechanisms, on the software and physical dynamics of the system. We also demonstrate integrated evaluation of key metrics and their visualization to provide real-time feedback to security researchers.

In this paper, we describe a domain-specific framework for simulations in the railway domain. The framework allows analyzing the resilience of railway operations in the presence of cyber-attacks. In particular, our simulation framework allows modeling and integrated simulation of the railway cyber communication network and the railway transportation. The framework is developed as an online graphical modeling tool that allows multiple users to collaborate, through a web-based interface, over the same model for the railway infrastructure as well as network attacks. In the framework, we have developed methods to define and calculate key operational metrics to study the impact of cyber-attacks on railway operations. Using this approach, one can design and evaluate different mechanisms for network defense and determine system's key network vulnerabilities. In the following sections we attempt to focus on the following objectives:

- Develop a software platform for rapidly designing and evaluating cyber-attacks for connected railway architectures.
- Design a component-based modeling approach that leverages our modular libraries for deploying cyber-attacks and collecting metrics from domain-specific experiment results in real-time.
- Integrate HIL testbed in order to evaluate the impact of cyber-attacks and physical effects in a hardware environment similar to that in the real-world.
- Create a case study using the Washington, DC Metro railway network model for demonstrating the capabilities of our experiment design platform.

The remainder of the paper is organized as follows. Section 2 provides the rationale for evaluating cybersecurity in the railway domain. Section 3 describes the architecture of our cybersecurity evaluation platform. Section 4 demonstrates the capabilities of our platform utilizing the case study of the Washington, DC Metro system. Section 5 discusses the work related to this research and Section 6 concludes.

2 RATIONALE

With the push to smart city implementations, railway transportation has experienced a significant disruption. New fuel sources, communication protocols, and control systems have rapidly increased the efficiency and safety of these systems, while reducing the operational cost. Trains now comprise several embedded electronic equipment dedicated for both internal operations and remote access purposes such as communicating with local infrastructure and central monitoring stations. With increased communication capabilities, manual mechanisms are no longer necessary for track configuration. Similar to the automobile industry, track control systems such as rail signals and switches are built with autonomous logic to systematically route trains. This advanced control requires vehicle to infrastructure (V2I) communication protocols which are largely being expanded due to the implementation of 5G.

Embedded microcontrollers and V2I communication have definitely disrupted the railway industry in a positive manner. However, this change has also negatively impacted cybersecurity of the system. Railway systems, like in the automotive industry, rely on a significant amount of legacy code, most of which has not been adapted in decades due to the safety and regulation costs. Consequently, the railway systems have a larger number of vulnerabilities compared to the traditional information technology infrastructure, which allows for nation states, terrorist organizations, and hacktivists to compromise these highly critical transportation networks. The presence of legacy code and remote communication capabilities effectively means that physical access is no longer necessary to disrupt train operations. Instead, an adversary can easily compromise train systems even when being several miles away. Furthermore, because safety-critical train networks are not isolated, once an attacker obtains access, they can pivot to safety-critical devices, causing them to behave dangerously that could lead to devastating crashes. Some of the high profile examples of attacks on railway systems include ransomware attacks against San Francisco and Sacramento, and system-wide disruption in train scheduling operations in London [12]. Fortunately, there haven't been any high profile examples of cyber-attacks leading to dangerous crashes. However, translating these results to the Amtrak crash in Philadelphia [25] paints a eye-opening picture of potential consequences of disruption of safety-critical control.

To successfully protect railway networks and systems, it is critical to utilize an objective and scientific methodology to evaluate the most effective cybersecurity defense mechanisms, as well as prioritizing relevant attack surfaces to address. As such, simulation has proved to be an effective technique in the CPS domain to quantitatively evaluate the software effects on the physical dynamics. This ensures that safety and security can be designed into system architectures in a cost-effective manner. Furthermore, for a smooth transition to deployment settings, software emulation in a hardware-in-the-loop environment can increase trust in reliable system performance.

2.1 HIL Testbed

In order to measure the impact of security mechanisms on the performance of the Industrial Control Systems (ICS), the US National Institute of Standards and Technology (NIST) has developed an HIL testbed. NIST has also published a guide for implementation of security in ICS [22]. The testbed utilizes Commercial-Off-The-Shelf (COTS) control hardware as well as several simulation tools for emulating realistic scenarios. For this particular application, the HIL testbed is used for measuring the performance impact of cybersecurity mechanisms on railway operations. The testbed uses realistic ICS hardware as well as an integrated framework called the Cyber Physical Systems Wind Tunnel (CPSWT) [8] [9] [11] [18] that enables integrating large-scale heterogeneous simulations. The HIL setup in the NIST testbed emulates a railroad crossing scenario. It has a COTS Programmable Logic Controller (PLC), a commercial industrial network switch, and two embedded sensors. The simulation is hosted in a virtual machine that has an Ethernet connection to the PLC. The PLC has a Controller Area Network (CAN) interface to communicate with the embedded sensors. The CAN protocol is used widely for ICS in the railroad and automotive industries. Transmission Control Protocol (TCP) and Internet Protocol (IP) are the standard protocols used in the worldwide internet. The HIL testbed simulator communicates with the PLC through a TCP/IP socket for sending commands to the PLC and receiving sensor information. The PLC uses the sensor information to determine the train location and speed at a crossing, then uses its output to control the barrier and warning signal at the crossing. The barrier control and warning signal in the testbed are represented by simple analog outputs from the PLC. When an experiment is performed in the simulator, the hardware is functioning in real-time instead of simulation time, allowing for a more accurate representation of the railway behavior in deployment environments. This setup allows the researcher to evaluate any impact induced by the experiment to the crossing.

In the past, we have focused our work on utilizing the CPSWT simulation integration framework to evaluate the cybersecurity of railway scenarios [9]. CPSWT takes advantage of the IEEE High Level Architecture (HLA) standard [2] to integrate various domain-specific simulators synchronously and analyze integrated simulations with different system configurations and parameters in the context of many different CPS experiments. This work takes a step further by developing a cloud-based experiment manager to rapidly develop and evaluate railway specific attack scenarios. Furthermore, we have made our testbed setup more user friendly by utilizing an open source simulator [21], allowing easier creation of transportation scenarios from scratch. The next sections present the architecture of our testbed and demonstrate its capabilities with the use of a railway case study.

3 SYSTEM ARCHITECTURE

Railway transportation system is one of the nation's critical infrastructure as a large number of people travel by trains as well as a large amount of packages and goods are transported by the system. A failure or attack in one of the components of the system can lead to cascading failures in other parts of the system, which can quickly result in substantial financial and human loss. This is the reason why these are safety-critical systems. Therefore, evaluating these systems for safety, reliability, and security in the presence of cyber attacks is necessary.

However, these systems are highly complex with many different types of components that work together. For example, the trains, its engine, train tracks, track signals and switches are physical components that are key part of these systems. There are also computational components such as sensors and controllers that make the train operations possible. In addition, there are many communication networks and devices that form the cyber communication network topology of railway systems. Moreover, humans are integral part of all of its operations and workflows. Therefore, a holistic evaluation of these systems requires one to integrate simulators of each of these parts of the system so that overall system-of-systems (SoS) level studies can be conducted. Fig. 1 shows the setup of our testbed. As shown, the front-end provides a modeling environment where users can design simulation studies and execute them using web-based plugins that execute the simulations in the backend. Additionally, the hardware devices connected to the testbed can be used for attacks and effects more practically and realistically realizable in the real hardware.

There are three main components in our simulation framework: *Experiment Controller*, *Simulation Backend*, and *Simulation Analyzer*. The key aspects for analyzing railway systems in our simulation platform include: the development of simulation experiments, scientific design for resilience, ensuring security and resilience amidst sophisticated real-world attacks, and the use of operational quantitative metrics for analysis. Thus, various approaches for securing the railway infrastructure can be objectively compared. Fig. 2 shows the three components of our framework and the sub-sections below describe them in detail.

3.1 Experiment Controller

The *Experiment Controller* (EC) serves as the main orchestrator of experiments. It allows for designing experiment scenarios including modeling and deployment of cyber-attacks. For modeling purposes, the EC uses a web-based graphical modeling environment (or WebGME) [26]. WebGME provides a metamodeling framework that allows users to customize the experiment modeling language. In addition, WebGME provides a multi-user modeling environment with change tracking and allows multiple designers to work on the same model using a web-browser from different locations. Moreover, WebGME allows incorporating domain-specific plugins that enable model interpretation, generation of executable artifacts such as code, scripts, and configurations, and also execution of simulations on the compute platforms (include cloud backends). Furthermore,

Potteiger, Bradley; Neema, Himanshu; Koutsoukos, Xenofon; Tang, CheeYee; Stouffer, Keith A. "Simulation Testbed for Railway Infrastructure Security and Resilience Evaluation." Paper presented at Hot Topics in the Science of Security (HotSoS) 2020, Lawrence, KS, US. April 07, 2020 - April 08, 2020.

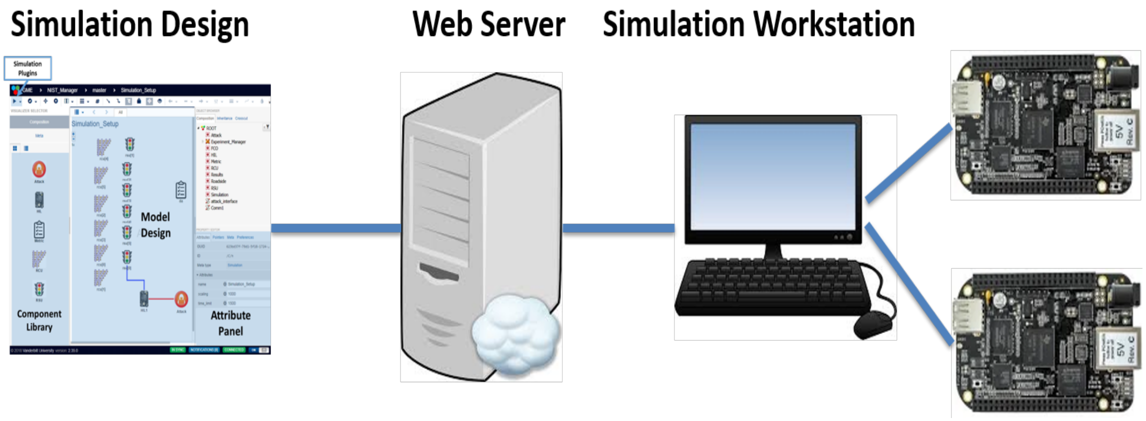

Figure 1: Railway Cybersecurity Evaluation Testbed Setup

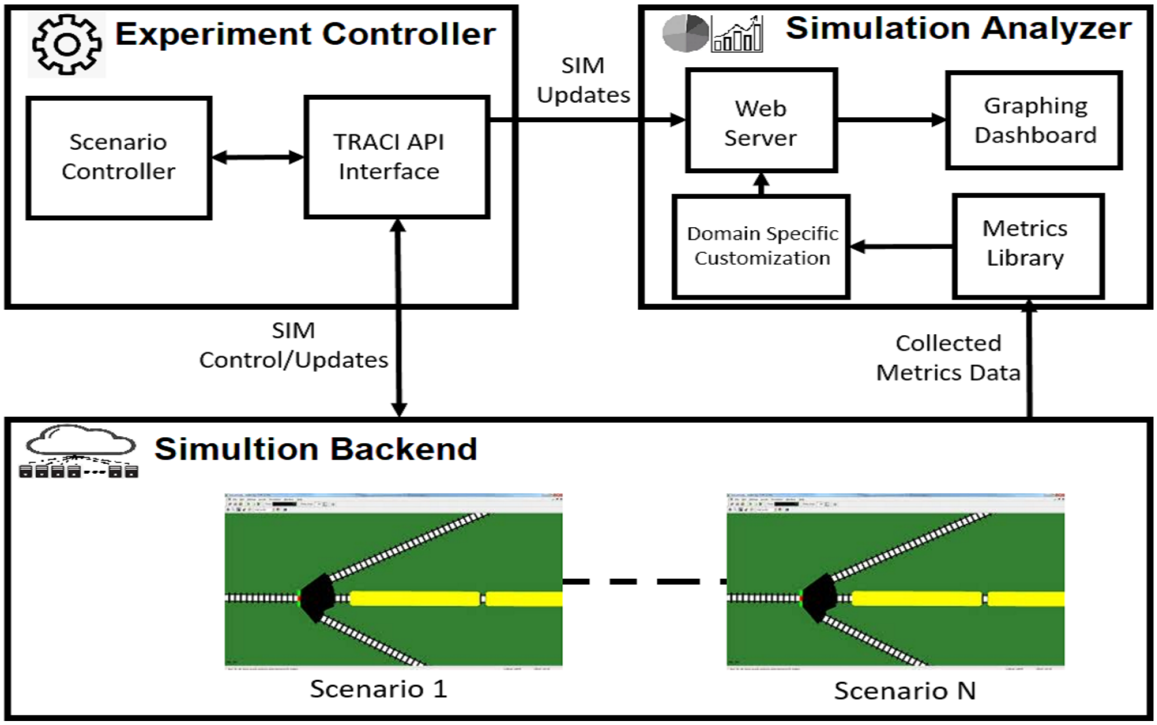

Figure 2: Testbed Architecture

for analyzing the scenarios, the EC monitors the executed simulations, collects the experiment results, and brings it on the front-end for analysis and display tools.

3.2 Simulation Backend

The *Simulation Backend* (SB) is responsible for providing the compute platform and the associated tools and methods for running large-scale experiments. In the SB, we use an open-source simulator, called Veins [21], for modeling and simulating the railway networks and railway transportation as well as the railway infrastructure's cyber communication network. Internally, the Veins simulator is composed of two separate simulators, viz. SUMO [16] for road transportation simulation and OMNeT++ [23] for cyber communication network simulation. With support for simulation experiments to run in the cloud, multiple experiments could be executed at the same time.

3.2.1 Attack Library. An important feature of our framework is that it comes with a reusable set of cyber-attacks that can be configured and utilized in different experiment scenarios. These cyber-attacks are packaged in the form of an attack library. For implementation of the cyber-attacks in the library, we extended the Veins V2X communication module for attack specific source-code and for parameterization of the attacks according to requirements of different experiment scenarios. Currently, we support incorporating denial of service (DOS), integrity, corruption, and delay attacks on railway nodes in simulation, while distributed-DOS (DDOS) attacks can be implemented on the integrated hardware nodes.

3.2.2 HIL Testbed. In order to test for attacks that be deployed only in the hardware, such as DDOS, large amount of network traffic, or attacks exploiting vulnerabilities in the hardware, we integrated our HIL testbed with the simulation framework to provide a rich experimentation environment. The attack library described above already contains such attacks. This environment enables analyzers to develop scenarios where the components can either be simulated in the software or emulated in the physical hardware. For example, in the context of railway simulations, one can design the railway network and transportation in the simulator and emulate railroad signals and actuators in a realistic integrated hardware. Our testbed is comprised of a cluster of multiple Beaglebone Black embedded microcontroller boards running the Ubuntu 16.04 operating systems. Additionally, we support realistic communication protocols by providing capabilities for 100 Mb/s Ethernet and 1 Mb/s CAN bus with the open source ZeroMQ and SocketCAN libraries.

3.3 Simulation Analyzer

The *Simulation Analyzer* (SA) component in our framework enables analysis of experiment results through integrated data capturing and visualization tools. When the users execute the experiment on the Simulation Backend, the experiment artifacts are generated both while the simulation is running and once it has completed. These artifacts are stored in a high-availability database using InfluxDB [3]. The SA has the ability to bring both types of artifacts to the web-based experimentation front-end. In addition, we developed several analysis tools and a presentation dashboard using Grafana [1]. The unique feature of SA is that the analyzed experiment results can be plotted and visualized to the users in real-time. This is accomplished by processing the artifacts as they get generated by the experiments and stored in the database and periodically running the analysis tools on them. Additionally, after experiment conclusion, final results are also plotted in a WebGME visualizer integrated with the user development environment. Moreover, the visualization tools also support comparing different domain-specific experimentation scenarios. For example, one can use these features to perform cyber-gaming experiments in the context of a particular railway scenario by playing various combinations of cyber-attacks against various security mechanisms.

3.3.1 Metrics Library. Domain-specific operational metrics [10] are require computation logic that is specific to the domain as well as the metric. However, many domain-specific aspects can be modularized in a form that becomes reusable for calculating different operational metrics. Our metrics library provides a set of customizable and extensible methods to enable incorporation of newer operational metrics. We implemented this library by integrating a graphical modeling interface with a custom data acquisition module that collects various generic component parameter values from the simulation, and calculates system-level metrics utilizing predefined formulas. As of this writing, we support railway domain specific metrics including the average speed at which trains move in the railway network, the average amount of fuel consumed by the trains, amount of time trains spend waiting for signals to go green, and total distance traveled by the trains. These metrics are important to the railroad operators and serve as high-level system metrics for the experiment. Key operational metrics are used to help determine the health and efficiency of the railroad operation. By evaluating these metrics, researchers can assess the impact to the railroad system caused by each experiment or the cyber-attack simulation.

3.3.2 Domain Specific Customization. In addition to collecting individual simulation experiment metrics defined in the metrics library, it is often necessary to utilize a more sophisticated interpretation for gaining relevant insights. For example, a different unit of measurement may be necessary, or a more descriptive statistic may be developed through a combination of the smaller individual simulation metrics. Our domain specific customization module supports these efforts by providing the ability to define equations that relate the respective data collected by the metrics library.

4 CASE STUDY

For demonstration purposes, we utilize a scenario based on the Washington, D.C. Metro Railway System (see Fig. 3. This scenario builds a railway network mirroring to a part of the Washington, D.C. Metrol railway system coupled with signals (for stopping trains on the tracks or letting them proceed) and control switches (actuators for dynamically changing the tracks on which the trains will proceed). These railway switches are mirroring the functions of real-world railway junctions, where trains can be directed in different directions depending on their programmed destinations. The control of the actuator switches is determined by a control program that is executed based on the wireless signals that the approaching trains send to the control unit.

4.1 Attack Scenario

In this particular experiment, we focused on demonstrating the framework features of both the simulation testbed as well as the HIL testbed. For demonstrating cyber-attacks on the simulation, we utilize an integrity attack from the attack library. In particular, the integrity attack causes the railway switch to get incorrect messages from the approaching trains, thereby causing the trains to go on undesired tracks. Also, for demonstrating the cyber-attacks that are realizable realistically only in the physical hardware, we use the attack library's HIL-specific attacks. In particular, the DDOS attack is used to cause flood the network traffic destined to a specific railway signal controller. Consequently, the attacked railway signal controller is overwhelmed with the messages that it needs to process resulting in invalid or unchanged signal states. The result

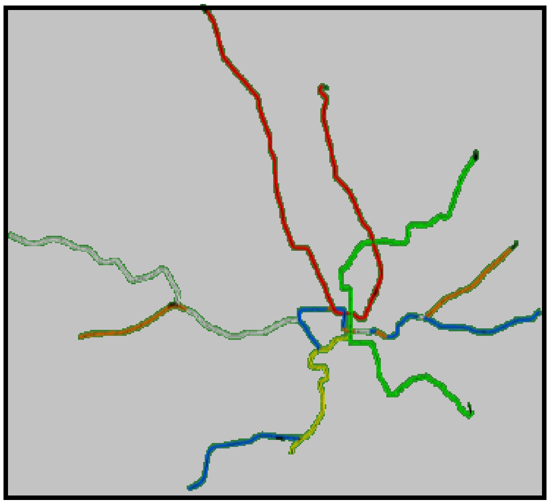

Figure 3: Washington, D.C. Metro Railway Network

of this is that the approaching trains get delayed until the railway signal updates to a green light. The experiment results from this scenario are described in the next subsection.

4.2 Results

To illustrate the results of our experimental scenario, we focus on analyzing the path of an individual train traveling through the Washington, DC metro network from Reston, VA to Greenbelt, MD. Utilizing the metrics library within our experiment design interface, we collect the following information: the average speed at which trains move in the railway network, the average amount of fuel consumed by the trains, amount of time trains spend waiting for signals to go green, and total distance traveled by the trains. Interestingly, the optimal path of the respective train is traveling east on the silver line, transferring to the blue line and traveling north of the inner city, and transferring to the green line to travel north east to Greenbelt. The attack process disrupts the train route through the following: the rail switch integrity attack results in the train being routed to the blue line south direction versus the optimal north route. As such, the train will have to travel around the southern perimeter of the city. Furthermore, while transferring to the green line, the DDOS attack on the corresponding rail signal causes a significant delay before the transfer is completed. Figures 4, 5, 6, and 7 illustrate the respective speed, fuel consumption, waiting time, and distance traveled for the train that experiences the worst impact due to attacks. In the figures, the red colored lines illustrate the train's metrics with the attack scenario enabled, while the blue colored line illustrates the train baseline scenario when traveling on the optimal path. The rail signal delay can be observed from approximately 9300 to 11000 seconds with the simulation. The figures show that there is a significant drop in speed at this time, the fuel consumption rate decreases as the train remains idle, and the accumulated waiting time increases sharply. Furthermore, the distance traveled metrics clearly show that the attack was successful as the train gets late in reaching its destination at Greenbelt by 1500 seconds.

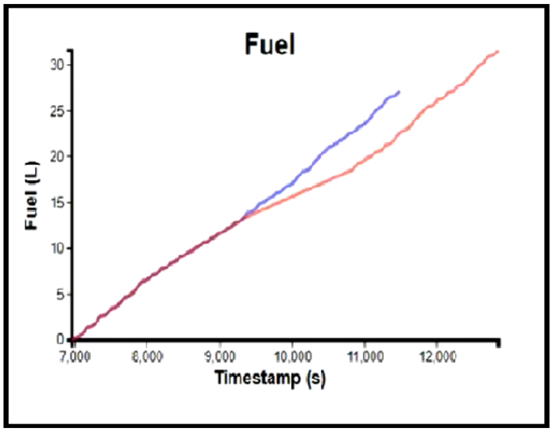

Figure 5: Fuel

5 RELATED WORK

With the significant increase in the utilization of digital technologies in the railway domain, including the European Railway Traffic Management System (ERTMS), is becoming more susceptible than ever to cyber-attacks [17]. The physical consequences of railway failures have been very publicly demonstrated in explosion-based attacks [24], as well as infrastructure failures [27]. Additionally, there has been much concern about the possibility of utilizing railway software for terrorist activities, serving as a prime vector to inflicting maximum damage to patrons who are not prepared for cyber-attacks [19]. As such, it is crucial to incorporate security and resilience requirements right from the design time, thereby maximizing trust in the safety of operations on their deployment into the field [14].

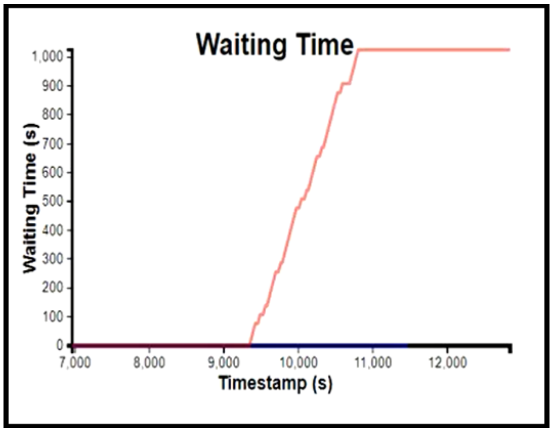

Figure 6: Waiting Time

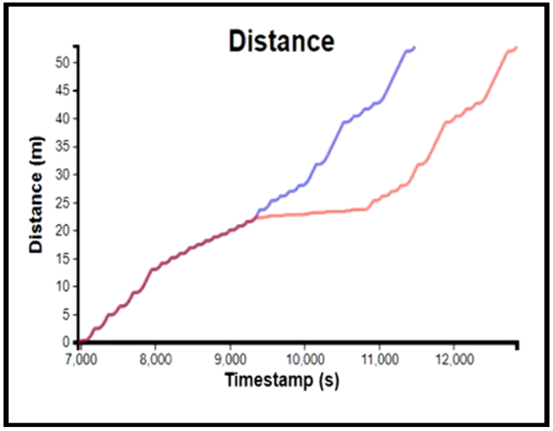

Figure 7: Distance

There has been increasing research in the railway industry focusing on the CPS perspective [20] including communication security, actuation safety [7], and train operator authentication [6]. Additionally, there has been a large amount of interest in the academic community in creating simulation testbeds for analyzing safety-critical CPS for security, safety, and resilience in the presence of cyber-attacks. The goal is to maintain predictable and safe operation during all scenarios, including when the system is under attack [5]. These frameworks have ranged from risk assessment tools [4], integrated simulation environments [8] [11], as well as transportation-specific attacker-defender modeling interfaces [15]. Additionally, the WebGME meta-modeling toolsuite has been a popular graphical user environment for easily and rapidly controlling CPS simulations [13].

6 CONCLUSION

In present day society, transportation is becoming more interconnected with the use of embedded devices for computation and control and wireless networking for communication. Railway is no exception, essentially becoming a computer on tracks. Even though there are significant benefits, including cost savings and an increase in travel efficiency, the introduction of electronic components and remote interfaces creates a significant avenue for attacker exploitation. With the safety-critical actuation of trains, locking down data from exfiltration is no longer enough as the railway operations also need to be maintained safely on a continual basis. A failure in this effort can lead to devastating consequences including high-speed train crashes, hazardous leaks of laboratory compounds or gasoline, and even loss of human life.

In this research work, we have illustrated a railway infrastructure experimentation platform, that can leverage cloud backend for large-scale computations, and that allows users to rapidly develop cyber-attack scenarios against train software to evaluate the resulting physical behavior. The goal of this approach is to allow railway designers to test the safety of algorithms and infrastructure well before deployment, providing trust in defense protections once in the field.

We developed three key components in our simulation framework, viz. the Experiment Controller, the Simulation Backend, and the Simulation Analyzer. The Simulation Backend provides the ability to evaluate railway infrastructure components in a simulation environment using the Veins simulator. Additionally, an integrated HIL testbed allows the users to emulate software on embedded microcontrollers similar to deployment environments. This allows for creating a realistic environment for getting a sense of the full spectrum of possible cyber-attack reactions, allowing for designers to have a more accurate sense of prioritizing the most critical vulnerabilities and attack vectors to protect against. Our Experiment Controller provides a graphical modeling environment for designing experiment scenarios including modeling and deployment of cyber-attacks. Further, we evaluated our platform with a case study of the Washington, DC metro network, where we captured domain-specific operational metrics as they were being generated, thereby validating our experimental design approach. We demonstrate the Simulation Analyzer that enables analysis of experiment results through integrated data capturing and visualization tools.

Further ahead, we plan to continue to extend our testbed for applying it to other transportation applications, including self-driving vehicles, and for enriching the re-configurable model libraries with more cyber-attacks and security solutions.

***Abstract*—There are several potential uses of artificial intelligence (AI) and machine learning (ML) in next-generation shared spectrum systems. However, while recognized datasets exist in certain domains such as speech, handwriting and object recognition, there are no equivalent robust and comprehensive datasets in the wireless communications and radio frequency (RF) signals domain. Therefore, we propose creating an RF signal database focused on the signals, schemes, systems and environments found in these applications. Our intention is to create datasets that have the following characteristics: targeted around specific applications and systems relevant to the next generation of advanced communications, composed of traceable elements and carefully curated to be representative of the target application. Datasets may consist of field measurements, data collected in a controlled laboratory setting, synthetically generated waveforms or any combination of the above.**

***Index Terms*—RF dataset, deep learning, machine learning, detection, classification**

I. Introduction

Machine learning (ML) using deep learning (DL) algorithms has recently found considerable success in numerous research fields and applications as diverse as computer vision, speech recognition, image processing, language modeling and natural language processing, information retrieval, clustering, finance, robotics, business management, energy, transportation, and health care [1]–[5]. In line with the surge of interest in DL research, there are a number of potential uses of artificial intelligence (AI) in general, and ML in particular, in the next generation communications systems. For example, ML could be used to improve the performance of individual components of fifth generation (5G) cellular systems such as antenna configuration, beamforming training and tracking and overall multiple-input multiple-output (MIMO) system optimization. They could be used to model the environment via channel estimation and to control end-to-end performance by mapping quality of service (QoS) and quality of experience (QoE) measures to system parameters for given channel conditions. Prior to deployment, they could be used at the radio frequency (RF) planning stage to ensure sufficient coverage. In most of these communications applications, there is a need for the system to adapt to changing conditions, whether they be a wireless channel, end user traffic, or the service area of a provider [5]–[7]. Furthermore, ML and DL techniques have been used for cognitive radio systems and proposed for applications of physical layer and propagation models [8]–[10].

Another area of next generation communications that is becoming adaptive by nature is spectrum allocation—how much spectrum is used, by which users, and at what radio frequencies. To address increasing demand of a finite resource, spectrum allocation is moving away from fixed, exclusive use and towards dynamic sharing, where multiple, heterogeneous systems share the same spectrum without interfering with one another. Agencies such as the Defense Advanced Research Projects Agency (DARPA) are looking to AI and ML as enablers of efficient, automated spectrum sharing [11].

In shared spectrum systems, where two or more tiers or priority levels of users share a band, AI and ML can be used to increase spectrum utilization. One example with several applications for dynamic sharing of spectrum is the detection and classification of RF signals. Such capabilities enable identification of available spectrum and its use by secondary users (SUs) while protecting higher-priority incumbent users. More broadly, they can also aid in the detection of interfering signals for the purpose of enforcement.

Because research in RF signal classification requires data for training and testing classification algorithms, the availability of high quality datasets is vital. While recognized datasets exist in certain domains such as speech, handwriting and object recognition, researchers in academia and industry have observed that “no robust competition datasets exist in the emerging field of machine learning in the radio domain” [12].

Therefore, in order to facilitate and support the use of ML in next generation shared spectrum communications systems, we propose creating a curated RF signal database focused on the signals, schemes, systems and environments found in these applications. The result will be a publicly available database of RF signal measurements that covers a range of signal types (e.g., radar, 4G/5G cellular, GPS, telemetry), RF environments (or channel characteristics), signal-to-noise ratio (SNR) levels, types of interference and transceiver equipment.

In the following, we identify the technical and non-technical challenges of creating such a database in Section II. In Section III we outline the sources of data and the expected outcomes. After discussing related work in Section IV, we describe our approach to an RF signal database in Section V. We then describe an application-specific example of an RF signal database, that of incumbent radar waveforms in the shared 3.5 GHz band, and our initial efforts towards creating this database.

Hall, Timothy; Caromi, Raied; Souryal, Michael; Wunderlich, Adam. "Reference Data Sets for Training and Evaluating RF Signal Detection and Classification Models." Paper presented at 2019 IEEE Global Communications Conference (GLOBECOM), Waikoloa, HI, US. December 09, 2019 - December 14, 2019.

II. Challenges

Creating a curated RF signal database that can be used to train AI detection systems requires overcoming several technical challenges. Modern communication systems, such as long term evolution (LTE) systems, have thousands of configuration settings. In addition, many modern communication systems are adaptive, i.e., they change the underlying modulation and coding scheme, vary transmission power and schedule resources as needed in response to the changing RF channel and network loading. Creating datasets that are representative of these systems, as well as the full range of real-world conditions in which they operate, is critical to training generally useful ML models. This requires taking into account the effect of many variables. Identifying these variables, such as different types of transceiver hardware, configuration settings, network loading, and channel effects, is a significant aspect of the research. Perhaps more critical is determining which of these variables are the most important to training effective models. Although individual communications systems are carefully engineered, there is no body of knowledge or theory for constructing representative datasets from this high-dimensional space of non-stationary random processes.

Tagging or labeling the data is critical for training ML models. Examples include indicating whether the desired signal is active or not, SNR level, or identifying the signal or signals present. The most realistic environments come from field measurements, but these measurements are the most difficult to tag and label because ground-truth information is often not available.

There are also challenges that are not purely technical. For example, some waveforms, such as those from military systems, may be sensitive and restricted from public release. We need methods to obfuscate such waveforms (that is, remove sensitive aspects from them) in order to protect classified information while still facilitating the development of commercial detectors sharing the same spectrum.

III. Sources and Outcomes

Representative RF signal data can, in principle, be obtained from a variety of sources. These sources are described below, along with their particular advantages and disadvantages.

- *Field measurements*. Field measurements provide data samples from operational commercial or government equipment in real environments. Conducting measurement campaigns is time-consuming and offers limited to no control over system settings, network loading, and physical effects due to noise, interference and channel characteristics. For example, it is not possible to capture the signal from an operating radar over a controlled range of SNR values. Field measurements also present the tagging/labeling challenges detailed above.
- *Laboratory Testbed*. More control is possible using a laboratory testbed. In this case real transceiver equipment is used, but the measurements are collected in a laboratory environment with emulated network loading, and possibly, a channel emulator. In this setting, much greater control over configuration settings, network loading, signal levels, and channel effects is possible. Furthermore, accurate and complete tagging/labeling is easily accomplished. However, the representation of real-world RF environments may be limited.
- *Simulation*. In most domains, the use of simulated data for training ML models is discouraged. However, in some cases simulation may be useful to generate surrogate waveforms when the actual measured waveforms are unavailable.
- *Data from other organizations*. While much useful data can be collected and generated using the above methods, other organizations may have unique access to valuable data. For example, government agencies that use special-purpose RF equipment as part of their mission, e.g., the National Oceanic and Atmospheric Administration (NOAA), could be sources of signals that are otherwise difficult to obtain. Other organizations that perform spectrum monitoring for operational reasons or research may already possess a large amount of over-the-air recordings.

We envision these efforts will produce the following outputs that benefit the communications community and advance its application of ML and AI:

- A reference RF signal database that provides high quality, curated and traceable datasets for use in researching, developing, measuring and comparing ML models used to solve problems in next generation advanced communications systems.
- Research into how well surrogate waveforms, such as those for a classified radar, perform when used to train ML models. A surrogate waveform can be either an obfuscated version of a classified waveform, a similar non-classified radar or a synthetically generated waveform.
- Pioneering theory and practice in developing representative datasets of high-dimensional state space non-stationary random processes. Can techniques from experimental design used to reduce the testing state space be applied to the design of datasets? For example, the number of combinations of subcarrier modulation-coding scheme, e.g., in orthogonal frequency division multiplexing (OFDM), transmit power levels, channel effects, SNR, transceiver hardware and interference signal types and corresponding signal-to-interference ratio (SIR) is extremely large. Can training be done apart from an exhaustive enumeration of all combinations of these factors? Another question is whether we can mix synthetic signals with those collected from field or lab measurements in the same dataset in order to cover a needed range and combination of variables.

IV. Related Work

In his essay "50 Years of Data Science" [13], Donoho identifies the Common Task Framework (CTF) as the key to the success of predictive modeling. The first of the three elements of a successful CTF instance he cites is a "publicly available training dataset involving, for each observation, a list of (possibly many) feature measurements, and a class label for that observation." As we noted in the introduction, recognized public datasets exist in many domains. One example is the modified National Institute of Standards and Technology (MNIST) handwritten digit database [14].

While recognized datasets like those mentioned above have greatly advanced the usefulness of ML models in their respective domains, there are no equivalents for the field of RF signals. Some researchers and programs have made partial datasets available, but these are a byproduct of their research and not complete or mature enough to be of general use. We discuss this research below.

In [12], O'Shea et al. construct datasets for classifying the modulation type of a received radio signal. They argue that while, in general, the use of synthetic or simulated data for the learning phase of ML is not recommended, radio communication signals are an exception. Most of the steps in a communications system are synthetic and deterministic, i.e., modulation and coding. Those that are not, such as channel effects, can be well characterized and modeled mathematically. The authors constructed datasets using several modulation schemes, including binary phase shift keying (BPSK), quadrature phase shift keying (QPSK), 8-phase shift keying (8PSK) and 16-quadrature amplitude modulation (16QAM). They used a matched filter to obtain a baseline performance result. The datasets are available for download [15]. Data are stored in Hierarchical Data Format 5 (HDF5) format [16] as complex floating point values representing baseband in-phase/quadrature (IQ) values with 2 million examples, each 1024 samples long.

While O'Shea et al. argue for the appropriateness of using synthetic data for developing ML models for communications systems, de Vrieze et al. show that real-world signals and conditions are important [17]. They chose two particular real-world examples: heterogeneous transceiver hardware (i.e., low-grade universal software radio peripherals (USRPs) and high-grade lab instruments), and in-band interference from a modulated signal. The authors describe the database of signal samples they created. Each element of the dataset is 1 ms of captured data sampled at 50 MHz. From each element a feature vector of 12 features, statistical and spectral, was computed. The modulation schemes used were BPSK, QPSK, 16QAM, 64QAM for both the desired signal and co-channel interference and OFDM for the desired signal only. The signals were transmitted over a short distance in a laboratory environment. Thus, realistic channel effects were not considered. The datasets are available online, though they contain only the features that the authors used in the experiments in the paper, not IQ samples.

V. Approach

Our intention is to create datasets that have the following characteristics:

- Targeted around specific applications and systems relevant to the next generation of advanced communications
- Composed of traceable elements that follow the Findable, Accessible, Interoperable and Reusable (FAIR) guiding principles for scientific data management and stewardship [18]
- Carefully curated to be representative of the target application

We discuss each of these characteristics in more detail below. First, the datasets are targeted in that we do not consider aspects of a communications system or application in isolation or combined in arbitrary ways, and we do not aim to be exhaustive, covering all existing schemes. For example, the previous work cited above focused on identifying a limited set of modulation and coding schemes not tied to a particular standard or system. While such datasets may be useful for initial, proof-of-concept investigations in ML for detection and classification, they are of limited use in solving practical research problems. Datasets that are directly relevant to a specific RF band, system, or standard with unresolved technical challenges are more likely to be useful.

Second, datasets should be traceable. All elements of the RF dataset must be identified and described in the documentation. This is in addition to any tagging or labeling. Specifically, the following must be documented for any dataset.

- A globally unique and persistent identifier, FAIR [18].
- Date, time and location of collection.
- Bandwidth and sample rate at time of collection.
- Type of data collected. This refers to the categories of field measurements, laboratory measurements or simulated (synthetic) signals.
- Signal(s). These could be radar signals, communication signals or some other type. The signal can be collected from an over-the-air transmission, conducted measurements, or synthetically generated. If it is synthetically generated, then the code used to generate it should be identified and made publicly available. Everything needed to replicate the signal must be available. There may be multiple signals in a single dataset, and depending on the application, a given signal may be considered to be the desired signal or an interfering signal.
- Transceiver equipment. This is the actual transmitter or receiver hardware used to send and receive the desired signal. It can be, for example, commercial hardware, lab-grade instruments or software-defined radios (SDRs). de Vrieze et al. demonstrated the importance of including real hardware effects from heterogeneous hardware in the training set [17]. For both the transmitter and receiver, the configuration should be specified, e.g., with configuration files, along with any software, including version number. In general, for a collected waveform, the receiver is the measurement instrument, so any measurement uncertainty should be specified, as well.
- Channel. The channel is not only the medium of transmission but more broadly the effects upon the signal during transmission. Thus, a channel could be an actual, physical path through which the transmission propagates

or it could be a set of channel propagation effects that operate on the signal via a channel emulator.

- Noise. In general these are components of the received signal other than the desired signal or an interfering signal. Noise usually follows some sort of probability distribution, such as additive white Gaussian noise (AWGN), and is present at a defined SNR.
- Processing of collected data. Any processing applied to the collected data must be included. This includes operations such as band filtering, down-conversion, downsampling and normalizing.
- Lineage. If this dataset is a subset of another one or has been derived from it in any other manner, e.g., downsampled, both the parent dataset's universally unique identifier and any operations applied to it must be identified.
- Any additional metadata that may be available, e.g., from diagnostic monitoring software.

The third quality we require is curation of the datasets. This means the careful selection of communications systems and applications and their documentation. It also includes a uniform format for storage and organization of the data and documentation files and careful management to keep a portion of the dataset sequestered for validation of models. More broadly, however, it addresses the more difficult problem of selecting a range of signals, equipment, channel, SNR levels and interference types necessary to have a representative dataset. As mentioned in Section I, there is no existing body of work on how to do this for RF signals, or for other problems of such high-dimensional state space. Developing theory and practice of how to do this is an important open research problem.

VI. RF Dataset Example: 3.5 GHz Radar Waveforms

Building on our extensive experience with measurements, standardization, and testing of systems in the shared 3.5 GHz Citizens Broadband Radio Service (CBRS) band in the U.S. [19], an initial dataset of interest to us is for the detection of incumbent radar signals in this band. In this application, a Navy shipborne radar is the incumbent operator. Secondary users are LTE operators, who can use the band when the radar is not present and active in their region of operation. Because the incumbent does not directly signal to the SUs when it is active, the SUs must rely on a network of detectors in order to determine the presence of radar and thus when to stop transmitting.

There are several advantages to starting with an application that we have experience with, namely radar detection in the CBRS band. The first is that we understand the problem well and have identified some of the relevant issues. We know the system performance requirements and have also been actively involved in associated measurement campaigns. Extensive experience with an application aids the curator in making the dataset representative and appropriately challenging for, in this case, detection and classification. For example, in the CBRS band, there are two primary sources of interference to a radar detector. The first is emissions from commercial CBRS systems that will be co-channel with the radar. The second is the out-of-band emissions (OOBE) of adjacent-band radars spilling into the CBRS band. Our prior work in support vector machine classifiers of the current radar in the band revealed the importance of including both types of interference in the evaluation [20]. As illustrated in the receiver operating characteristic (ROC) curves of Fig. 1, a peak analysis classifier (PAC) is more robust to the OOBE than a higher-order statistic classifier (HSC). While the HSC performs comparably to the PAC in the presence of co-channel commercial LTE emissions, it breaks down when subjected to OOBE. Not including samples with OOBE in the dataset would give a misleading indication of relative classifier performance.

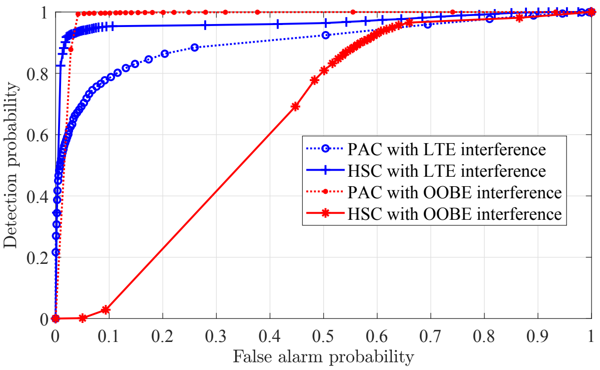

Figure 1. Two classifiers with two types of interference. Data taken from Fig. 5 and Fig. 6 in [20]

The current incumbent radar operating in the 3.5 GHz CBRS band is an unmodulated pulse radar of which we have made extensive field measurements [21], [22]. However, at the time of writing, these measurements are classified and not available for public release. Furthermore, more sophisticated radars are expected to be deployed in the band for which we currently have no field or laboratory measurements. As a result, a dataset of 3.5 GHz radar waveforms will have to rely on synthetically generated (simulated) waveforms, at least initially. Fortunately, because we have access to field measurements of the current radar, we can easily test the effectiveness of simulated waveforms against actual waveforms. For example, one could attempt to demonstrate that a classifier trained with simulated waveforms performs well with field-measured waveforms. Alternatively, it may be possible to match certain characteristics of simulated waveforms, e.g, power distributions of the signal, noise, and interference, to measured data.

We have begun to develop a dataset of simulated 3.5 GHz radar waveforms that will be made available to the public. The waveforms are derived from five categories of pulse radar that are representative of current and future systems in the 3.5 GHz band [23]. They consist of unmodulated and frequency/angle modulated radar signals with a range of values for operating parameters such as pulse width and pulse repetition rate. Each parameter has a defined range of values with a specific step size that ensures a minimum change in value. The waveforms are generated by randomly selecting the values of these parameters from the discrete ranges given in [23, Table 1]. In addition, other parameters for the waveforms—such as SNR, power level of the radar signal and noise or interference, sampling frequency, and waveform duration—are carefully chosen to render a representative and useful dataset. Finally, each waveform is saved with the full set of parameters that were used during the generation process. The inclusion of these parameters is important for both analyzing the performance of a classifier against a specific parameter as well as providing the traceability of each waveform.

The success of commercial deployment in the CBRS band in the U.S. may motivate the use of similar spectrum sharing techniques in additional bands. For example, the National Telecommunications and Information Administration (NTIA) is currently studying the 3450 MHz to 3550 MHz band (3.4 GHz band) for potential commercial wireless broadband use [24]. In the U.S., military radar systems also operate in this band. Therefore, a dataset developed for the 3.5 GHz CBRS band is potentially applicable to the 3.4 GHz band, as well.

VII. Summary

In summary, we propose creating an RF signal database focused on the signals, schemes, systems and environments found in next generation spectrum sharing systems. Datasets will be targeted around specific applications and systems, composed of traceable elements and carefully curated to be representative of the target application. We plan to use field measurements, data collected in a controlled laboratory setting, synthetically generated waveforms or any combination of the above.

Abstract — **We developed models for a 0.8 mm coaxial vector network analyzer (VNA) calibration kit within the NIST Microwave Uncertainty Framework. First, we created physical models of commercially-available standards and included error mechanisms in each of the standards' constituent parameters that were utilized to propagate uncertainties. Next, we calibrated a network analyzer with this calibration kit and compared measurements and uncertainties of two verification devices with data provided by the manufacturer. We found the measurements agreed to within their respective uncertainties.**

Index Terms — **calibration, coaxial, physical models, uncertainty, vector network analyzer, verification.**

I. Introduction

With the demand for faster data-transfer rates, the wireless industry continues to develop technology in the millimeter-wave (30-300 GHz) spectrum. One potential impediment is the connector interface. Typically, waveguides are used at higher frequencies since they are easier to manufacture and less lossy than coaxial lines. The main disadvantage of waveguides, however, are their limited bandwidths, precluding broadband frequency coverage. As an alternative, 0.8 mm coaxial connectors have recently been developed that provide uninterrupted coverage up to 145 GHz [1-2].

Researchers at the National Institute of Standards and Technology (NIST) are actively pursuing research in millimeter-wave frequencies, including small- and large-signal network analysis, modulated-signal characterization, over-the-air (OTA) testing for advanced cellular applications, antenna metrology, channel measurements and modeling [3], and mismatch correction for electro-optic sampling (EOS).

The EOS system at NIST is the United States' primary standard for high-speed waveform calibration of photodiodes and is traceable to the SI through fundamental physics. A photodiode calibrated using this system serves as a time- and frequency-domain transfer standard and allows for subsequent calibrations of high-speed oscilloscopes, light-wave component analyzers, comb generators, and high-speed modulated signals [4]. To calculate the electrical waveform at the photodiode's coaxial connector from the voltage measured in the coplanar waveguide (CPW) by the EOS system, a change in reference plane is required. This requires vector network analysis to characterize the reflection coefficients of the photodiode and on-wafer resistor, as well as the scattering-parameters (*S*-parameters) of the probe head. Currently, the EOS system is limited to 110 GHz due to the 1.0 mm coaxial connectors on the photodiode and probe head. If these two devices were fitted with 0.8 mm coaxial connectors and characterized with correlated uncertainties, the EOS system could provide calibrated photodiodes at frequencies up to 145 GHz.

With extending the EOS capabilities as one of our prime motivators, we utilized the NIST Microwave Uncertainty Framework (MUF) [5] to develop physical models of a commercially-available 0.8 mm coaxial calibrations kit. The MUF utilizes parallel sensitivity and Monte-Carlo analyses, and enables us to capture and propagate the significant *S*-parameter measurement uncertainties and statistical correlations among them [6]. By identifying and modeling the physical error mechanisms in the calibration standards, we can determine the uncertainties in *S*-parameters, including their cross-frequency correlations. These uncertainties can then be propagated to measurements of devices under test. In the following sections, we describe our methodology in further detail, and compare measurements and uncertainty estimates made on two verification devices with data provided by the manufacturer.

II. Model Development

Our commercial 0.8 mm calibration kit consisted of two sets of standards – male and female offset opens, offset shorts, and loads (OSL) for frequency coverage up to 80 GHz, and three pairs of offset shorts (SSS) with differing lengths for frequency coverage between 80 GHz and 145 GHz [7]. The manufacturer included dimensions and uncertainties for the offset lengths and inner and outer conductor diameters, as well as polynomial models for each of the standards.

Using the MUF, we constructed our own physical models of the calibration standards with closed-form expressions for coaxial lines of finite metal conductivity [8]. The MUF was also used for automatically propagating the uncertainties to the calibrated verification devices in conjunction with the calibration engine, StatistiCAL [9-10], which utilizes a "mix-and-match" philosophy to VNA calibrations.

In our previous work with Type-N, 3.5 mm, and 2.4 mm coaxial calibrations standards, we have compared our physical models to measurements of the standards performed with an independent multiline thru-reflect-line (TRL) calibration [11-12]. Since we do not have access to any 0.8 mm airlines, we were unable to do so here. However, we did compare our physical models to the manufacturer's polynomial models and

Jargon, Jeffrey; Long, Chris; Feldman, Ari; Martens, Jon. "Developing Models for a 0.8 mm Coaxial VNA Calibration Kit within the NIST Microwave Uncertainty Framework." Paper presented at 94th ARFTG Microwave Measurement Conference, San Antonio, TX, US. January 26, 2020 - January 29, 2020.

optimized our inductances and capacitances to match the frequency responses of the manufacturer's standards, especially with regards to the phase delays.

The low-band (< 80 GHz) OSL standards were modeled with the values and uncertainties (standard errors) listed in Tables I and II. Table I lists the physical error mechanisms related to the inner and outer conductors and pins of the offset transmission lines, and Table II lists the physical error mechanisms specific to the pairs of opens, shorts, and loads. The high-band (80 GHz to 145 GHz) offset-short (SSS) standards were modeled with the values and uncertainties listed in Tables I and III. Table III lists the physical error mechanisms specific to the offset shorts. The thru connection was modeled as a zero-length transmission line and included error mechanisms.

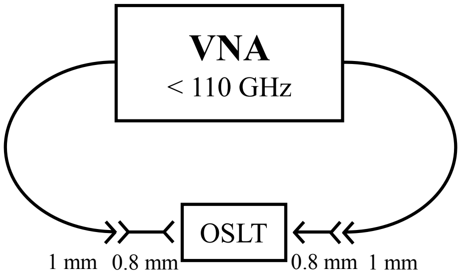
III. Measurement Comparison

Figure 1 illustrates our VNA measurement configuration. One VNA, equipped with 1 mm test ports, enabled us to make measurements at frequencies up to 110 GHz (200 MHz spacing, 20 Hz IF bandwidth, and -10 dBm output power), and the other VNA, equipped with WR-8 test ports, allowed us to measure at frequencies between 90 GHz and 140 GHz (100 MHz spacing, 10 Hz IF bandwidth, and -10 dBm output power). Both VNAs were equipped with 0.8 mm adapters (Port 1 being female and Port 2 being male). Even though our OSL standards (low-band) were specified by the manufacturer up to only 80 GHz, we used them to 110 GHz since our VNA equipped with 1 mm test ports had the capability to measure these frequencies. Our SSS standards (high-band) were measured from 90 GHz to 140 GHz using the VNA equipped with WR-8 test ports. Thus, the two calibrations overlapped between 90 GHz and 110 GHz.

Figures 2-5 show calibrated *S*-parameters and corresponding confidence bounds calculated for the two verification devices – a Beatty line and a matched airline. The dark red curves correspond to the manufacturer's values using the OSLT calibration up to 80 GHz, and the light red curves correspond to the manufacturer's values using the SSST calibration from 80 GHz to 140 GHz. The dark blue curves correspond to our measured values using the OSLT calibration up to 110 GHz, and the light blue curves correspond to our measured values using the SSST calibration from 90 GHz to 140 GHz. The dashed curves correspond to confidence bounds, in our case at 95% intervals.

In Figures 2-5, we see that our measurements appear to be noisier than those provided by the manufacturer. This may be in part due to our frequency spacing being 100 or 200 MHz and the manufacturer's being 1 GHz. Our confidence intervals were also smaller in general but did not include a repeatability component. The manufacturer stated their confidence intervals were "extremely conservative" and "include a large budget for cable flex and connector repeatability."



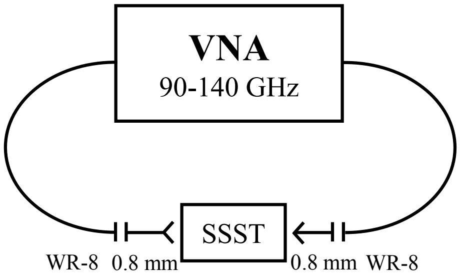


Figure 1. VNA measurement configuration.

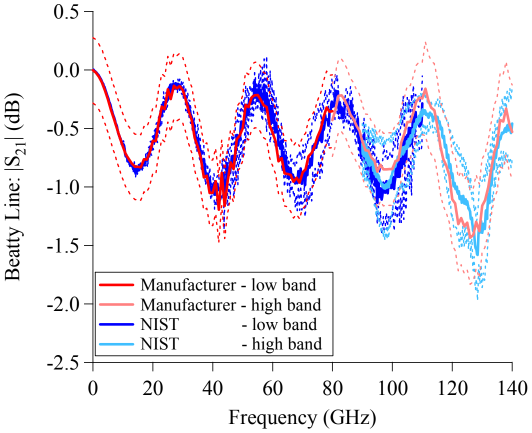

Fig. 2. Measurements and confidence intervals of the Beatty line's transmission coefficients.

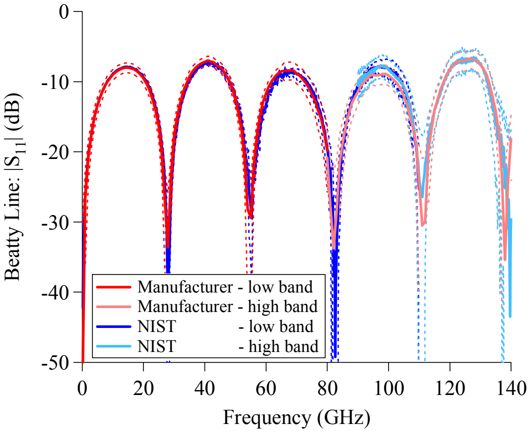

Fig. 3. Measurements and confidence intervals of the Beatty's lines reflection coefficients.

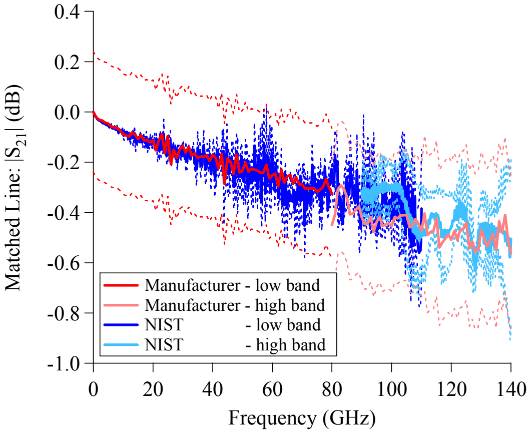

Fig. 4. Measurements and confidence intervals of the matched line's transmission coefficients.

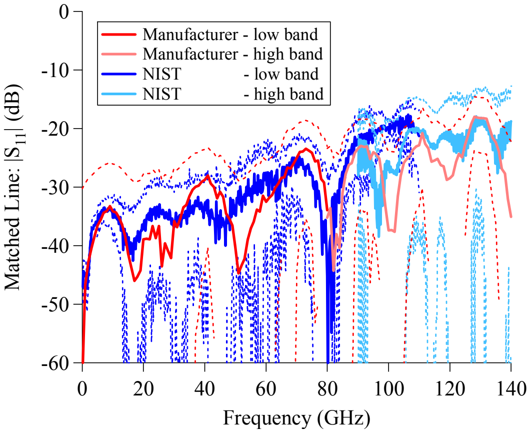

Fig. 5. Measurements and confidence intervals of the matched line reflection coefficients.

Nonetheless, the variations between our measurements and the manufacturer's agreed to within their respective confidence intervals at most frequencies. Some discrepancies may be attributed to connector repeatability, and the different calibration algorithms and standard definitions. Additionally, our measurements on the two VNAs agreed to within their respective confidence intervals for the overlapping frequencies between 90 GHz and 110 GHz, as illustrated in Figures 6-7, which zoom in on the areas from Figures 2 and 4, respectively.

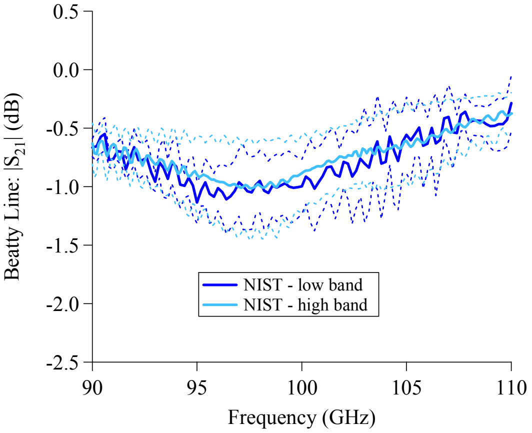

Fig 6. Comparing NIST measurements of the Beatty line's transmission coefficients from 90 GHz to 110 GHz.

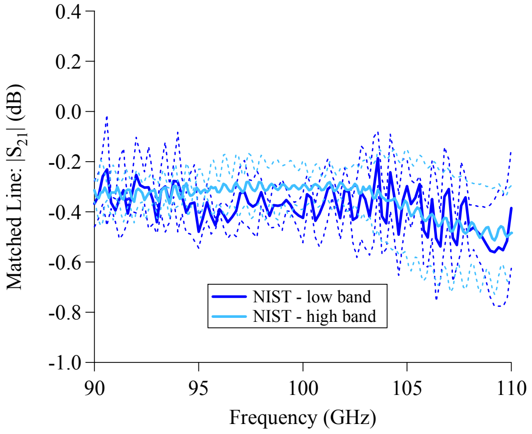

Figure 7. Comparing NIST measurements of the matched line's transmission coefficients from 90 GHz to 110 GHz.

IV. Conclusions

We have developed physical models of a 0.8 mm coaxial calibration kit for vector network analyzers that support calibration algorithms within the NIST Microwave Uncertainty Framework. After calibrating a network analyzer with this calibration kit and comparing measurements and uncertainties of two verification devices with data provided by the manufacturer, we found the measurements agreed to within their respective uncertainties.

Future work in this area includes a study of connector repeatability and developing an approach for achieving traceability. Traceability would require that the OSL standards be measured with a more fundamental calibration, such as multiline TRL or SSST, where dimensional tolerances are traceable to NIST. Then, the resulting measurements from the fundamental calibration would be used as models for the OSL standards.

***Abstract*—The UE-to-Network Relay functionality was introduced to Long Term Evolution (LTE) cellular networks by the 3rd Generation Partnership Project (3GPP) in Release 13. In this technology, User Equipment (UEs) acting as Relay UEs are used to extend network coverage to cell-edge and out-of-coverage Remote UEs. One important part of this functionality is direct discovery, which is used by the Remote UEs willing to reach the network to detect the Relay UEs in proximity that can provide the desired connectivity service. In this paper, we study this protocol considering both discovery models defined in the LTE standard, and we develop analytical models to characterize the average time a Remote UE takes to discover a Relay UE using each discovery model. We validate the analytical models using system level simulations and we study the sensitivity of the metrics to different parameters of the protocol and number of UEs involved in the UE-to-Network Relay discovery.**

***Index Terms*—LTE, D2D, ProSe, UE-to-Network Relay, Discovery, Network Modeling**

I. INTRODUCTION

The 3rd Generation Partnership Project's (3GPP) Long Term Evolution (LTE) Proximity Services (ProSe) technology allows User Equipment (UEs) to communicate on a Device-to-Device (D2D) basis, directly sending information to one another (if the range permits it) via a direct link known as the sidelink (SL). This technology not only allows direct communication in areas within the network coverage, where an eNodeB (eNB) could coordinate SL resource allocation, but it also enables out-of-coverage UEs to communicate using the SL, in which case autonomous resource allocation is used based on pre-configured parameters [1].

One important feature of the ProSe technology is the UE-to-Network Relay functionality, where in-coverage UEs (Relay UEs) can act as network relays, redirecting traffic to and from another UE (Remote UE) in proximity of the network. Using UE-to-Network Relay UEs to extend coverage is critical to Public Safety users, especially in emergency scenarios where communication between intervening team members and incident command stations should not be interrupted. Thus, team members equipped with ProSe-enabled UEs can act as Relay UEs and ensure service continuity to out-of-coverage or cell-edge team members whose UEs will act as Remote UEs.

In order to reach the network, a Remote UE should search for Relay UEs in proximity using a ProSe direct discovery procedure, select the most suitable one, and connect to it using the one-to-one ProSe direct communication procedure [2]. In this paper, we focus on the ProSe direct discovery procedure for UE-to-Network Relay.

Both ProSe direct discovery models defined in the 3GPP standard (A and B) can be used for UE-to-Network Relay discovery [3]. In Model A, Relay UEs periodically broadcast *announcement* messages to advertise their presence and the connectivity service they can provide. Remote UEs actively listen for those messages. In Model B, the procedure is initiated by the Remote UE, which broadcasts *solicitation* messages with the connectivity service it is looking for. Listening Relay UEs that provide the solicited service will then send a *response* message. The received discovery announcements (Model A) or responses (Model B), and their associated signal strengths, are then used by the Remote UE to conduct the Relay UE selection and start the one-to-one ProSe direct communication procedure.

ProSe-enabled UEs use the Physical Sidelink Discovery Channel (PSDCH) to broadcast discovery messages on the SL. The UEs are provisioned with a pool of discovery resources to use, which repeats periodically in time. The resource allocation within each pool can be either *network-assisted*, i.e., the eNodeB persistently schedules the resources to be used by the UEs, or *UE-selected*, where each UE selects randomly the resources to be used.

In this paper, we focus on the UE-selected allocation, as eNodeB scheduling information may not be always available for the Remote UEs, e.g., when they are out-of-coverage. The UE-selected allocation brings a risk of collision interference if multiple UEs pick the same resources for a given transmission, which may result in Relay UEs not being discovered by a Remote UE even though they are in proximity. To alleviate this issue, a transmission probability was defined in the 3GPP standard as part of the discovery resource pool, which is used by each transmitter UE to decide whether to transmit a discovery message in a given discovery period. We developed an analytical framework to quantify the time taken by a Remote UE of interest to discover any Relay UE and also a given Relay UE in proximity depending on the discovery pool parameters and the discovery model used by the UEs. We validated the theoretical models using system level simulations performed in our ns3 ProSe module described in [4] and enhanced with the UE-to-Network Relay functionality.

The rest of the paper is organized as follows. We discuss

Gamboa Quintiliani, Samantha; Moreaux, Alexandre; Griffith, David W.; Rouil, Richard A. "UE-to-Network Relay Discovery in ProSe-enabled LTE Networks." Paper presented at International Conference on Computing, Networking and Communications (ICNC 2020), Big Island, HI, US. February 17, 2020 - February 20, 2020.

prior works related to ProSe direct discovery and the contributions of this paper in Section II. In Section III, we describe the models that allow us to obtain the time a Remote UE takes to discover any Relay UE and a given Relay UE in proximity. In Section IV, we provide numerical results to validate the models and we discuss the protocol sensitivity to the model parameters. Finally, Section V summarizes our contributions and discuss future work.

II. Related Work

As discussed in the previous section, the direct discovery resource allocation can be either network-assisted or UE-selected. Early works have focused on network-assisted direct discovery. In [5], Xenakis et al. provide an analytical model to determine the probability that two UEs in the network detect each other using a D2D link and provide a sensitivity analysis considering several network parameters such as transmission power and eNodeB density. In [6] and [7], the authors rely on centralized scheduling schemes to avoid collisions and expedite the discovery process. These studies assume full knowledge of the network and deviate from the 3GPP standard procedures in place for ProSe direct discovery.

The following works address direct discovery with UE-selected allocation. In [8], the authors present a model based on stochastic geometry and use it to calculate how many UEs can be discovered in a given number of discovery periods considering channel conditions. Bagheri et al. consider similar metric in [9], and propose that UEs randomly select their transmit power to alleviate interference in the discovery channel. Both models consider that the UEs are sending discovery messages every discovery period, disregarding the transmission probability mechanism.

Li and Liu proposed an alternative to the transmission probability to avoid collision interference [10]. Instead of the UEs deciding each period if they should transmit based on the transmission probability, they randomly decide in which discovery period to transmit within a set of successive periods.

In [11], Griffith and Lyons developed an analytical model used to obtain the optimal transmission probability for a given discovery resource pool configuration and number of UEs performing discovery. This optimal transmission probability minimizes the time required for a successful discovery message transmission, and near-optimal performance can be achieved when rounding it up to the next higher multiple of 1/4 to be consistent with the values in the 3GPP standard. These results are used in [12] to develop an adaptive algorithm in which the UEs adjust their transmission probabilities depending on the number of discovered UEs over time.

In this paper, we build upon the model in [11] and generalize it to differentiate between Remote UEs and Relay UEs. We also complete it to determine the average time a Remote UE needs to find an unspecified Relay UE. Additionally, we characterize Model B discovery using state machines as has been explored by Griffith et al. in [13], obtain equivalent performance metrics, and compare both models performances for a given discovery pool configuration. Finally, we validate the models using system level simulations of the actual standard protocol implementation.

III. Analytical Model

The notation we use in the paper is summarized in Table I.

A. System Model

1) Scenario: We consider a group of N_x Remote UEs (G) and a group of N_y Relays UEs (H) deployed without prior knowledge of the area. All the devices are in each other's respective ranges, X is a given Remote UE and Y a given Relay UE; both randomly chosen. We consider that devices are either Remote or Relay UEs (i.e., $G \cap H = \varnothing$).

2) The Discovery Resource Pool: Resource allocation will happen by UEs choosing their own resources in the PSDCH discovery resource pool independently from each other. The PSDCH resource pool is a periodical grid in the time-frequency plane composed of Physical Resource Blocks (PRB) that we model as a $N_f \cdot N_t$ matrix as depicted in Fig. 1. Each row corresponds to a PRB pair and each column to a subframe set. Each resource is a single transport block composed of a pair of adjacent PRB that occupy the same subframe. Any UE wishing to transmit is to generate a uniformly distributed random value $p_1 \in [0, 1]$ that it compares with a given threshold value denoted by *txProbability*. The 3GPP standard defines that *txProbability* can take the values 0.25, 0.50, 0.75, or 1.00. The discovery message is sent if $p_1 <$ *txProbability*. If successful, the UE picks a resource in the pool with uniform probability. Let $\theta = P(p_1 \leqslant \textit{txProbability})$ for the rest of this paper.

3) Metrics of interest: This paper focuses on two metrics: The average time a given Remote UE of interest needs to find:

- A given Relay UE, and
- Any Relay UE, referred to as First Relay UE.

We will establish analytical models for these two metrics for Model A and B. We elected a probabilistic approach and looked into the behaviors of our system in a given PSDCH period and deduced how many periods are necessary on average to complete the discovery for each case. For the rest of the paper, let $Z_1 \rightarrow Z_2$ be the event 'UE Z_1 successfully sends UE Z_2 a message', $Z_1 o Z_2$ be 'UE Z_1 discovers UE Z_2', $Z?$ be 'UE Z successfully sends a message to a Relay/Remote UE' and $Z \sim$ be 'UE Z discovers a Relay/Remote UE'. Note that Z, Z_1, and Z_2 can designate interchangeably a Relay or Remote UE, depending on the model in context.

4) Final Considerations: The following assumptions were made for the development of the analytical models presented in the next sections:

- We assume that all UEs belong to the same security domain and are authorized to perform UE-to-Network Relay discovery. This approach could be deemed Open Access although its long-term applications are focused around Restricted Access in the Public Safety context.
- We assume a worst-case transmission scenario were the devices other than our devices of interest are permanently trying to send messages.

Gamboa Quintiliani, Samantha; Moreaux, Alexandre; Griffith, David W.; Rouil, Richard A. "UE-to-Network Relay Discovery in ProSe-enabled LTE Networks." Paper presented at International Conference on Computing, Networking and Communications (ICNC 2020), Big Island, HI, US. February 17, 2020 - February 20, 2020.

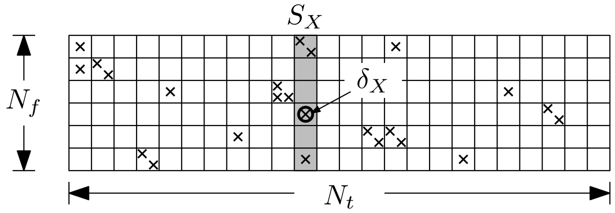

Fig. 1. The discovery resource pool model, showing the transmissions of various UEs and indicating the location of X's discovery message δ_X and the set of subframes it occupies S_X [11, Fig. 3].

TABLE I
LIST OF SYMBOLS

Symbol	Definition
$P(A)$	Probability of event A
G	The set of Remote UEs in context
N_x	card(G)
UE X	Randomly chosen Remote UE of interest from G
H	The set of Relay UEs in context
N_y	card(H)
UE Y	Randomly chosen Relay UE of interest from H
δ_X	Discovery message sent by UE X
S_X	Set of subframes occupied by δ_X
N_r	Number of resources in discovery pool
N_f	Number of PRB pairs in discovery pool
N_t	Number subframe sets in discovery pool
θ	Probability that a given UE transmits
T	Markov state transition matrix
P_1,P_2	Illustration probability functions
N	T's Fundamental Matrix
Z, Z_1, Z_2	Arbitrary UEs ($\in G \cup H$)
$Z_1 \to Z_2$	$'Z_1$ successfully sends a message to Z_2'
$Z_1 o Z_2$	$'Z_1$ discovers Z_2'
$Z?$	$'Z$ successfully sends a message to a Relay/Remote UE$'$
$Z \sim$	$'Z$ discovers a Relay/Remote UE$'$

- We assume that senders other than our UEs of interest do not stop sending discovery messages after receiving responses from other devices. This condition guarantees us a stable environment to work in.
- The half-duplex effect prevents devices from transmitting and listening simultaneously on the SL. Although it is a factor that could impact the discovery when using Model B, we assume the Remote UEs transmit solicitations every other discovery period. This allows that the following period is dedicated to the reception of the Relay UE responses.
- Lastly, this paper will neglect processing times completely. As soon as there is an intent to transmit, the involved device attempts to do so. These delays are probably not as significant as control channel loss probability and other phenomena but do still exist.

B. Relay Discovery Model A

1) Given Relay UE: In Model A, given the absence of transmission from Remote UEs and the systematic one of all Relay UEs, XoY is equivalent to $X \to Y$ and furthermore to 'Y's discovery message does not collide'. By Bayes' Theorem on the universe $\{\{\text{`}Y \text{ emits'}\}, \{\text{`}Y \text{ does not emit'}\}\}$:

$$P(X \to Y) = P(\text{`}Y \text{ emits'})P(\text{`}Y\text{'s message does not collide'}) \tag{1}$$

with $P(\text{`Y emits}') = \theta$.

To determine P('Y's message does not collide') , we condition on how many of the other $N_y - 1$ Relay UEs transmit, which has a binomial distribution with probability mass function $f(k; N_y - 1; \theta) = \binom{N_y-1}{k}\theta^k(1-\theta)^{N_y-1-k}$. The probability that a Relay UE other than Y picks the same resource if it transmits successfully is $\frac{1}{N_r}$. By applying the Binomial Theorem, we get:

$$P(XoY) = \theta\left(1 - \frac{\theta}{N_r}\right)^{N_y-1}. \tag{2}$$

<u>$N.B$</u>: This method is reminiscent of the one used in [11].

2) First Relay UE: A discovery ($X \sim$) is equivalent to a successful transmission ($X?$) in Model A. The only way $X?$ does not happen is if all transmissions collide. By conditioning on the number of devices that transmit and using Bayes' Theorem:

$$P(X?) = \sum P(\text{`at least one request does not collide'} \\ |\text{`k requests are emitted'})P(\text{`k requests are emitted'}). \tag{3}$$

Let C_k be the event 'All of k requests collide'. Determining $P(C_k)$ now comes down to a classic balls in bins problem where we look for the number of combinations leaving no ball alone in a box:

$$P(C_k) = \sum_{i=0}^{min(k,N_r)} (-1)^i \binom{N_r}{i}\binom{k}{i} i! \left(\frac{1}{N_r}\right)^i \left(1 - \frac{i}{N_r}\right)^{k-i}. \tag{4}$$

$Proof$: The probability that no ball is alone in a box is $P(C_k) = 1 - P(\text{`at least one ball alone'})$. Let ν be the number of balls that are alone after k balls are randomly distributed into N_r bins. We can define a set of k events, $S = \{A_i\}_{i=1}^{k}$ such that event A_i occurs if the ith ball is alone in a box. Jordan's formula gives the probability that at least j events in the set S occur, which is

$$P(\nu \geqslant j) = \sum_{i=j}^{j} (-1)^{i-j}\binom{i-1}{j-1} B_i, \tag{5}$$

where $B_i = \sum_{1 \leqslant m_1 \leqslant m_2 \leqslant \ldots \leqslant m_i \leqslant k} P(A_{m_i} \cap \ldots \cap A_{m_i})$ is the ith binomial moment of ν, which here corresponds to the probability of balls numbered $m_1, ..., m_i$ being alone in i bins. We compute this probability by taking the ratio of the number of ways that k distinguishable balls can be arranged so that the balls with the index values $m_1, m_2, \ldots, m_i$ are alone in i distinguishable bins to the number of ways that k balls can be arranged in N_r bins. The former is the product of the number of ways to choose i bins out of N_r bins, the number of ways to arrange the i isolated balls among the i chosen bins and the number of ways to arrange the remaining $(k - i)$ balls among the remaining $(N_r - i)$ bins (note that this can include cases where some of these balls end up alone, but we are concerned only with balls $m_1, m_2, \ldots, m_i$) whereas the latter is simply N_r^k. We now have

$$\begin{aligned} P(A_{m_i} \cap ... \cap A_{m_i}) &= \binom{N_r}{i} i! \frac{(N_r - i)^{k-i}}{N_r^k} \\ &= \binom{N_r}{i} \frac{i!}{N_r^i} \left(1 - \frac{i}{N_r}\right)^{k-i}. \end{aligned} \tag{6}$$

We can now deduce

$$B_i = \binom{k}{i} \binom{N_r}{i} \frac{i!}{N_r^i} \left(1 - \frac{i}{N_r}\right)^{k-i}. \tag{7}$$

And finally

$$\begin{aligned} &P(C_k) = 1 - P(\nu \geqslant 1) \\ &= \sum_{i=0}^{min(k,N_r)} (-1)^i \binom{N_r}{i} \binom{k}{i} i! \left(\frac{1}{N_r}\right)^i \left(1 - \frac{i}{N_r}\right)^{k-i}. \end{aligned} \tag{8}$$

This results leads us to:

$$\begin{aligned} &P(X \sim) = \sum_{k=1}^{N_y} \binom{N_y}{k} \theta^k (1-\theta)^{N_y - k} \\ &\sum_{i=0}^{min(k,N_r)} (-1)^{i+1} \binom{N_r}{i} \binom{k}{i} i! \left(\frac{1}{N_r}\right)^i \left(1 - \frac{i}{N_r}\right)^{k-i}. \end{aligned} \tag{9}$$

3) Deducing desired metrics: For both these models, given that the resource selection process is independent in distinct periods, the number of PSDCH periods to accomplish the aforementioned events has a geometric distribution. We can conclude that the mean time (in number of periods) for each of the scenarios is the inverse of the probabilities, given by:

$$t(XoY) = \frac{1}{P(XoY)} \tag{10}$$

and

$$t(X \sim) = \frac{1}{P(X \sim)}. \tag{11}$$

N.B: In model A, the probability of X discovering a given group of Relay UEs is equal to the one where all the Remote UEs discover the same Relay UEs, given that messages are broadcasted to all Remote UEs in range.

C. Relay Discovery Model B

With Model B, other Remote UEs than X will be using and competing for resources. Thus, N_x will now logically appear in the models and all N_x Remote UEs we take into account are active. The approach we used for Model A cannot lead us to the time metric for Model B as the geometric distribution criteria is no longer fulfilled. We elected Markov models as the most appropriate to handle Model B. In fact, the sojourn times of the states in our model do not exactly follow the geometric distribution, which is a requirement for Markov chains. Nevertheless, using a semi-Markov chain adds considerable complexity to the model for an incremental gain in accuracy and does not bring any significant insight to this paper. Therefore, we can reasonably approximate the sojourn times and continue using standard Markov chains.

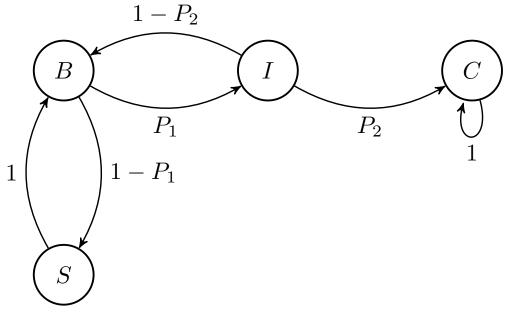

Fig. 2. Markov chain modeling the system when using discovery Model B.

We propose to study a simplified version of Model B, were PSDCH pools are divided into solicitation and response periods, meaning that Remotes UEs would attempt to send solicitations only every other period and that Relay UEs would have the following period to try responding. The discovery is now achieved when a successful solicitation and response happen in any pair of neighboring PSDCH periods. Any of the Remote UEs in G can trigger a response that allows X to discover the concerned Relay UE. This simpler approach still depicts Model B's behaviors and metrics appropriately, whilst neglecting timer expirations and the half-duplex effect.

1) The Model: The Markov chain depicted in Fig. 2 models our system when using discovery Model B and is used for obtaining both metrics of interest. We define P_1 to be the probability that a Remote UE's solicitation is successfully received by a Relay UE, and define P_2 to be the probability that a Relay UE's response is successfully received by a Remote UE in the general case. In our model, the Remote UE starts in the Beginning state, B, and progresses to the Intermediary state, I, if a Relay UE receives its solicitation. Otherwise the Remote UE moves to sleeping state S (as the current period is not a Remote UE transmission one) and then returns to state B to attempt transmission once again. If the Relay UE's response reaches the Remote UE, then it progresses to the Completion state, C, which is the sole absorbing state in the Markov chain.

The chain in Fig. 2 has the following transition matrix:

$$T = \begin{bmatrix} 0 & P_1 & 1 - P_1 & 0 \\ 1 - P_2 & 0 & 0 & P_2 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}. \tag{12}$$

That we can partition likewise:

$$T = \begin{bmatrix} Q & R \\ \mathbf{0} & 1 \end{bmatrix}. \tag{13}$$

This chain's fundamental matrix defined by $N = (1-Q)^{-1}$ with $Q = T_{[1;3][1;3]}$ can be determined directly by the cofactor method:

$$N = \frac{1}{P_1 P_2}\begin{bmatrix} 1 & P_1 & 1-P_1 \\ 1-P_2 & P_1 & (1-P_1)(1-P_2) \\ 1 & P_1 & 1-P_1(1-P_2) \end{bmatrix}. \quad (14)$$

By definition, the average time to reach the absorbing state (in periods) when starting at state B is:

$$t(B \to C) = \sum_{j=1}^{3} N_{1,j} = \frac{2}{P_1 P_2}. \quad (15)$$

For both our metrics P_1, i.e., the probability of a successful solicitation, is essentially the same as Model A's first Relay UE model with the Remote UEs being the transmitters. This is the case because any of the Remote UEs can solicit a specific (or any) Relay UE for it to answer X, our Remote UE of interest. Given our assumptions, we can be certain of the solicitation reaching our Relay UE of interest if it does not collide, and therefore

$$P_1 = P(X?) = \sum_{k=1}^{N_x} \binom{N_x}{k} \theta^k (1-\theta)^{N_x-k} \sum_{i=1}^{min(k,N_x)} (-1)^{i+1} \binom{N_r}{i} \binom{k}{i} i! \left(\frac{1}{N_r}\right)^i \left(1-\frac{i}{N_r}\right)^{k-i}. \quad (16)$$

The response however does vary depending on the desired metric. The given Relay UE Model will have one Relay UE competing with others for resources to reach X, whereas the first Relay UE Model requires any Relay UE to reach X.

a) Given Relay UE: For the Given Relay UE model, we simply have:

$$P_2 = P(Y \to X) = \theta \left(1 - \frac{\theta}{N_r}\right)^{N_y - 1}, \quad (17)$$

which leads to:

$$t(XoY) = \frac{2}{P(Y \to X)P(X?)}. \quad (18)$$

b) First Relay UE: For the First Relay UE model, the response can be issued by any Relay UE, leading to:

$$P_2 = P(Y?) = \sum_{k=1}^{N_y} \binom{N_y}{k} \theta^k (1-\theta)^{N_y-k} \sum_{i=1}^{min(k,N_y)} (-1)^{i+1} \binom{N_r}{i} \binom{k}{i} i! \left(\frac{1}{N_r}\right)^i \left(1-\frac{i}{N_r}\right)^{k-i}, \quad (19)$$

and finally:

$$t(X \sim) = \frac{2}{P(Y?)P(X?)}. \quad (20)$$

IV. Numerical Results

A. System Level Simulations

We validated the models using system-level simulations. We used the ns-3 ProSe model described in [4] enhanced to support the UE-to-Network Relay functionality. We deployed N_y Relay UEs and N_x Remote UEs in proximity and all UEs are configured with the same discovery pool parameters (N_f, N_t, *txProbability*). The discovery period was set to 320 ms which is the minimum value defined in the standard. All UEs start the direct discovery at the same time. Relay UEs send discovery announcement messages on every period when using Model A, and Remote UEs send discovery solicitations every other period when using Model B. We considered ideal channel conditions and discovery messages sent by multiple UEs in the same resources are dropped to be consistent with the analytical models. Message recovery depending on Signal to Interference plus Noise Ratio (SINR) and error models will be addressed in future work. The metrics of interest were calculated for a given Remote UE, which was chosen randomly in each trial. In the simulations, we consider that a Remote UE discovers a Relay UE when it successfully receives an announcement (Model A) or response (Model B) message from that Relay UE. We performed 1000 independent trials for each configuration, and all results are presented using the mean values and 95 % confidence intervals for each metric.

B. Results Discussion

The results shown in Fig. 3 and Fig. 4 were generated using a resource pool of $N_f = 2$ PRBs and $N_t = 5$ subframes (SFs), and we present results for the four values of *txProbability* defined in the 3GPP standard $(0.25, 0.50, 0.75, 1.00)$. We observe a close agreement between the theoretical and the system level simulations results, validating the accuracy of our models.

The results illustrate the effect of the number of UEs contending for resources in the discovery time for the Remote UE of interest. On the one hand, we observe in Fig. 3(a) and Fig. 3(b) that $t(X \sim)$ decreases when N_y increases, as the probability of at least one Relay UE choosing a non-colliding discovery resource increases with N_y. The scenario with $N_y = 1$ and *txProbability* = 1.00 is of course the exception, as there is no contention for resources and the discovery messages are received in every discovery period. On the other hand, Fig. 4(a) and Fig. 4(b) show that $t(XoY)$ increases with N_y, as the number of UEs contending for discovery resources increases, the probability that the Relay UE of interest choose a non-colliding discovery resource decreases, thus delaying the discovery.

While Fig. 3(b) and Fig. 4(b) shows results for $N_x = 10$ Remote UEs, we observed similar trends depending on N_y for different values of N_x when using Model B.We do not show these results due to space limitation. Please note that in this evaluation, the results for Model A are independent of N_x, as Remote UEs are only listening for announcements and all Remote UEs receive them at the same time.

Fig. 3(c) and Fig. 4(c) show the trend when varying N_x for Model B and $N_y = 20$ Relay UEs. The discovery time

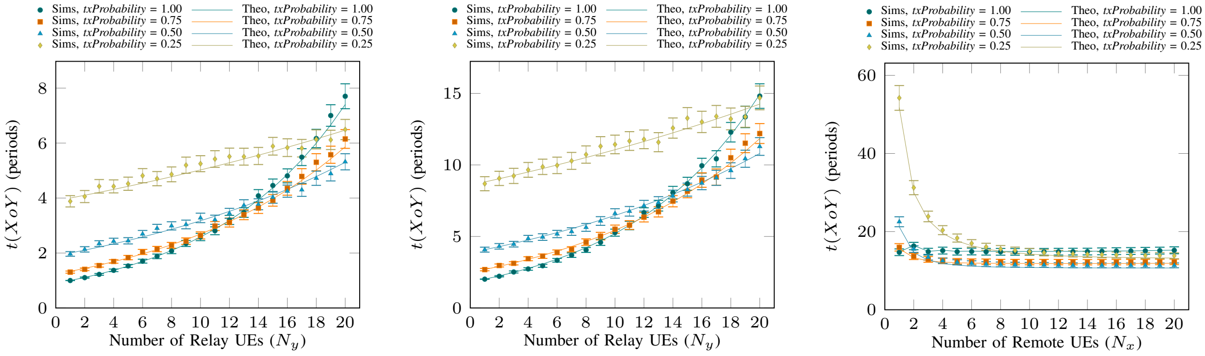
(b) Model B, N_x = 10 Remote UEs.

(c) Model B, N_y = 20 Relay UEs.

Fig. 3. Average number of discovery periods needed by a Remote UE to discover the first Relay UE ($t(X \sim)$). Mean and 95 % confidence intervals are shown for the system level simulation results.



(a) Model A.

(b) Model B, N_x = 10 Remote UEs.

(c) Model B, N_y = 20 Relay UEs.

Fig. 4. Average number of discovery periods needed by a Remote UE to discover a given Relay UE ($t(XoY)$). Mean and 95 % confidence intervals are shown for the system level simulation results.

decreases when N_x increases because the probability that at least one solicitation is sent in a non-colliding discovery resource increases with the number of Remote UEs sending solicitations (N_x). Then, the discovery time is affected by all N_y Relay UEs trying to respond to this solicitation in the following discovery period, similar to Model A behavior with $N_y = 20$. Similar trends were observed for other values of N_y and results are not shown due to space limitations.

Fig. 3 and Fig. 4 also allow us to see the effect of *txProbability* on the discovery time. When the number of UEs contending for resources is small, the largest discovery times are observed in all plots for *txProbability* = 0.25. When N_y and N_x increases, the benefits of reducing concurrent transmissions with a lower transmission probability become more evident; as seen in Fig. 4 the value of *txProbability* that minimizes the discovery time varies depending on N_y and N_x. These observations are consistent with similar evaluations made for group member discovery in [11].

We observe that the discovery time with Model B is longer than with Model A when using equivalent pool configuration. This is expected, as the Relay UE discovery depends on the successful reception of two messages by different UEs when using Model B, i.e., the solicitation from the Remote UE and the response from the Relay UE. Thus, the average discovery time is at least doubled when using Model B. However, when looking at different pool configurations and for low number of UEs, Model B can provide lower discovery times than Model A. For example, if we consider $N_y = 4$ Relay UEs, Fig. 4(a) shows that for Model A the average discovery time for *txProbability* = 0.25 is 4.32 discovery periods, while in Fig. 4(b) the given Relay UE can be discovered in 2.77 discovery periods for *txProbability* = 1.00, or in 3.41 discovery periods for *txProbability* = 0.75 when using Model B. Although we have focused our analysis on time metrics, it is important to keep in mind that the difference in the dynamics of the discovery models impacts other metrics such as energy consumption, which may balance out the extra time needed by Remote UEs when using Model B.

In Fig. 5 we illustrate the impact of the resource pool size on the discovery time for both models. Increasing N_f

Fig. 5. Average number of discovery periods needed by a Remote UE to discover a given Relay UE ($t(XoY)$). Parameters: *txProbability* = 0.50, $N_y = 20$ Relay UEs and $N_x = 20$ Remote UEs. Mean and 95 % confidence intervals are shown for the system level simulation results.

impacts favorably the discovery time, but we observe that the benefits become negligible for larger values of N_f. Increasing N_t provides considerable reductions in the discovery time. However, increasing the discovery resource pool size may come to the expense of reducing the time and frequency resources available for other ProSe operations.

Our analytical models and system level simulator could be used by network operators to select a suitable configuration depending on the targeted performance, expected deployment, and use cases. A typical use case example in the public safety context is a group of First Responders working on an incident in an area with partial network coverage. In this scenario, N_y units stay in the in-coverage area and their devices act as Relay UEs. The other N_x units move to the out-of-coverage area and their devices act as Remote UEs. In this context, operators can use our models to search for the combination of N_f, N_t, and *txProbability* parameters that minimizes the discovery time, i.e., $t(XoY)$ or/and $t(X\sim)$, for the N_x out-of-coverage units, and thus minimize the impact on their service continuity. As the number of units responding to an incident is highly variable, operators can use the models to find a configuration that can provide acceptable results for the largest number of expected N_x and N_y combinations. Furthermore, dynamic algorithms that choose suitable configurations depending on local conditions could help to further improve the discovery performance and are currently open research topics.

V. Conclusions and Future Work

The UE-to-Network Relay discovery time in UE-Selected mode is affected by the discovery pool configuration, the amount of UEs contending for discovery resources, and the discovery model used by the ProSe-enabled UEs. In this paper, we developed a model to quantify the average time taken by a Remote UE of interest to discover any Relay UE and a given Relay UE in proximity depending on those parameters. We validated the model using system level simulations and we have shown the sensitivity of the protocol to the discovery model, number of UEs participating on the discovery, and pool configurations. In future work we plan to extend the models to quantify the time a Remote UE of interest takes to discover all the Relay UEs in proximity and study its impact on the Relay UE selection process. Further extensions of our work will analyze the UE-to-Network Relay discovery protocol under non-ideal channel conditions, considering different propagation environments, and discovery packet recovery based on SINR.

ABSTRACT

This paper describes an ongoing, comprehensive research program being conducted at the National Institute of Standards and Technology (NIST) under the sponsorship of the U.S. Nuclear Regulatory Commission (NRC). The study aims to develop technical basis for evaluating effects of Alkali-Silica Reaction (ASR), which occurs when the high pH concrete pore solution reacts with certain aggregate mineral phases to form expansive ASR gel and create internal expansive forces that cause cracking in concrete, on engineering properties and structural capacities of reinforced concrete structures. Description of this study focusing on experimental evaluation of: (1) the influence of different degrees of steel confinement and ASR expansions (0.1%; 0.3%; 0.5% ultimate expansion) on concrete's mechanical properties; (2) effects of ASR on the bonding between concrete and reinforcements (development and lap splice lengths) and on overall flexural capacities of reinforced concrete beams; and (3) effects of ASR on seismic performance of typical reinforced concrete walls with and without steel confinement in the wall boundary element, will be provided.

INTRODUCTION

Alkali-silica reaction (ASR) has long been recognized as a major cause of concrete internal cracking and deterioration (Stanton 1940; Swenson 1957). This concrete deterioration mechanism begins with reaction between the alkali hydroxides in the cement paste and certain amorphous or micro-crystalline siliceous phases in the aggregates, which produces an alkali-silica gel that forms initially in the partially saturated pore space of the hardened cement paste. The alkali-silica gel is hygroscopic and will continue to absorb moisture in the concrete matrix and expand. This expansion is not reversible and will continue over time as long as moisture is present. The continued expansion of alkali-silica gel creates increasing internal pressure that ultimately leads to internal cracking and degradation of the mechanical properties of concrete (Hansen 1944, Taylor 1990).

Generally, the rate of ASR expansion is relatively slow and is a function of the reactivity of the mineral phases, the alkalinity of the pore solution, and the availability of moisture. Thus, the onset of ASR-induced cracking can take years or decades after construction to occur. However, once occurred, this deterioration at the material level may affect the bonding characteristics between the concrete and the reinforcement and the overall capacity and service life of reinforced concrete structural member or system.

Phan, Long; Sadek, Fahim H.; Thonstad, Travis; Lew, Hai; Marcu, Sorin; Philip, Jacob. "Effects of Alkali-Silica Reaction on Mechanical Properties and Structural Capacities of Reinforced Concrete Structures." Paper presented at Structural Mechanics in Reactor Technology (SMiRT) 25, Charlotte, NC, US. August 04, 2019 - August 09, 2019.

At present, the industry solution is to identify the reactive aggregates and avoid using them through sourcing of materials for construction. This would help with avoiding ASR problem in new construction but does not address the problem in existing structures. Given the current lack of knowledge on ASR effects and standards and codes provisions to account for the effects of ASR on structural capacities, the questions of how to (1) predict the progression of ASR-induced deterioration once occurred and (2) assess the residual material properties and in-situ structural capacity of the affected structures, especially if they are safety-related facilities that are required to maintain a certain safety margin over an extended period of service life, become extremely relevant for certain critical components of the nation's infrastructure (e.g., dams, bridges, and nuclear power plants). Accurate predictions of the progression of ASR and future, residual structural capacities can provide critical support for decision on whether the affected structures can continue safe operation or if it is time for cessation of operations given the increased risk to public safety.

This paper describes work that is part of a comprehensive research program being conducted by the Engineering Laboratory of the National Institute of Standards and Technology (NIST) to study the effects of ASR on the structural performance of nuclear power plant concrete structures. The work is funded by the U.S. Nuclear Regulatory Commission (NRC) under Inter-Agency Agreement NRC-HQ-60-14-I-0004. The objective of this research program is to develop the technical basis for generic regulatory guidance for evaluation of ASR-affected nuclear power plant (NPP) concrete structures throughout its service life. Specifically, the program will develop measurements for evaluation of (1) effects of ASR on structural performance and capability to perform intended function under design basis static and dynamic loads, and (2) characteristics of an asset management program to adequately monitor and manage aging effects of ASR degradation such that intended functions are maintained through the period of extended operation of renewed licenses. The intended outcome is a methodology for determining for an existing ASR-affected structure (1) the in-situ structural capacity to resist design-basis static and dynamic loads and (2) future structural capacity.

NIST EXPERIMENTAL PROGRAM

The NIST experimental program is comprised of two parts. Part 1 focuses on effects of ASR on concrete material properties and performance of reinforced concrete structures subjected to static and pseudo-dynamic loadings. Part 2 examines degradation mechanisms of concrete at micro-structural level. This paper describes Part 1 of the NIST research program focusing on concrete mixture design and curing to achieve certain level of ASR expansion, and the test plan for assessing the effects of ASR on (1) concrete mechanical properties, (2) bonding characteristic and anchorage of steel reinforcement and flexural capacity of reinforced concrete beams, and (3) seismic performance of reinforced concrete walls.

Concrete Mixture Proportioning and Curing

To facilitate examination of the effects of different degrees of ASR expansion on structural capacities of reinforced concrete structural members, four concrete mixtures, namely ASR1 to ASR4, were developed. The first three mixtures, ASR1, ASR2, and ASR3, were designed to have ASR with specific ultimate expansions ε_{ASR} of 0.15%; 0.3%; and 0.5%, respectively. These ultimate expansion levels, from low (ε_{ASR} = 0.15%) to high (ε_{ASR} = 0.5%), were achieved using Type I/II cement with minimum alkali equivalent (Na_2O) content of ≥ 0.87%, alkali reactive coarse aggregate (Placitas, sourced from Albuquerque, New Mexico), and different combinations of reactive (Jobe, sourced from El Paso, TX) and non-reactive (Chaney, sourced from Hagerstown, MD) fine aggregates that meet the grading specification of ASTM C33. The fourth mixture (ASR4) was designed to be non-reactive, utilizing Type I/II cement with low alkali equivalent (Na_2O) content (<0.87%) and non-alkali reactive aggregates, for use in reference specimens for comparison purpose. All coarse aggregates have a maximum size of ¾ inch (20 mm). All four mixtures utilized high range water reducer (BASF MasterGlenium 7710 for the three reactive concrete

Typical curing conditions to accelerate ASR in laboratory conditions involve wetting the top surface prior to form removal and covering the test specimens with wet burlap and plastic sheets after form removal for the first 90 days after casting, at normal ambient temperature and relative humidity, to prevent excessive moisture loss on the specimen's surface layer and minimize potential for drying shrinkage cracks during the hydration process. At 90 days of age, the plastic and burlap covers were removed and the curing temperature and relative humidity in the curing chamber were increased to 75°F (24 ºC) and 75 %. At 180 days of age, the relative humidity was increased again to the range of 95 % to 100 %. The 75°F (24 ºC) and 95 % - 100 % relative humidity curing conditions were then maintained until test time.

Assessing In-Situ Mechanical Properties of ASR-Affected Concrete

This task aims to assess the relationship between ASR-induced expansion and: (1) concrete mechanical properties; (2) surface cracking and expansion, and (3) the influence of hoop reinforcement (i.e., stirrups) on the expansion through measurements conducted on four large block specimens, 3.5 ft × 6 ft × 16 ft (1.07 m × 1.83 m × 4.88 m). Three of the block specimens were made with the ASR1, ASR2, and ASR3 concretes shown in Table 1, and the fourth specimen was made with non-reactive ASR4 concrete and served as the control specimen.

For reinforcement, each block specimen was divided into three regions (Regions 1 to 3, see Figure 1), each region was isolated by a 2-inch (51-mm) thick polystyrene divider to minimize the possible interaction of expansion with the adjoining region and reinforced longitudinally with a combination of #8 and #10 headed bars and transversely with #8 and #10 stirrups and cross ties. The variation in the bar sizes used in each region and inclusion of cross ties in Region 3 were designed to produce different degrees of concrete confinement in the three regions of each block specimen (see Figure 2). Region 2 of each block specimen was not transversely reinforced (no stirrups, reinforcement ratio in the transverse and vertical, or *x* and *y*, directions $\rho_x = \rho_y = 0\%$) and will provide measurements of concrete material properties and cracking characteristics corresponding with the unconfined expansion condition. Region 1 measurements will correspond with intermediate level of expansion confinement ($\rho_x = 0.2\%$), and Region 3 measurements will correspond with a higher level of expansion confinement ($\rho_x = 0.6\%$).

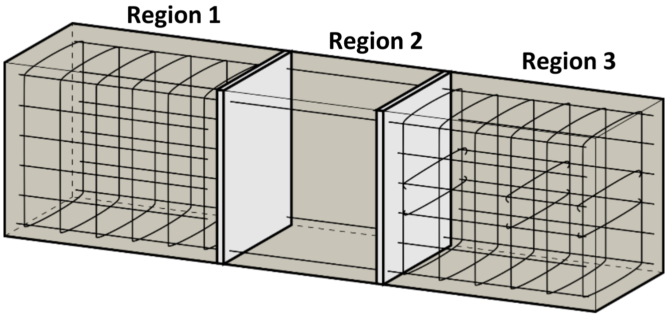

Figure 1. Regions and Reinforcement Scheme of Block Specimen.

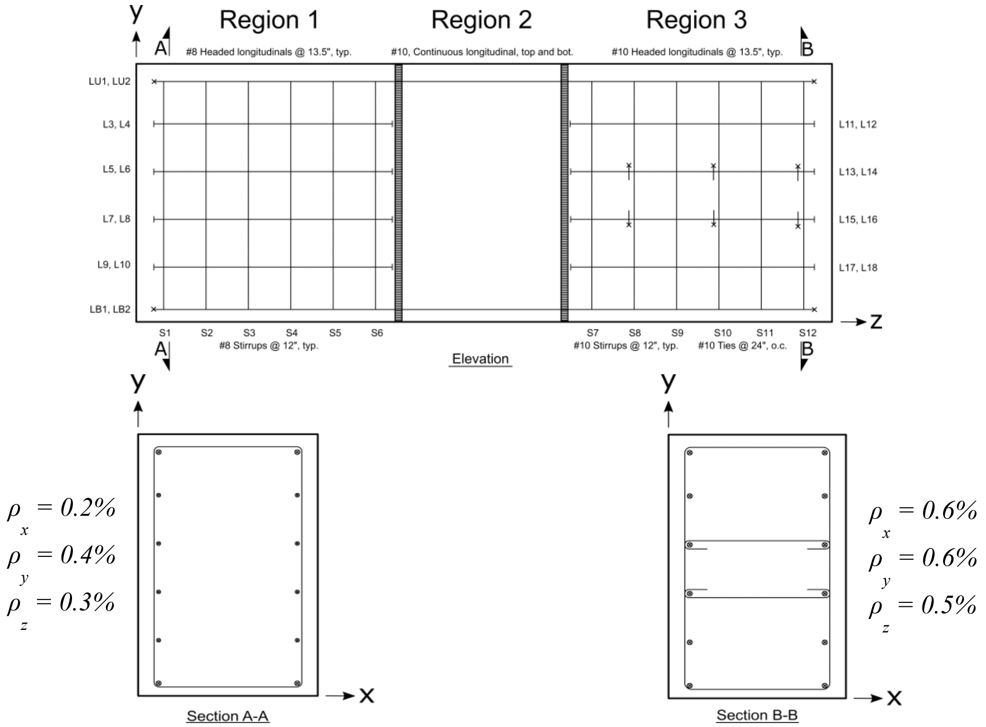

Figure 2. Reinforcement Details of Block Specimen.

All four block specimens were heavily instrumented, each with approximately 164 strain gages attached to the reinforcements, strain transducers to measure tri-directional concrete strain, as well thermo-couples and wireless relative humidity sensors. Figure 3 shows the typical strain gage instrumentation scheme. ASR-induced expansion of concrete, evidenced by increasing strain over time in the reinforcement, are measured and recorded continuously. Figure 4 shows a sample time-history of ASR-induced strain development in the reinforcement in Region 1 of ASR3 block specimen. The time-history provides a correlation between the rates of concrete expansion and the curing conditions and indicates yielding of longitudinal reinforcements shortly before 480 days of curing for this specimen. Correlation of degree of ASR expansion with changes in concrete mechanical properties as a function of time and different levels of confinement is performed through mechanical properties testing of concrete cylinders and cores extracted from different regions of the block specimens. Surface expansion is monitored by measuring changes in vertical and horizontal distances between targets that form square grid (10 ¾ × 10 ¾) on the side of the block specimens using laser tracking device and high-precision calliper.

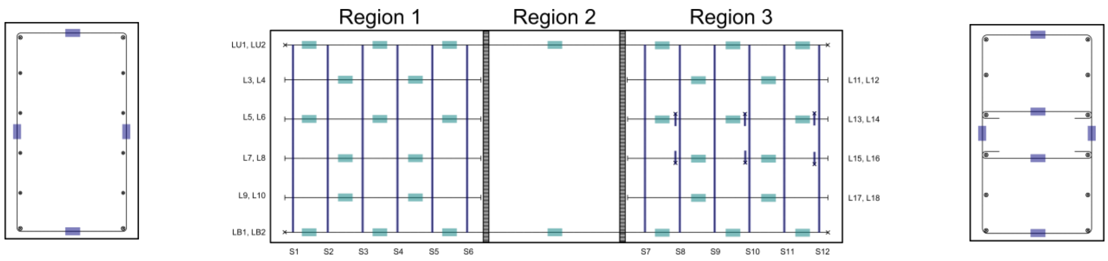

Figure 3. Locations of Strain Gages on the Reinforcements of the Block Specimen.

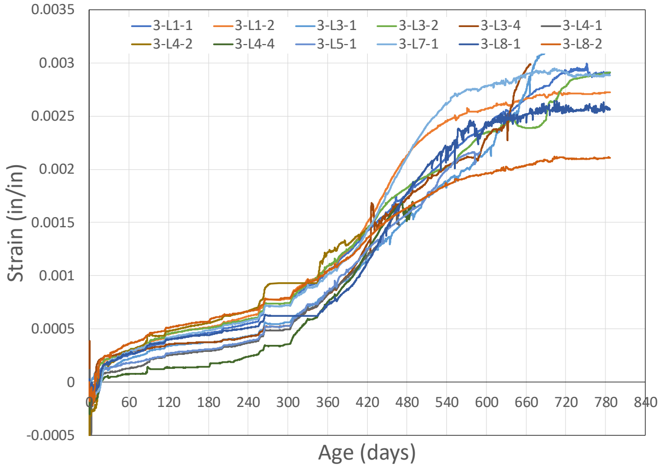

Figure 4. Time-Histories of Strain Development in Region 1 of ASR3 Block Specimen.

Concrete cylinders and cores extracted from different regions of the block specimens are tested periodically for time-histories of concrete compressive strength, splitting tensile strength, and elastic modulus. Data are being processed and compared for evaluation of effects of ASR on concrete mechanical properties. Comparison will also be made with ACI empirical equations to assess applicability of these equations to ASR-affected concrete.

Assessing Bond and Anchorage of Steel Reinforcement

This task aims to examine how ASR influences (1) the bonding characteristic between concrete and steel reinforcement, both for continuous, axially loaded, reinforcing bars and for lap splices in flexural members and (2) the possible loss of rebar anchorage and overall reduction of member's flexural capacities. To facilitate this examination, a series of 19 beam specimens, consisting of 16 reactive beams made of ASR3 concrete and 3 reference, non-reactive beams (also made of ASR3 concrete but with addition of Lithium Nitrate to neutralize the ASR), were constructed and tested under four-point bending. The test series was designed to facilitate examination of the effects of the following three main variables, as well as their interactions, on flexural capacities of reinforced concrete beams: degree of ASR expansion (ε_{ASR}(t)); degree of concrete confinement (K_{tr}/d_b); and ratio of lap splice and development length (l_s/l_d). The test matrix for this test series is shown in Table 2. Beam dimensions and test configuration are shown in Figure 5. Values of $\varepsilon_{ASR}(t)$ shown in Table 2 indicate the nominal expansion level, measured as maximum strain in the reinforcement, relative to the target expansion level $\varepsilon_{ASR}(t)$ = 0.3% for ASR3 concrete when the beam is to be tested (e.g., beam specimen 1, with $\varepsilon_{ASR}(t)$ = 25%, is to be tested when the ASR-induced expansion has resulted in a nominal strain in the reinforcement in the amount of 25% × 0.3% = 0.00075 in/in).

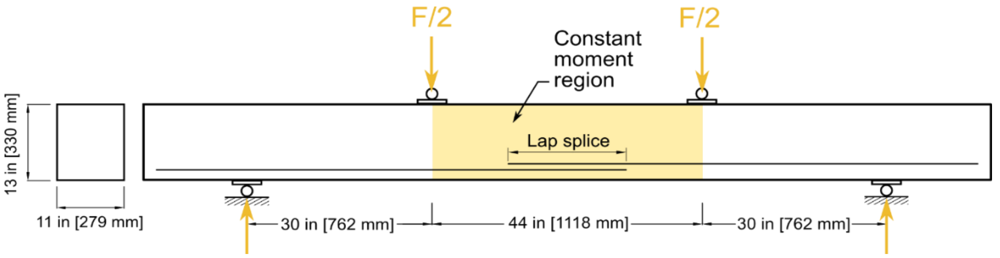

Figure 5. Beam Dimensions and Test Configuration

To date, 16 of 19 beams have been tested. Data analysis is being conducted to examine the effects of the mentioned variables on the bonding characteristic, anchorage strength, and overall flexural beam capacities. Results of the analysis and findings will be presented in a more detailed report to the project sponsor at a later date. Preliminary test results, in the form of maximum vertical load vs. maximum mid-span deflection, are shown in Figure 6. This plot shows the varied modes of failure observed in the 16 tested beams, which ranged from bond failure prior to yielding of the tension reinforcement, yielding of tension reinforcement followed by bond failure, and yielding of tension reinforcement followed by compression failure of concrete in the compression zone.

Assessing Seismic Performance of ASR-Affected Structural Walls

This task aims to assess the effects of ASR on seismic capacity of typical reinforced concrete walls. Seismic capacities – in terms of lateral stiffness, ultimate strength, ductility, and energy dissipation – of four reinforced concrete wall specimens will be measured through pseudo dynamic cyclic lateral load tests. Three of the wall specimens are made of reactive ASR3 concrete and the fourth non-reactive concrete made of ASR3 concrete modified with Lithium Nitrate (reference specimen). Experimental variables to be studied include (1) degree of ASR expansion $\varepsilon_{ASR}(t)$ and (2) degree concrete confinement, represented by the transverse reinforcement ratio, in the wall's boundary element (ρ_s). Figure 7 shows the dimensions and typical reinforcement details on a cross section of a wall specimen. Table 3 shows the test matrix for this series of wall seismic lateral load test. For testing, the wall specimens are subjected to constant axial compression load to simulate service load while simultaneously subjected to cyclic lateral displacement with increasing magnitude, as shown in Figure 8. At present, the wall specimens have been constructed and are being cured to accelerate ASR expansion for testing.

"Effects of Alkali-Silica Reaction on Mechanical Properties and Structural Capacities of Reinforced Concrete Structures." Paper presented at Structural Mechanics in Reactor Technology (SMiRT) 25, Charlotte, NC, US. August 04, 2019 - August 09, 2019.

SUMMARY

An experimental plan to measure and quantify the effects of ASR on concrete material properties and structural capacities of reinforced concrete beam and walls, being conducted at NIST under the sponsorship of the NRC, is described. Measurements obtained from this study will be used to develop a methodology for determining the in-situ and future structural capacity of ASR-affected structure and will form the technical basis underpinning possible generic regulatory guidance for evaluation of ASR-affected nuclear power plant (NPP) concrete structures throughout its service life. Discussions of test results and findings will be provided in detail in subsequent joint NIST/NRC publications.

LABEL-FREE SURFACE ACOUSTIC WAVE-BASED EMBEDDED FLOW SENSOR

Aurore Quelennec, Jason J. Gorman, and Darwin R. Reyes*
National Institute of Standards and Technology (NIST), Gaithersburg, USA

ABSTRACT

This paper presents a label-free flow sensor embedded in a microfluidic system. This sensor is based on surface acoustic waves, where the acoustic intensity is dependent on the flow rate of the propagating medium. The range of flow rates studied was between 10 µL/min to 1 mL/min, with a sensitivity of 7 µV/(µL/min). Different to readily available sensors that need tracers (*e.g.*, particles, fluorophores) or the use of temperature distribution to measure flow, this sensor requires no external optical components, and can be used with any type of liquid at a broad range of temperatures and liquid conditions.

KEYWORDS: Flow Metrology, Electroacoustics, SAW Sensor

INTRODUCTION

Interdigitated (IDT) electrodes can generate surface acoustic waves (SAW) within a piezoelectric material. The propagation medium interacts with the SAW altering the SAW's acoustic frequency and intensity. This interaction makes SAW transducers useful as both actuators [1] and sensors [2]. SAW have previously been used in microfluidic systems to measure the flow rate [3] of the propagating medium. However, current SAW flow sensors used in microfluidic systems, based on thermal, doppler shift or time-of-flight measurements, are not label-free sensors. In this work, we report a new method for flow measurement over the range of 10 µL/min to 1 mL/min in a microfluidic channel. The technique presented here relates to the ability of the fluid to absorb the acoustic waves as a function of the flow rate.

EXPERIMENTAL

A complete description of the fabrication process can be found in [4]. Three pairs of IDT electrodes (Figure 1) are fabricated using a lift-off process and an e-beam evaporator on a 128 Y-cut lithium niobate (LN) wafer. The electrode is composed of 90 nm of gold on 10 nm of titanium. A 100 nm thick silicon oxide layer is sputtered on the chip. Figure 1A shows the IDT electrode E1 has a single-phase unidirectional transducer (SPUDT) structure, while E2 has a standard IDT structure. Each transducer studied (E1 and E2) has 32 pairs of fingers, which are 3 mm long with a pitch (p) of 80 µm. The 80 µm deep microchannel in polydimethylsiloxane (PDMS) is fabricated using soft lithography techniques.

Our assumption was that the acoustic intensity depends on the flow speed (v_F). E1 is excited with a 10 V peak-to-peak sine wave (V_{in} in Figure 2) at the acoustic resonance frequency. E2 is connected to an oscilloscope to measure the amplitude (V_p) of the received wave at E2 for different v_F. Deionized water is injected in the microchannel using a syringe pump. The flow rate is controlled from 0 µL/min to 1,000 µL/min.

RESULTS AND DISCUSION

As shown in Figure 2 (insets), the peak amplitude increases with an increase in v_F, but the received signal has a low Signal/Noise ratio. We calculated that the average error in the measurement is 1 mV. To extract the sensor response to v_F, the difference between the received signal at different v_F and the one at no flow is calculated (noted as $V_p - V_p(0)$). In Figure 3, the amplitude variation, $V_p - V_p(0)$, of the 1st, 2nd and 5th peaks, is represented as a function of flow, and a linear fit was obtained for each of them. The first peak is not sensitive to v_F, while the others have an average sensitivity of 7 µV/(µL/min). The mean-squared error between the measured value and the linear estimation is 1 mV. These results confirm that the acoustic intensity depends on v_F.

CONCLUSION

This work shows that the acoustic intensity of a SAW is dependent on the flow rate of the propagating medium. This technique represents a step forward towards the development of a calibration-free flow device. This system could, ultimately, become a standard reference device to be used in any microfluidic system and application.

On Wacker's Essential Equation in the Extrapolation Measurement Technique

Alex J. Yuffa
National Institute of Standards and Technology
Boulder, CO 80305, USA
alex.yuffa@nist.gov

***Abstract*—The generalized three-antenna method is a standard method for measuring on-axis gain and polarization of an antenna without a priori knowledge. The cornerstone of the method is the use of the extrapolation technique and the key relationship in the extrapolation technique is Wacker's equation. This equation expresses the received signal as a function of the separation distance between any two antennas. The derivation of Wacker's equation is not readily available in the literature. In this paper, we provide a streamlined derivation of Wacker's equation and address some of the common misconceptions associated with it.**

I. Introduction

The extrapolation technique is commonly used to measure on-axis gain and polarization of an antenna. This technique was introduced almost five decades ago by Newell, Baird, and Wacker in their seminal paper [1]. The technique is based on an equation that represents the received signal as a function of the separation distance between any two antennas. This equation, see equation (26) in [1], is equally accurate when the antennas are close together or far apart because it accounts for the multiple scattering effects between the two antennas. In the seminal paper, the derivation of the equation is attributed to an unpublished technical report by Wacker. Two years before the seminal paper was published Newell and Kerns [2] attributed the derivation of the equation to another of Wacker's unpublished works with an almost identical title. A decade later Kerns, in his classic monograph [3, p. 148], attributes the derivation of the equation to the unpublished report by Wacker. Furthermore, Kerns cites private communication with Yaghjian (presumably Arthur D. Yaghjian) and states that Yaghjian derived an almost identical equation to Wacker's (26) in [1] via a different method [3, p.148]. At this point the referencing of unpublished literature ends and Kerns gives a brute-force derivation of the equation under a greatly simplifying assumption of no multiple scattering [3, pp. 147–159]. It is not clear why the authors cited the report as unpublished as it was *published* almost a year before the seminal paper was submitted for publication [4]. The front page of the report is shown in Fig. 1 and may be obtain from the National Oceanic and Atmospheric Administration (NOAA) library in Boulder, Colorado.

Fig. 1. (Color online) The cover of the allusive Wacker's report [4] is shown.

Perhaps because of the perceived lack of availability of Wacker's report, we have encountered a number of practitioners with a misleading interpretation of Wacker's equation. One misconception is that the distance between the two antennas should be measured from the phase centers of the antennas. Another misconception is that Wacker's equation only *approximately* accounts for the multiple scattering effects. This misconception seems to be caused by the input reflection coefficient of the probe antenna in *free space*. To eliminate some of these misconceptions, we present an abridged derivation of Wacker's equation with the aim of pedagogical clarity.

II. Orders-of-Scattering Interpretation

Consider two on-axis antennas separated by free space as shown in Fig. 2. Without lost of generality, we let the antenna under test (AUT) be the antenna on the left-hand side (LHS) in Fig. 2 and the probe antenna to be on the right-hand side (RHS). The scattering-matrix for each antenna is defined by

$$\begin{bmatrix} b_1^\alpha \\ b_2^\alpha \end{bmatrix} = \begin{bmatrix} S_{11}^\alpha & S_{12}^\alpha \\ S_{21}^\alpha & S_{22}^\alpha \end{bmatrix} \begin{bmatrix} a_1^\alpha \\ a_2^\alpha \end{bmatrix}, \tag{1a}$$

where $\alpha = \ell$ for the LHS antenna and $\alpha = \mathrm{r}$ for the RHS antenna. We can also define a scattering-matrix for the space

Yuffa, Alex. "On Wacker's Essential Equation in the Extrapolation Measurement Technique." Paper presented at Annual Symposium of the Antenna Measurement Techniques Association (AMTA), San Diego, CA, US. October 06, 2019 - October 11, 2019.

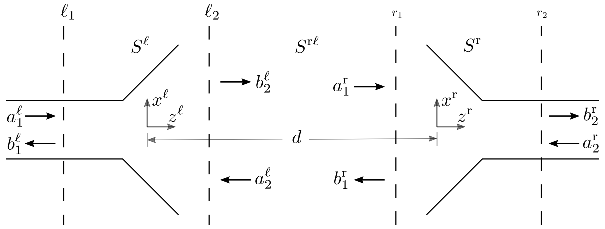

Fig. 2. Two on-axis antennas separated by free space are shown. The terminal surfaces are represented by the labeled dashed lines. The complex amplitudes of the incident and emergent modes are denoted by $a_1^\ell, a_2^{\mathrm{r}}$ and $b_1^\ell, b_2^{\mathrm{r}}$, respectively.

between the antennas via

$$\begin{bmatrix} a_1^{\mathrm{r}} \\ a_2^\ell \end{bmatrix} = \begin{bmatrix} 0 & S_{12}^{\mathrm{r}\ell} \\ S_{21}^{\mathrm{r}\ell} & 0 \end{bmatrix} \begin{bmatrix} b_1^{\mathrm{r}} \\ b_2^\ell \end{bmatrix}, \tag{1b}$$

where the diagonal elements vanish because there is no coupling between the incident and emergent waves at the r_1 terminal surface and the ℓ_2 terminal surface. The scattering-matrix for the whole system is defined by

$$\begin{bmatrix} b_1^\ell \\ b_2^{\mathrm{r}} \end{bmatrix} = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix} \begin{bmatrix} a_1^\ell \\ a_2^{\mathrm{r}} \end{bmatrix} \tag{2}$$

and can be expressed in terms of $S^\ell, S^{\mathrm{r}\ell}, S^{\mathrm{r}}$ by eliminating a_2^ℓ, b_2^ℓ and $a_1^{\mathrm{r}}, b_1^{\mathrm{r}}$ from (1) and comparing the result to (2) to obtain

$$S_{11} = S_{11}^\ell + S_{12}^\ell R^{\mathrm{r}} \left[1 - S_{22}^\ell R^{\mathrm{r}}\right]^{-1} S_{21}^\ell, \tag{3a}$$

$$S_{12} = S_{12}^\ell S_{21}^{\mathrm{r}\ell} \left[1 - S_{11}^{\mathrm{r}} R^\ell\right]^{-1} S_{12}^{\mathrm{r}}, \tag{3b}$$

$$S_{21} = S_{21}^{\mathrm{r}} S_{12}^{\mathrm{r}\ell} \left[1 - S_{22}^\ell R^{\mathrm{r}}\right]^{-1} S_{21}^\ell, \tag{3c}$$

$$S_{22} = S_{22}^{\mathrm{r}} + S_{21}^{\mathrm{r}} R^\ell \left[1 - S_{11}^{\mathrm{r}} R^\ell\right]^{-1} S_{12}^{\mathrm{r}}, \tag{3d}$$

where

$$R^{\mathrm{r}} = S_{21}^{\mathrm{r}\ell} S_{11}^{\mathrm{r}} S_{12}^{\mathrm{r}\ell} \qquad \text{and} \qquad R^\ell = S_{12}^{\mathrm{r}\ell} S_{22}^\ell S_{21}^{\mathrm{r}\ell} \tag{4}$$

In (4), R^{r} (R^ℓ) is the reflection coefficient of the RHS (LHS) antenna as seen by the LHS (RHS) antenna.

By the nth orders-of-scattering approximation we mean an expansion of (3) in "powers" of R^{r} or R^ℓ up to and including order n [5]. It is important to realize that although we have treated the elements of the scattering-matrices as scalar numerical entities they are not. In general, the elements of the scattering-matrices are integral operators, and thus (2) contains not algebraic equations but rather integral equations in disguise. Therefore, the operators in the square brackets in (3) should be expanded in the Neumann series [6, §3.2],

$$[1 - G]^{-1} = 1 + G + GG + \cdots = \sum_{n=0}^{\infty} G^n, \quad ||G|| < 1, \tag{5}$$

rather than the Taylor series. In other words, the G^n term in (5) should be interpreted as the nth iterated kernel and 1 should be interpreted as the identity operator.

To gain some physical insight into (5) let's consider the 2nd orders-of-scattering approximation of S_{21} and S_{22}. In other words, expanding the square bracket terms in S_{21} and S_{22} in the Neumann series yields

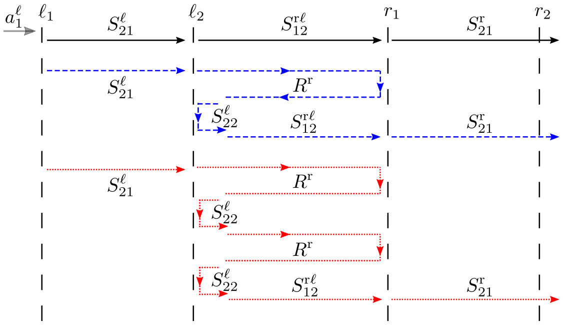

Fig. 3. (Color online) The 2nd orders-of-scattering approximation of $S_{21}^{(2)}$ is schematically illustrated.

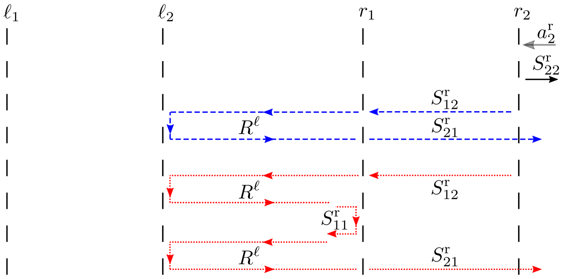

Fig. 4. (Color online) The 2nd orders-of-scattering approximation of $S_{22}^{(2)}$ is schematically illustrated.

$$S_{21}^{(2)} = S_{21}^{\mathrm{r}} S_{12}^{\mathrm{r}\ell} S_{21}^\ell + S_{21}^{\mathrm{r}} S_{12}^{\mathrm{r}\ell} \left(S_{22}^\ell R^{\mathrm{r}}\right) S_{21}^\ell + S_{21}^{\mathrm{r}} S_{12}^{\mathrm{r}\ell} \left(S_{22}^\ell R^{\mathrm{r}}\right)^2 S_{21}^\ell, \tag{6a}$$

and

$$S_{22}^{(2)} = S_{22}^{\mathrm{r}} + S_{21}^{\mathrm{r}} R^\ell S_{12}^{\mathrm{r}} + S_{21}^{\mathrm{r}} R^\ell \left(S_{11}^{\mathrm{r}} R^\ell\right) S_{12}^{\mathrm{r}}, \tag{6b}$$

where the superscript (2) denotes the order of the approximation. In Fig. 3, the first, second, and third terms on the RHS of (6a) are schematically shown by the solid, dashed, and dotted lines, respectively. From Fig. 3, we see that the first term corresponds to the direct transmission of a_1^ℓ and the second term includes the reflections of the signal by the probe and the AUT. A similar interpretation may be constructed for (6b), see Fig. 4. It is important to note that the first term on the RHS of (6b) corresponds to the direct reflection of a_2^{r} by the RHS antenna (probe) as seen from its feed. In other words, this is the reflection coefficient that one would measure in the absence of the LHS antenna (AUT).

III. Wacker's Equation

In the previous section, we provided a physical insight into the mutual coupling between the two antennas. This was done in a general and abstract manner by formal manipulation of the scattering-matrices. In this section, we will remove the abstraction layer by constructing an explicit form of the S-matrix.

If we assume the probe antenna is connected to a load with the reflection coefficient Γ^{r}, then $a_2^{\mathrm{r}} = \Gamma^{\mathrm{r}} b_2^{\mathrm{r}}$ and from (2) we have

$$b_2^{\mathrm{r}} = \left[1 - S_{22}\Gamma^{\mathrm{r}}\right]^{-1} S_{21} a_1^{\ell}. \tag{7}$$

Notice that the square bracket on the RHS of (7) contains the integral operator S_{22} and *not* the reflection coefficient of the probe S_{22}^{r}.

A. Zeroth Order-of-Scattering

To obtain the zeroth order-of-scattering approximation of (7) we substitute the first term on the RHS of (6) into (7) to obtain

$$b_2^{\mathrm{r}(0)} = \left[1 - S_{22}^{\mathrm{r}}\Gamma^{\mathrm{r}}\right]^{-1} S_{21}^{\mathrm{r}} S_{12}^{\mathrm{r}\ell} S_{21}^{\ell} a_1^{\ell}. \tag{8}$$

In (8), the term inside the square bracket is a complex *scalar* quantity, and thus we only need to determine the explicit form of

$$T \equiv S_{21}^{\mathrm{r}} S_{12}^{\mathrm{r}\ell} S_{21}^{\ell} a_1^{\ell}. \tag{9}$$

The key to obtaining the explicit form of T is to recognize that it may be written as [4, pp.12–13]

$$T = \int\limits_{-\infty}^{\infty}\int\limits_{-\infty}^{\infty} a_1^{\ell} f_1(k_x) f_2(k_y) f_3(k_z) \frac{\mathrm{e}^{+\mathrm{i}k_z d}}{k_z}\, \mathrm{d}k_x \mathrm{d}k_y, \tag{10a}$$

where f_1, f_2, and f_3 are *entire* functions and wave vector $\boldsymbol{k} = k_x \hat{\boldsymbol{e}}_{x^\ell} + k_y \hat{\boldsymbol{e}}_{y^\ell} + k_z \hat{\boldsymbol{e}}_{z^\ell}$ is such that

$$k_z = \begin{cases} +\sqrt{k^2 - \kappa^2} & \text{for} \quad \kappa < k \\ +\mathrm{i}\sqrt{\kappa^2 - k^2} & \text{for} \quad \kappa > k \end{cases}, \tag{10b}$$

with $\kappa^2 = k_x^2 + k_y^2$, see Fig. 2. Recall that for an entire function the principal part of the Laurent series vanishes [7, p.17], and thus we have

$$f_1 = \sum_{m=0}^{\infty} A_m^x k_x^m, \quad f_2 = \sum_{n=0}^{\infty} A_n^y k_y^n, \quad f_3 = \sum_{p=0}^{\infty} A_p^z k_z^p. \tag{11}$$

Substituting (11) into (10a), and noting that the odd powers of k_x and k_y integrate to zero, we obtain

$$T = a_1^{\ell} \sum_{mnp} A_m^x A_n^y A_p^z \times \int\limits_{-\infty}^{\infty}\int\limits_{-\infty}^{\infty} k_x^{2m} k_y^{2n} k_z^p \frac{\mathrm{e}^{+\mathrm{i}k_z d}}{k_z}\, \mathrm{d}k_x \mathrm{d}k_y, \tag{12}$$

where the triple sum is over all non-negative integers. Converting the double integral in (12) to polar coordinates via $k_x = \kappa\cos\theta$ and $k_y = \kappa\sin\theta$, then using the orthogonal property of cosines and sines yields

$$T = a_1^{\ell} \sum_{n=0}^{\infty}\sum_{p=0}^{\infty} A_n^x A_n^y A_p^z \int_0^{\infty} \kappa^{4n} k_z^p \frac{\mathrm{e}^{+\mathrm{i}k_z d}}{k_z} \kappa\, \mathrm{d}\kappa. \tag{13}$$

Changing the integration variable in (13) from κ to k_z by recalling that κ^2 is a function of k_z^2, see (10b), yields

$$T = -a_1^{\ell} \sum_{n=0}^{\infty}\sum_{p=0}^{\infty} A_n^x A_n^y A_p^z \times \int_k^{\mathrm{i}\infty} \left(k^2 - k_z^2\right)^{2n} k_z^p \mathrm{e}^{+\mathrm{i}k_z d}\, \mathrm{d}k_z. \tag{14}$$

If we parameterize the line integral in the complex k_z-plane in (14) via $k_z = k + \mathrm{i}t$, then the product of the two infinite sums in (14) can be written as

$$\sum_{n=0}^{\infty}\sum_{p=0}^{\infty} A_n^x A_n^y A_p^z \left(k^2 - k_z^2\right)^{2n} k_z^p = \sum_{q=0}^{\infty} B_q t^q, \tag{15}$$

where the unknown B_q coefficients depend on the A_n^x, A_n^y, A_p^z coefficients and the wavenumber k. Substituting (15) into (14) and changing the integration variable from k_z to t yields

$$T = -\mathrm{i}a_1^{\ell} \sum_{q=0}^{\infty} B_q \mathrm{e}^{+\mathrm{i}kd} \int_0^{\infty} t^q \mathrm{e}^{-td}\, \mathrm{d}t. \tag{16}$$

Recognizing the integral in (16) as the Laplace transform of t^q [8, §17.13] we immediately obtain

$$T = a_1^{\ell} \frac{\mathrm{e}^{+\mathrm{i}kd}}{kd} \sum_{n=0}^{\infty} \frac{A_n}{(kd)^n}, \tag{17}$$

where the unknown A_n coefficients depend on the B_q coefficients. The form of (17) is not surprising because according to the Wilcox expansion theorem [9] any electromagnetic wave produced by a *finite* charge distribution has an expansion of the form

$$\frac{\mathrm{e}^{+\mathrm{i}kr}}{kr} \sum_{n=0}^{\infty} \frac{\boldsymbol{A}_n(\theta,\phi)}{(kr)^n}, \qquad r > r_c, \tag{18}$$

where (r, θ, ϕ) are the usual spherical coordinates and r_c is the radius of the smallest circumscribing sphere containing the finite charge distribution. Finally, after substituting (17) into (8) we obtain the zeroth order-of-scattering approximation of the signal measured by the probe; namely,

$$b_2^{\mathrm{r}(0)} = a_1^{\ell} \left[1 - S_{22}^{\mathrm{r}}\Gamma^{\mathrm{r}}\right]^{-1} \frac{\mathrm{e}^{+\mathrm{i}kd}}{kd} \sum_{n=0}^{\infty} \frac{A_n}{(kd)^n}. \tag{19}$$

From the derivation of (17) we see that the A_n coefficients in (19) are *independent* of S_{22}^{r} and Γ^{r}. This observation is obvious in the current context but it will become camouflaged when we consider all orders-of-scattering.

B. All Orders-of-Scattering

The first orders-of-scattering approximation of S_{21} includes the first two terms on the RHS of (6a); namely, the zeroth order-of-scattering, which we computed in Section III-A, and the $S_{21}^{\mathrm{r}} S_{12}^{\mathrm{r}\ell}\left(S_{22}^{\ell} R^{\mathrm{r}}\right) S_{21}^{\ell}$ term. Similar to the computation of the zeroth order-of-scattering approximation, the key to obtaining the explicit form of $\mathbb{T} = S^{\mathrm{r}}_{21} S^{\mathrm{r}\ell}_{12} \left(S^{\ell}_{22} R^{\mathrm{r}}\right) S^{\ell}_{21} a^{\ell}_{1}$ is to recognize that it may be written as [4, p.24]

$$\mathbb{T} = a_1^{\ell} \iint\limits_{-\infty}^{\infty} \mathrm{d}k_x \mathrm{d}k_y \iint\limits_{-\infty}^{\infty} \mathrm{d}k'_x \mathrm{d}k'_y \iint\limits_{-\infty}^{\infty} \mathrm{d}k''_x \mathrm{d}k''_y$$

$$f(k_x, k_y, k'_x, k'_y, k''_x, k''_y) \frac{\mathrm{e}^{\mathrm{i}(k_z + k'_z + k''_z)d}}{k_z + k'_z + k''_z}, \quad (20)$$

where the function f is an entire function in each variable. The integrals in (20) may be evaluated following the procedure of Section III-A to obtain

$$\mathbb{T} = a_1^{\ell} \frac{\mathrm{e}^{3\mathrm{i}kd}}{(kd)^3} \sum_{n=0}^{\infty} \frac{A'_n}{(kd)^n}. \quad (21)$$

In general, we can use the above method for all orders-of-scattering. Therefore, we can obtain *exact* explicit forms of S_{21} and S_{22}. These forms are given by [4, pp.25–27],

$$S_{21} = \frac{\mathrm{e}^{\mathrm{i}kd}}{kd} \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \frac{\mathrm{e}^{2m\mathrm{i}kd}}{(kd)^{2m}} \frac{A_{mn}}{(kd)^n}. \quad (22a)$$

and

$$S_{22} = \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \frac{\mathrm{e}^{2m\mathrm{i}kd}}{(kd)^{2m}} \frac{B_{mn}}{(kd)^n}, \quad (22b)$$

where $B_{0n} = S^{\mathrm{r}}_{22} \delta_{0n}$ and δ_{0n} is the Kronecker delta function. In (22b), $B_{0n} = S^{\mathrm{r}}_{22} \delta_{0n}$ because (22b) must agree with the zeroth order-of-scattering approximation, i.e., $S^{(0)}_{22} = S^{\mathrm{r}}_{22}$.

To obtain Wacker's equation, we use the Neumann series to expand the square bracket term in (7) and then substitute (22) into the resultant, i.e.,

$$\frac{b^{\mathrm{r}}_2}{a^{\ell}_1} = \frac{\mathrm{e}^{\mathrm{i}kd}}{kd}$$

$$\times \sum_{p=0}^{\infty} \left[\Gamma^{\mathrm{r}} \sum_{mn} \frac{\mathrm{e}^{2m\mathrm{i}kd}}{(kd)^{2m}} \frac{B_{mn}}{(kd)^n} \right]^p \sum_{m'n'} \frac{\mathrm{e}^{2m'\mathrm{i}kd}}{(kd)^{2m'}} \frac{A_{m'n'}}{(kd)^{n'}} \quad (23)$$

Wacker's equation (23) may be written in a more traditional form by multiplying out the sums in (23) to obtain

$$\frac{b^{\mathrm{r}}_2}{a^{\ell}_1} = \frac{\mathrm{e}^{\mathrm{i}kd}}{kd} \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \frac{\mathrm{e}^{2m\mathrm{i}kd}}{(kd)^{2m}} \frac{C_{mn}}{(kd)^n}, \quad (24)$$

where, in general, the C_{mn} coefficients depend on the A_{mn}, B_{mn} coefficients and Γ^{r}. We can simplify (24) further by noting that for $m = 0$ it must agree with the zeroth order-of-scattering approximation given by (19); thus, we have

$$\frac{b^{\mathrm{r}}_2}{a^{\ell}_1} = \frac{1}{1 - S^{\mathrm{r}}_{22}\Gamma^{\mathrm{r}}} \frac{\mathrm{e}^{\mathrm{i}kd}}{kd} \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \frac{\mathrm{e}^{2m\mathrm{i}kd}}{(kd)^{2m}} \frac{F_{mn}}{(kd)^n}, \quad (25)$$

where F_{00} and only F_{00} is *independent* of S^{r}_{22} and Γ^{r} (see the end of Section III-A).

IV. Discussion

Wacker's equation is given by (25) and it accounts for *all* multiple scattering effects between the two antennas. Unfortunately, it can also be improperly derived leading to misconceptions. To see this, substitute the *exact* form of S_{21} given by (22a) into the zeroth order-of-scattering approximation (8) to obtain

$$\frac{1}{1 - S^{\mathrm{r}}_{22}\Gamma^{\mathrm{r}}} \frac{\mathrm{e}^{\mathrm{i}kd}}{kd} \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \frac{\mathrm{e}^{2m\mathrm{i}kd}}{(kd)^{2m}} \frac{A_{mn}}{(kd)^n}. \quad (26)$$

This improper derivation suggests that Wacker's equation accounts for the multiple scattering effects contained in S_{22} only to the zeroth order-of-scattering. Of course, this conclusion is incorrect as we have shown in Section III-B.

Another source of confusion comes from the separation distance variable d. In general, d should be measured from behind the face of the AUT to behind the face of the probe as shown in Fig. 2. With this choice, the sums in (25) will usually converge for any d as long as the two antennas are not touching [4, pp.15–22]. A sufficient, but not necessary, condition for the sums in (25) to converge is given by

$$d > r_{\text{AUT}} + r_{\text{probe}}, \quad (27)$$

where r_{AUT} (r_{probe}) is the radius of the smallest circumscribing sphere containing the AUT (probe) [3, Ch. III, §5]. It is important to note that if the sums in (25) converge, then the on-axis gain and polarization of the antenna are *not* affected by the choice of origin of the separation distance. To see this, we shift the coordinate system by d_0 so that the new separation distance is given by

$$d' = d - d_0 \quad (28)$$

and substitute (28) into (25) to obtain

$$\frac{b^{\mathrm{r}}_2}{a^{\ell}_1} = \frac{1}{1 - S^{\mathrm{r}}_{22}\Gamma^{\mathrm{r}}} \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \frac{\mathrm{e}^{(2m+1)\mathrm{i}kd'}}{(kd')^{2m+1+n}} \frac{F_{mn}\mathrm{e}^{(2m+1)\mathrm{i}kd_0}}{(1+\varepsilon)^{2m+n+1}}, \quad (29)$$

where $\varepsilon = d_0/d'$. Then, expanding $1/(1+\varepsilon)^{2m+n+1}$ in the binomial series and relabeling the expansion coefficients yields

$$\frac{b^{\mathrm{r}}_2}{a^{\ell}_1} = \frac{1}{1 - S^{\mathrm{r}}_{22}\Gamma^{\mathrm{r}}} \frac{\mathrm{e}^{\mathrm{i}kd'}}{kd'} \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \frac{\mathrm{e}^{2m\mathrm{i}kd'}}{(kd')^{2m}} \frac{F'_{mn}}{(kd')^n}, \quad (30)$$

where $F'_{00} = \mathrm{e}^{\mathrm{i}kd_0} F_{00}$. In the far field, the gain and polarization are independent of the $F'_{mn}, m > 0, n > 0$ coefficients. Thus, if we tactfully assume that the different polarization states of the antenna are measured in the same coordinate system, then from $F'_{00} = \mathrm{e}^{\mathrm{i}kd_0} F_{00}$ we see that the gain and polarization of the antenna are unchanged by an absolute phase shift [1, p.427]. In other words, only the relative phase between the different polarization states is of consequence.

V. Conclusions

In this paper, we provided orders-of-scattering interpretation of the scattering-matrix for a two antenna system. We obtained the orders-of-scattering interpretation by first expressing the scattering-matrix of the system in terms of its individual components before formally expanding it in the Neumann series, see Section II. Using the series representation of the scattering-matrix we obtained the explicit forms of its elements and derived Wacker's equation. We showed that Wacker's equation is exact and discussed its convergence properties. Furthermore, we also discussed from where the separation distance between the two antennas should be measured and showed that the choice of the origin does not affect the gain and the polarization of the antenna.

***Abstract* — We verified the performance of a correlation-based channel sounder in the 3550 MHz to 3650 MHz band with a calibrated vector network analyzer (VNA) by comparing measurements in a stable, coaxial environment at the same reference planes. The purpose of this experiment was to focus on the performance of the channel sounder's hardware, as opposed to antenna effects or channel variations. Two conducted propagation channels were utilized – one consisting of a length of cable and an attenuator to simulate a line-of-sight channel, and another with a pair of splitters joined by cables of different lengths to simulate a multipath environment. Performing repeated measurements and estimating the components of uncertainty due to random effects, we found that the channel sounder and VNA measurements agreed to within 0.25 dB for values of path gain, and the peaks in the power delay profile agreed to within 2 dB.**

***Keywords* — comparison, conducted channel, correlation-based channel sounder, measurement, path gain, power delay profile, vector network analyzer, wireless systems.**

I. Introduction

Channel sounding is a method for evaluating the electromagnetic environment for wireless communications. Radio signals propagate between a transmitter and receiver over multiple paths due to natural terrain, manmade obstacles, and environmental conditions [1]. Channel sounders measure characteristics of a radio propagation channel including path gain, decay time, and angular dispersion. Models developed from these measurements are typically the first step in standardizing new wireless technologies. While many models currently exist, applications are constantly under development that necessitate new and improved channel models. For example, in the 3550 MHz to 3650 MHz ("3.5 GHz") band, rules for spectrum-sharing systems are being developed based on specific channel models [2]. Success of the spectrum-sharing systems will, in part, depend on the accuracy of these models.

Recently, researchers at the U.S. National Institute of Standards and Technology (NIST) and the Institute for Telecommunication Sciences (ITS) collaborated to conduct a series of channel-sounder verifications to identify sources of uncertainty due to systematic and random effects in channel-sounder hardware. Three separate channel sounders operating in the 3.5 GHz frequency band, each having significantly different architectures, were studied [3]. Uncertainties in the channel sounders were studied by comparing coaxial measurements made by these systems to measurements performed on a VNA, which included reference-plane translations for direct comparison and a thorough uncertainty analysis.

Conducted-channel measurements were performed to focus on the performance of the channel sounders' hardware, as opposed to antenna effects or channel variations. Two propagation channels were studied – one consisting of a length of coaxial cable and an attenuator to simulate a line-of-sight channel, and another with a pair of splitters joined by coaxial cables of different lengths to simulate a multipath environment.

Here, we focus on the comparison between the VNA and the NIST correlation-based channel sounder using path gain and power delay profile (PDP) as the metrics. Path gain is a measure of attenuation an electromagnetic field experiences as it propagates through space. We have slightly modified this definition to include propagation through a conducted channel. PDP gives the intensity of a signal received through a multipath channel as a function of time delay, which is the difference in travel time between multipath arrivals [4].

Propagation of the VNA's uncertainties to the metrics of interest (path gain and PDP) were performed using NIST's Microwave Uncertainty Framework software [5]. Furthermore, we shifted the VNA reference planes to align directly with the channel sounder's reference planes using characterized switches that connected both systems to the conducted channels. This scheme, illustrated in Figure 1, enabled direct comparisons. We also studied the variability in measurements with respect to various timescales of relevance to channel measurements, including repeated measurements conducted in rapid succession, measurements made on an hour-scale timeframe, and measurements reproduced over several days.

Below, we describe the correlation-based channel sounder, explain how we derived path gain and PDP from VNA measurements, and provide results of our comparison.

II. Correlation-Based Channel Sounder

The channel sounder is a Pseudo-Noise (PN)-sequence correlation-based system [6]. It consists of a transmitter and receiver synchronized with two rubidium clocks. The synchronized clocks ensure that drift between samples is small enough for accurate resolution of the delay spread and allows for measuring the absolute timing between transmitter and receiver.

Jargon, Jeffrey; Quimby, Jeanne; Remley, Kate; Koepke, Amanda; Williams, Dylan. "Verifying the Performance of a Correlation-Based Channel Sounder in the 3.5 GHz Band with a Calibrated Vector Network Analyzer." Paper presented at Asia-Pacific Microwave Conference (APMC) 2019, Singapore, SG. December 10, 2019 - December 13, 2019.

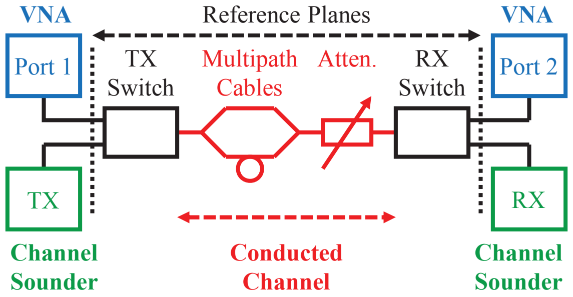

Fig. 1. Measurement setup.

The channel sounder's transmitter contains a vector signal generator that generates a PN code sequence and modulates a binary-phase-shift-keying (BPSK) signal since this type of modulation is robust and widely used in long-distance communications [7]. The transmitter then upconverts the BPSK signal to the 3.5 GHz RF carrier frequency. The bandwidth of the channel sounder corresponds to the bandwidth of the BPSK symbols modulated by the PN sequence. The vector signal generator we used is specified to have a maximum output power of +10 dBm with a -161 dBm/Hz noise floor. The waveform corresponding to each PN sequence is oversampled by four times, providing 8188 samples with a 5 nanosecond/symbol sampling rate. Therefore, a single record of 400 PN sequences (or "code words") has a duration of 16.37 milliseconds.

The channel sounder's transmitter repetitively transmits a PN sequence of digital symbols with a maximum sequence length of 2047 (order of 11). The average power transmitted is maintained through the continuous transmission of the signal. The modulated signal is amplified and filtered to reduce harmonics. The signal is transmitted either through an attenuator for a back-to-back measurement or through the pair of splitters joined by coaxial cables of different lengths.

The channel sounder measures a set of raw complex data, which are corrected with a back-to-back measurement to remove hardware effects. The corrected data are then used to estimate path gain and PDP of the measured channel. Further details of this system can be found in Reference [6].

III. Vector Network Analyzer

Channel sounding can be performed in the frequency domain with a VNA, however, this approach is typically too slow in dynamic environments to capture the time-varying nature of a wireless channel across a wide bandwidth. Furthermore, VNAs are problematic for channels where the transmitter and receiver need to be spaced far apart since the VNA requires that the transmit and receive sides must be tethered together for timing synchronization. Other systems, such as the NIST correlation-based channel sounder, are usually preferred since they can make measurements quickly and are equipped with rubidium clocks to provide untethered synchronization.

In the case of stable conducted channels, VNAs are ideal for verification purposes since they have a high dynamic range, can make extremely wideband channel measurements (dependent on the bandwidth of the VNA), and are capable of traceable uncertainties, as explained below.

In this experiment, we made use of a short-open-load-thru (SOLT) calibration kit with Type-N coaxial connectors. Physical models of the calibration standards were developed and validated using a TRL calibration within the NIST Microwave Uncertainty Framework [8]. This software tool utilizes parallel sensitivity and Monte-Carlo analyses, and enables us to capture and propagate the *S*-parameter measurement uncertainties and statistical correlations between them. By identifying and modeling the physical error mechanisms in the calibration standards, we can determine the statistical correlations among the *S*-parameters. These uncertainties, due to systematic effects, can then be propagated to measurements of devices under test. The uncertainties are propagated to the calculated metrics of interest (path gain and PDP) while maintaining correlated uncertainty mechanisms throughout the process.

PDP and path gain may be calculated from *S*-parameter measurements. Prior to computing these metrics, the VNA hardware settings were chosen in consideration of the channel and channel sounder. The IF bandwidth of the VNA was set to 20 Hz to ensure adequate dynamic range (greater than 110 dB). The VNA frequency range was set to 3.3–3.7 GHz, which was the range used by the correlation-based channel sounder. A dwell time of 1 ms was applied to the VNA measurements to ensure proper settling while taking measurements. The number of frequency points, N_{VNA}, taken by the VNA was computed from the spatial resolution of the channel sounder.

We compute the bandwidth-limited, measured impulse response, $\mathrm{h}_{\mathrm{VNA}}(t)$, and power delay profile, $\mathrm{PDP}_{\mathrm{VNA}}(t)$, of the channel by taking an average of the calibrated transmission parameters, S_{12} and S_{21}, assuming the channel is reciprocal:

$$\mathrm{h}_{\mathrm{VNA}}(t) = \mathit{IFFT}\left(\frac{\mathrm{S}_{12}(f)+\mathrm{S}_{21}(f)}{2}\right). \qquad (1)$$

$$\mathrm{PDP}_{\mathrm{VNA}}(t) = |\mathrm{h}_{\mathrm{VNA}}(t)|^2. \qquad (2)$$

The VNA path gain, G_{VNA}, can be computed by averaging over the frequency-domain data. Note that the path gain in this work does not include antenna gains since the channel included only coaxial cables and attenuators. For a VNA measurement, the path gain may be computed from the calibrated frequency-domain *S*-parameters as:

$$G_{\mathrm{VNA}} = \left(\frac{1}{\mathrm{N}_{\mathrm{VNA}}}\sum_{n=1}^{\mathrm{N}_{\mathrm{VNA}}}\left|\frac{\mathrm{S}_{12}(f)+\mathrm{S}_{21}(f)}{2}\right|^2\right)^{1/2}. \qquad (3)$$

Jargon, Jeffrey; Quimby, Jeanne; Remley, Kate; Koepke, Amanda; Williams, Dylan. "Verifying the Performance of a Correlation-Based Channel Sounder in the 3.5 GHz Band with a Calibrated Vector Network Analyzer." Paper presented at Asia-Pacific Microwave Conference (APMC) 2019, Singapore, SG. December 10, 2019 - December 13, 2019.

IV. Measurement Comparison

Despite the VNA and the correlation-based channel sounder sharing the same conducted channel, imperfections in the switches and differences in cable lengths used by the VNA and channel sounder meant that the two instruments were connected to slightly different channels. To overcome this, the reference planes of the VNA measurement were shifted to those of the channel sounder in post-processing. Having characterized the *S*-parameters of the switches, de-embedding and embedding procedures were used to shift the reference planes of the VNA to the channel sounder's reference planes, thus enabling a direct comparison of the two instruments [9].

Table 1 lists the correlation-based channel sounder and the VNA path gains for both the direct and multipath channels. A variable attenuator was switched among three values (approximately 18 dB, 28 dB, and 38 dB) for each channel. The standard uncertainties accompanying the VNA measurements include components due to both systematic and random effects, while the standard uncertainties for the correlation-based channel sounder only include components due to random effects. The nominal values and standard uncertainties were calculated from five repeated sets of five measurements taken in rapid succession each day for a duration of five days. For comparison purposes, the differences are also tabulated in column 3, as are the root-sum-of-squares (RSS) of the uncertainties. The data show the differences are within 0.25 dB for all cases, and the path gains measured by the VNA are always slightly lower. The uncertainties for the differences are always less than or equal to the actual differences, which is likely because the standard uncertainties for the correlation-based channel sounder do not include components due to systematic effects, such as impedance mismatches between components, and frequency-dependent distortions in the transmitter and receiver.

Figure 2 illustrates the PDPs of the correlation-based channel sounder and VNA for multipath channel 1. The peaks at 49 ns and 104 ns are aligned to within 2 dB. Additionally, the noise floor of the channel sounder is considerably higher than that of the VNA.

V. Conclusions

We verified the performance of a correlation-based channel sounder in the 3.5 GHz band with a calibrated vector network analyzer by comparing measurements in two conducted propagation channels at the same reference planes. We estimated the components of uncertainty due to systematic effects of the VNA and random effects of both systems and found that the channel sounder and VNA measurements agreed to within 0.25 dB for values of path gain, and the peaks were aligned to within 2 dB for values of PDP.

Table 1. Comparisons of path gain between the correlation-based channel sounder and the VNA.

Direct Channel		Path Gain ± Std. Unc. (dB)	Difference ± Unc. (dB)
1	VNA	-53.52 ± 0.13	0.14 ± 0.14
	Channel Sounder	-53.38 ± 0.05	
2	VNA	-63.38 ± 0.03	0.25 ± 0.08
	Channel Sounder	-63.13 ± 0.07	
3	VNA	-73.43 ± 0.09	0.16 ± 0.10
	Channel Sounder	-73.27 ± 0.05	
Multipath Channel		**Path Gain ± Std. Unc. (dB)**	**Difference ± Unc. (dB)**
1	VNA	-60.63 ± 0.12	0.24 ± 0.14
	Channel Sounder	-60.39 ± 0.07	
2	VNA	-70.56 ± 0.07	0.14 ± 0.11
	Channel Sounder	-70.42 ± 0.09	
3	VNA	-80.58 ± 0.11	0.25 ± 0.15
	Channel Sounder	-80.33 ± 0.10

ABSTRACT

This paper provides a case study and lessons learned through the roll-out of the U.S. National Institute of Standards and Technology and U.S. Department of Energy Green Button electricity, natural gas, and water data-access initiative: to make readily available energy and water consumption data for consumers and third-party companies assisting mutual customers of utilities while protecting the security and privacy of the data. Energy and water usage data are important for smart cities in addition to individual consumers. Smart-city solutions rely heavily on the availability of such data to provide situational awareness as well as to inform control, actuation, and decision-making processes. However, the data need to be protected both for security and integrity. This paper presents a case study using the Green Button standard and the steps taken to ensure data security and privacy while enabling access to those consumption data by the consumer and third parties. Data security and privacy were achieved through use of the Green Button standard and subsequent implementation by the Green Button Alliance of a compliance-testing program. Considerations and solutions were needed for data in transit, data at rest, and the authorization mechanisms for allowing unregulated third-party companies to interface directly to utilities on behalf of the consumer while ensuring the consumer maintains complete control of what is to be shared and the ability to revoke that sharing at any time. The lessons learned from this approach could be applicable to other smart-city data.

1 INTRODUCTION

The Green Button initiative [1] was led and implemented by the U.S. National Institute of Standards and Technology (NIST), the U.S. Department of Energy (DOE), and industry partners in response to a White House call-to-action [2] to provide consumers with machine-readable energy-usage information in a standard electronic format. The ultimate goal of the initiative was to build an ecosystem that enables utility customers to have easy and secure access to their energy-usage information in a consumer-friendly and machine-readable format for electricity, natural gas, and water usage, and to readily and securely share this data with partners identified by the consumer. NIST identified energy usage information as a priority in its coordination effort with industry on smart grid interoperability standards under the Energy Independence and Security Act of 2007 [3]. The Green Button initiative leveraged the development of a standard for energy usage information. NIST led this effort with the public-private partnership known as the Smart Grid Interoperability Panel (SGIP)—now a part of the Smart Electric Power Alliance (SEPA)—that completed the North American Energy Standards Board (NAESB) REQ18/WEQ19 Energy Usage Information and REQ21 Energy Services Provider Interface (ESPI)/Green Button technical standards [4]. The Green Button standard(s) provided an extensible markup language (XML) format for data exchange. Beyond the standard, NIST (David Wollman, Martin Burns, and John Teeter) led the development team that worked on open-source reference implementations, test tools, and technical artifacts to support the creation of a Green Button ecosystem, and supported initial utility Green Button implementations in California and elsewhere. The next major step for the effort was to create an organization that would maintain the development and evolution of the standard and manage-and-grow the ecosystem. The Green Button Alliance (GBA) was formed as a non-profit organization with support from NIST, DOE, and industry partners.

There are two main methods for utility customer to obtain their Green Button data: Download My Data (DMD) and Connect My Data (CMD). DMD provides a mechanism for the customer to view and monitor their energy-usage information directly from a utility website or portal. CMD allows the customer to share their usage information with a third-party service provider, such as an

Nguyen, Cuong; Roberts, Jeremy. "Green Button Data-Access Model for Smart Cities." Paper presented at The 2nd ACM/EIGSCC Symposium On Smart Cities and Communities, Portland, OR, US. September 10, 2019 - September 12, 2019.

application developer. One of the main focuses of the development was to ensure data security and privacy, to help address concerns that energy-usage data can be disaggregated to show the activities within a home; including whether the occupants are present [5]. Another focus of the effort was to create a testing program to assure that Green Button implementations conform to the standard, to improve interoperability within the Green Button ecosystem. The last major focus was to grow the Green Button ecosystem including to enhance the adoption and maintenance of the standard.

2 APPROACH TO PLATFORM STRUCTURE AND PLANNING

Significant planning and consideration went into determining the structure of energy-usage data. It was imperative to choose or create a format that would allow for future enhancements with backward compatibility. Electricity-usage data were the first data envisioned to be carried by Green Button, named after a government initiative for the sharing of Veteran Administration medical history information downloading known as the Blue Button [6]. Because the Green Button standards also included capability to handle other energy types, expansion of Green Button to include natural-gas data was quickly added, followed by water-usage data. Billing information and the concept of a split-and-parallel stream of data to carry personal information separate from the energy usage data were also implemented. Anticipating that there would be later additions—that were unknown at the time of inception—XML was deemed to be the most-flexible and readily available data-formatting language. It is one that could also be used with off-the-shelf tools and unaltered Web servers. The use of XML provided for a customer-friendly format, whereby the data are digital but can be read in a 'self-defining tag' system that allows people with an interest in the data to be able to see the data in a format that includes labels or tags without having to download or purchase a special parser. While XML is not visually friendly, it does allow for those who have an interest in understanding the underlying format to be able to view and interpret the data with an XML viewer or, with some difficulty, a text editor. Combined with XML Schema Definition (XSD) files—dictionary-like files that describe the format of the XML elements (tags), limits of values, and data types of values—most of the context of the data can be surmised.

The Atom Syndication Format, which acts as a wrapper to the Green Button -specific information, was selected to facilitate the ease of use in programming and conveyance of data using off-the-shelf tools that could already handle XML, since Atom itself is based on XML. Atom provided the ability to have data streamed without a need for defining a relational database structure or other non-flat file format but to still achieve the benefits of such non-flat relationships of data-to-other-data. XML transfers easily and can be parsed by most web servers without customization or need for add-on parsers. Atom parsers are readily available as well.

The U.S. Federal Government, along with some State and Canadian provincial governments, encouraged utilities and vendors to work together to make the Green Button a reality. The initial utility implementations of the standard were used to identify needed iterations in the standard. The advantage of this parallel activity was that the standard could be modified while it was being developed as things were discovered necessary or unnecessary in the implementations. The disadvantage was that there was no "gold standard" or "litmus test" for the implementations to mirror for interoperability. One lesson learned from this approach was that the latter disadvantage turned out to be greater than the advantage of parallel efforts due to the inability for third parties to create a single tool that would read and interpret data from multiple utilities without customization or tweaking of those data files. For most small companies, this proved too much of an effort to overcome with their limited resources.

Enhancements now (as then), come to the standard through an open workgroup known as the OpenADE Task Force (where ADE refers to automated data exchange) [7]. With industry and NIST leadership of OpenADE Task Force, both within the Utility Communications Architecture International Users Group (UCAIug) and its current home in the GBA, an effective forum was created to identify and track requested standards improvements. The OpenADE Task Force participation requires no membership, fees, commitments, or registrations by any company or individual. The results of these initial and subsequent enhancement efforts were given to the NAESB Energy Services Provider Interface (ESPI) Task Force (TF), a group of their Retail Electric Quadrant (REQ) and Retail Gas Quadrant (RGQ), which are focused on issues impacting the retail sale of energy to Retail Customers [8]. The ESPI TF was, and still is, used as the mechanism to standardize Green Button enhancements which are published and known officially as NAESB REQ.21 ESPI [9].

3 APPROACH TO THE PROTECTION OF PRIVACY/SECURITY

Security of customer energy-usage data and any personally identifiable information (PII) was a key and critical component of defining the solution for data in transit. While the Green Button standard scope of effort does not cover how data are to be stored at the utility nor at the third-party providing services for a mutual customer (data in situ), Green Button focuses on the security of these data in terms of their authorization and deliverance.

Green Button emphasizes five core tenets:

- multiple streams of data,
- adherence to modern web-transit standards,
- verification of party identity,
- the authority of the data custodian for customer verification, and
- the concept of customer consent and control.

3.1 MULTIPLE STREAMS OF DATA

As part of an approach to ensure that man-in-the-middle attacks do not breach entire sets of data, data in transit are separated into two streams: energy-usage information (EUI) and PII. In this way, any breach on one of the two data streams would not reveal the content of the other data stream. The information is obtained out of context of the other and usage data without context to whom it belongs, or personal information, like an address, without the associated usage values. Figure 1 below illustrates the separate streams of data. Security of customer energy-usage data and any personally identifiable information was a key and critical component of defining the solution for data in transit.

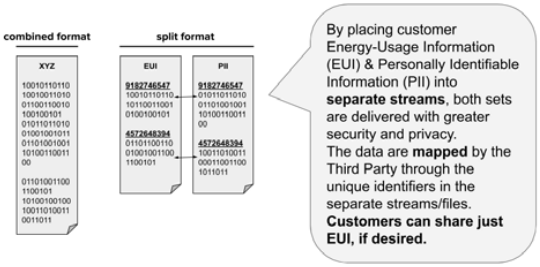

Figure 1: Split Data Format

3.2 ADHERENCE TO MODERN WEB-TRANSIT STANDARDS

In addition to the separation of data streams, security transit is ensured by the reference of NIST Federal Information Processing Standards (FIPS) 140-2 L1 cybersecurity standards [10] and use of the latest cipher suites on both ends—sending and receiving—and through the use of TLS 1.2 (or greater) and Certificate Authority - issued web certificates for the transfer of data. Figure 2 below illustrates the protection scheme for the data transfer.

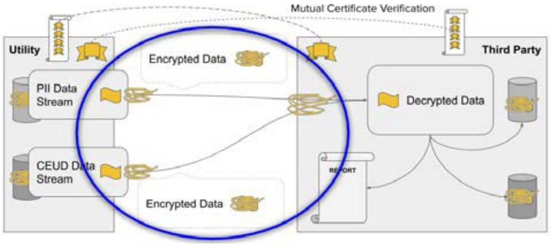

Figure 2: Encrypted Transfer

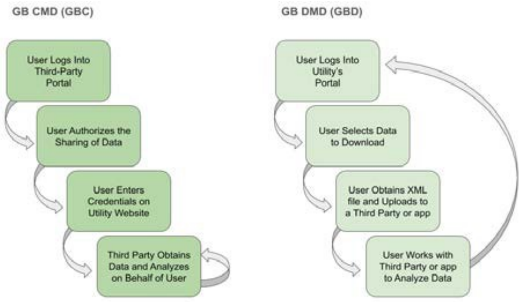
3.3 DOWNLOAD VS. CONNECT

As mentioned in an earlier section, the Green Button ecosystem is comprised of two different methods for obtaining data: (1) for a customer to download their data after defining the parameters of the scope of that data set and (2) for a customer to connect their data directly from the utility to a third- party provider after defining the scope of the data set. In the former method, DMD, there is no Alliance- or standards-defined way for obtaining these data; only for the format of these data in terms of the file structure. In the latter method, CMD, the Green Button defines the handshaking and exchange of these data in addition to the file (or stream) structure. While the workflows are different, the end goal is the same: that the customer is provided their data—either before analysis in the case of DMD or after analysis in the case of CMD.

Since DMD is nearly a subset of CMD, verification of party identity and the use of authorization are only necessary for CMD. There are inherent benefits of both methods—with DMD being easier from the standpoint of security and conveyance of data and CMD being more robust for continued access to data—but overall, CMD provides for an easier user experience at the expense of a greater development effort on the side of both the utility and the third-party provider for CMD deployment. Further, the workflows have different starting and ending paths, which must be considered in the development of a Green Button platform.



GB CMD (GBC)
User Logs Into Third-Party Portal
User Authorizes the Sharing of Data
User Enters Credentials on Utility Website
Third Party Obtains Data and Analyzes on Behalf of User
GB DMD (GBD)
User Logs Into Utility's Portal
User Selects Data to Download
User Obtains XML file and Uploads to a Third Party or app
User Works with Third Party or app to Analyze Data

Figure 3: Workflow of CMD and DMD

As shown in Figure 3, the workflow for CMD begins with a customer starting at a third-party provider's website where they would select their utility from a menu of utilities for which the third-party provider has a relationship; what is known as the third-party provider being already on-boarded with that utility (having met the technical and legal requirements set forth by the utility and/or jurisdictional authorities). The third-party provider would then direct the customer to the utility website with an application programming interface (API) call: essentially a web link and associated parameters. The API call would include the desired scope (the type of data, historical amount, interval, etc.). Subsequently, the utility would present the customer with verification screens for authentication (proof of the customer identity) and authorization (agreement to share the data scoped by the parameters in the API call). When complete (successful), the customer would then be sent back to the third-party provider's website using the provided return web link to complete the relationship with that provider.

Everything else is handled behind the scenes: the sharing of unique "tokens" for the establishment of the relationship in addition to the subsequent and ongoing data exchanges (more on that later). The customer would then utilize the services of the third-party provider for understanding their data.

The workflow for DMD begins by the customer/user logging into a utility's customer portal where they would select the data they wish to download, would obtain that data set as an XML file (or multiple XML files), and would then leave the utility's customer portal to go to a third-party providers portal or application where they would upload these data sets for their desired analysis and interpretation of their data.

3.4 VERIFICATION OF PARTY IDENTITY

Because the workflow for CMD includes the handshaking between utilities and third-party providers, verifying the identity of the other party can be an important addition to the security toolbox. Both utilities and third-parties can verify and prove the identity of their interfacing party by keeping repositories of each other's public certificates to ensure that the certificate chain is intact and that the entity interacting with them is that which is expected. This repository or databasing of certificates (or the databasing of digital signatures/thumbprints of a certificate) is an out-of-band exercise and thus by being out of band, can provide additional security at the expense of a manual process when those certificates change and need to again be shared with the interfacing party. The party-identity verification, as shown in Figure 4, would take place before any transfer of data between the utility and third-party to help in ensuring that the data in transit are in fact between those two entities.

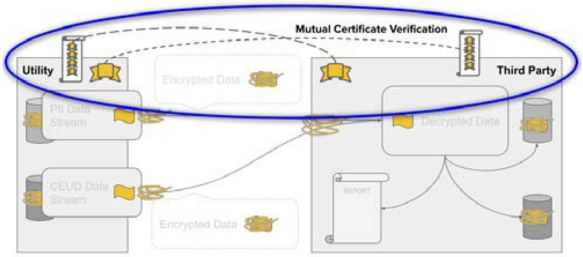


Figure 4: Mutual Certificate Verification

While data-at-rest is out of scope for Green Button, GBA and NIST have worked closely with the U.S. Department of Energy's DataGuard Energy Data Privacy Program [11] as a partner in promoting their *à la carte* menu of options available to utilities and third parties—as well as to commissions and jurisdictions—for ensuring the safeguarding of data in situ. GBA also recommends the separated EUI and PII in transit be kept separated in situ to keep a potential security breach of EUI confined to EUI without ownership (PII) and a potential security breach of PII confined to PII without context (EUI). Further, GBA recommends encryption- at-rest at both the utility and the third party; with independent, non-shared keys. That is, third-party providers would have no keys to the utilities' databases and utilities would have no keys to the third-party providers' databases.

3.5 THE AUTHORITY OF THE DATA CUSTODIAN FOR CUSTOMER VERIFICATION

In consideration of authorization for access, it was determined that the primary relationship for data sharing is between the utility (the Data Custodian) and the customer; more so than between the customer and the third-party, because the utility already has pre-established relationships with customers that include knowledge of their verified physical domicile and contact information. Therefore, it was decided for Green Button that the utility would act as an identity authority for data-sharing authorization by the customer; certainly, for DMD (as it is the utility's portal that the customer navigates) but as well for CMD representing the sharing of data with a third-party provider.

It has become commonplace for Google, Facebook, LinkedIn, and other online, identity-based companies to act as identity authorities for the ease and security of creating online accounts with disparate companies across the web; that is, to use, for example, LinkedIn credentials to create an account, log into that account, and share information with a website unrelated to LinkedIn—a website of a third-party provider—rather than creating a brand-new and separate account with that provider. The method for doing that is the Open Authorization (OAuth) [12] where authorization is granted by the customer for a defined scope of access and that authorization/scope combination is represented by a unique "token" used for subsequent reference of the authorization and its scope. OAuth 2.0 (the latest OAuth version at the time of this paper) is an ongoing effort of the Internet Society's Internet Engineering Task Force (IETF) OAuth Working Group [13].

3.6 THE CONCEPT OF CUSTOMER CONSENT AND CONTROL

Similar to the online identity-based social-media companies, utilities act as identity authorities for the sharing of electricity, natural gas, and water information with third-party companies that will be serving their mutual customers. Therefore, a customer can request the sharing of information with the third-party by authorizing that third-party access data on their behalf; data that are restricted by a given scope that can include the type of data (electricity, natural gas, and/or water), the interval of reading (e.g., monthly, daily, hourly), the level of personal information (e.g., service address, meter number, only usage data), and the duration of the authorization (e.g., one year, two years) if customer-initiated or utility-initiated revocation does not take place sooner. The result of that OAuth authorization is the unique token that is shared between the utility and the third-party provider of services—and no utility's customer-login information is shared. Thus, the sharing of data is always subject to customer consent and the customer always retains the right to determine the level of that sharing with the ability to revoke that relationship at any time. Revocation of third-party-provider access by the mutual customer occurs at the utility via OAuth.

Use of OAuth allows for yet-another-set of off-the-shelf tools in the Green Button ecosystem; making deployment on implementations easier and the user experience across the web more consistent [14]. However, today, not all methods of creating OAuth tokens are secure: The Green Button standard does not allow the use of the OAuth 2.0 "Implicit" method of token creation; a method which has enabled several known cybersecurity breaches. Further, no use of the OAuth "Resource Owner" method is allowed for Green Button; a method which allows the use of User ID and Password for authorization of tokens—a potential insecurity.

3.7 DESTRUCTION AND BACKUP OF DATA

Although not within the scope of Green Button, it is also important to consider the full data lifecycle including destruction and backup of data: Any customer- initiated destruction of third-party provider collected data would need to be ensured via local regulation or via third-party provider contract with the utility at the time the third-party provider was on- boarded as a viable party to transact with the utility's mutual customer. The availability/ability for a customer to download a backup of data—from either the utility or the third-party provider— should be instituted by local regulation and set forth to be made available in the standardized Green Button XML file format to allow comparison and/or porting of the data.

4 GREEN BUTTON TESTING AND CERTIFICATION PROGRAM

Testing and certification (T&C) program development is another critical component of the Green Button ecosystem. The standard provides the specifications and requirements for implementation. However, testing is needed to ensure that the product is implemented correctly in accordance with the standard's requirements. There are three types of T&C programs [15]. First-party certification is often known as "self-certification," where a manufacturer will attest that the product meets the requirements of the standard. Second-party certification is when a user tests and certifies the product; and in the case of the smart grid, it is mostly the utility that serves this role. Third-party certification is done through an independent authority that includes a certification body and associated test lab. The Green Button T&C was developed under the third-party structure with the UCAIug as the certification authority (administered by the GBA) and UL serving as both the certification body and the test lab. Most recently, GBA has taken the role of the certification authority and can also conduct testing, with the goal of the program being a cost- sensitive examination of implementations for compliance to the standard.

The T&C program-development effort was conducted in parallel with the standard development-and-enhancement to ensure that feedback from initial implementations could be incorporated into the standard. One effective approach was to develop the testing tools in an open-source environment that allowed the interested parties to contribute and use them. This has helped to speed up the testing of initial implementations. Also beneficial in driving the need for T&C development was information coming from hack-a-thons—gatherings of application programmers with the goal of determining interoperability between suppliers of data and readers of data.

4.1 LESSONS LEARNED

As mentioned in the discussion of the standardization effort, utilities (and vendors to utilities) were developing their Green Button implementations in parallel with the initial standardization effort. This resulted in DMD implementations that were producing customer usage files that were inconsistent with the format proposed in the standard XSD and inconsistent with the output of other utilities. In concert with the DOE and NIST, hack-a-thons were held to see how communities of interested parties would build the Green Button ecosystem.

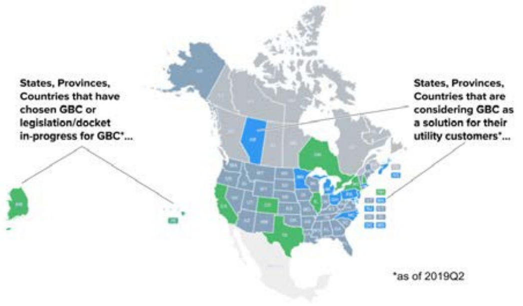
The hack-a-thons had demonstrated that there needed to be more than standardization to ensure interoperability among implementations so that customization per utility was not necessary. While utilities were producing a file that would be used in a limited capacity geographically, third parties were expecting that their solutions could be rolled out to numerous customers in multiple geographies across North America and this was proven to be onerous without a way to ensure similar implementations by the utilities and the utilities' vendors.

It was upon the realization that there needed to be (a) a concerted and singular place for standardization efforts, (b) a way to verify and certify that implementations were compliant to the standard, and (c) a go-to place for finding reference implementations, technical support, educational materials, and collaboration, that the idea of a nonprofit organization to support the Green Button was conceived.

5 ECOSYSTEM DEVELOPMENT

Having a robust ecosystem is very important for any technologyto maintain development and enhance adoption of that technology. Through the efforts of the initial participants, and those that were interested in unified implementations, the GBA was launched in February 2015 to provide these services. The Green Button ecosystem was conceived to be a public-private initiative that would serve as an initial model for subsequent public-private initiatives for the collective benefit of American citizens and be a part of smart-city solutions. The Green Button initiative is seen as a way to take private, corporate and individual goals under the wing of the government to foster the efforts into a single focusand then to spin it out into its own initiative of self-preservation and growth. The creation of the nonprofit GBA was the culmination of those efforts and the handoff of government assistance; allowing the industry to grow in the hands of the corporate and individual participants in a concerted and unified manner. The GBA continues these initial missions through the support of grants and primarily, through the membership of interested parties.

To date, the Green Button ecosystem has grown to include the United States, Canada, and the Republic of Korea; and it is being considered by other countries as a model for their own energy-data-sharing programs. Figure 5 below shows the geographic extent of the Green Button ecosystem. The GBA and its partners continue to work with interested parties to grow the ecosystem and encourage further adoptions.



States, Provinces, Countries that have chosen GBC or legislation/docket in-progress for GBC*...
States, Provinces, Countries that are considering GBC as a solution for their utility customers*...

Figure 5: Ecosystem Map

6 CONCLUSION

The Green Button initiative for electricity, natural gas, and water data-access focused on freeing up consumption data. It provides a case study for the development and maintenance of a data-centric ecosystem. The first step of the initiative was a focus on the platform through the selection of XML as the data format. The next step was to standardize the requirements. This has helped with the initial implementation of products. A key aspect of the design was to ensure data security and privacy. The approach taken in Green Button is effective in ensuring security and privacy for the sharing of consumption data. The next important step was to develop a T&C program to assure that the implementation would be conformant to the standard. The last step was to form an ecosystem with a lead organization to further develop the technology and encourage further adoption. The lessons learned from this approach could be applicable to other smart-city data efforts as a model that addresses authorization, consent, and control in addition to cybersecurity when data access involves regulated and non-regulated entities' handling and sharing of data.

***Abstract*—Wearable medical sensors are one of the key components of remote health monitoring systems which allow patients to stay under continuous medical supervision away from the hospital environment. These sensors are typically powered by small batteries which allow the device to operate for a limited time. Any disruption in the battery power could lead to temporary loss of vital data. Kinetic-based micro-energy-harvesting is a technology that could prolong the battery lifetime or, equivalently, reduce the frequency of recharge or battery replacement. Focusing on a Coulomb-Force Parametric Generator (CFPG) micro harvesting architecture, several machine learning approaches are presented in this paper to optimally tune the electrostatic force parameter, and therefore, maximize the harvested power.**

***Index Terms*—energy harvesting, wearable sensors, microgenerator, CFPG**

I. Introduction

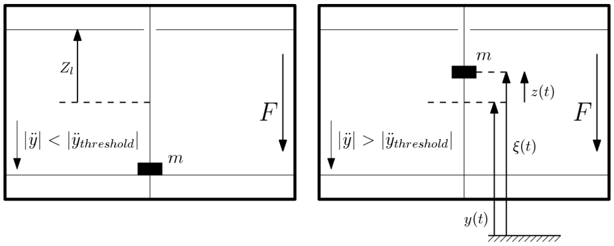
Wearable and implantable medical sensors are considered a key component of future telemedicine systems, allowing clinicians to have remote access to real-time patient's data [1], [2]. These devices typically operate by using small batteries; therefore, frequent recharge or battery replacement might be necessary to keep the device functioning properly. Prolonging the lifetime of these batteries and reducing their frequency of recharge could have a paramount impact on their everyday use. This is especially important for implanted devices, where battery replacement is not easily possible.

Energy harvesting refers to the process of scavenging energy from external sources (ambient environment such as solar power, wind and kinetic energy) [3]. For wearable devices, kinetic energy can be a reliable solution for power generation in medical sensors. For cases of nonstationary vibrations (for example, as a result of the human body motion), Coulomb-force parametric generator (CFPG) architecture has been proposed as a promising solution to extract power form human movements. [4], [5]. In this type of system, a proof mass can move between upper and lower bounds $\pm Z_l$ as shown in Fig. 1. The summation of the device motion to the inertial frame $\xi(t)$ and the relative motion of the proof mass with respect to the device $z(t)$ make the absolute motion of the proof mass equal to $y(t) = \xi(t) + z(t)$.

To model the dynamics of the proof mass motion in CPFG, the following nonlinear differential equation was proposed in [6]:

$$m\ddot{y}(t) = -m\ddot{z}(t) - F \times \text{Relay}(z(t)) \tag{1}$$

where m is the proof mass, $\ddot{y}(t)$ is the acceleration of the frame of CPFG with respect to the inertial frame, z is the relative acceleration of the proof mass with respect to the frame of CFPG, and F is the electrostatic holding force which acts against the motion of the proof mass. The generated mechanical power of the system is equal to the product of the electrostatic holding force and the relative velocity of the proof mass with respect to frame and is calculated as:



Z_l
F
$|\ddot{y}| < |\ddot{y}_{threshold}|$
m
m
$z(t)$
F
$|\ddot{y}| > |\ddot{y}_{threshold}|$
$\xi(t)$
$y(t)$

Fig. 1. Generic Model of a CPFG: (a) proof mass attached to one end, and (b) proof mass in flight

$$P(t) = F \times \dot{z}(t) \tag{2}$$

Fig. 1 displays the process of energy generation in CPFG. The proof mass is initially located at either upper or lower plates. The mass does not move until the external acceleration exceeds a certain limit. To harvest power, the external acceleration must be strong enough to create a full displacement of the mass from one plate to the other. If the mass cannot complete a full flight to the other plate, all generated power is consumed in the electrical field of CFPG by the electrostatic force F.

A further investigation of the power equation of CFPG coupled with its dynamics reveals how adaptation of F affects the output power of the generator [7]. The power is a function of both relative velocity $\dot{z}(t)$ and force F. Meanwhile, $\dot{z}(t)$, as evident from equation (1), is a function of both external acceleration $\ddot{y}(t)$ and force F. Therefore, an optimal strategy that ensures proper adaptation of the electrostatic force F leads to the maximization of the average output power exists. As such, the following optimization problem is considered:

$$\underset{F_i}{\text{argmax}} \left[\frac{1}{\Delta} \times \sum_{t=t_i}^{\Delta+t_i} P(t) \right], \tag{3}$$

with the constraints given by equations (1) and (2). In other words, it is desired to maximize the average harvested power

Sayrafian, Kamran; Roudneshin, Masoud; Aghdam, Amir. "Output Power Maximization of a Microgenerator Using Machine Learning Approach." Paper presented at The 7th Annual IEEE International Conference on Wireless for Space and Extreme Environments, Ottawa, CA. October 16, 2019 - October 18, 2019.

during the time interval $[t_0 + (i-1)\Delta, t_0 + i\Delta]$ by selecting the optimal value of the electrostatic force F_i.

The authors in [6] demonstrate that the output power of a CFPG micro-harvester can be maximized by proper adjustment or adaptation of the electrostatic force F. A methodology for optimizing F by observing the input acceleration in the previous time interval is also proposed in [6]. The average output power for different values of the holding force F and various locations of the wearable sensor is evaluated in [7].

In this paper, we propose a novel method for the estimation of the suboptimal value of the electorstatic force in a micro energy-harvester, according to the current absolute acceleration of the CFPG frame. We use the frequency spectrum of the human body acceleration data in our analysis. Eight different machine learning classification schemes are then used and their performances are compared in terms of accuracy in estimating the suboptimal value of the holding force in the next time step for power maximization. To the best of the authors' knowledge, this is the first time the frequency spectrum of the human body acceleration is used for power maximization in CFPG microgenerators.

The rest of the paper is organized as follows. In Section II, we illustrate our proposed method, and the procedure for generating artificial data is explained. Then in Section III, we discuss various methods of classification of labeled data. In Section IV, results for eight classification structures is obtained and their accuracy is discussed. Finally, conclusions are drawn in Section V.

II. Problem Definition

A. Acceleration in Human Body

The authors in [8] demonstrate that during normal daily activities, bulk of the frequency content of the human motion acceleration in the upper extremity is within the range 0.8-5Hz. Also, it is shown in [9] that 99% of the acceleration power spectral density, when walking barefoot, is concentrated below 15Hz. Based on these findings, we make the following assumption.

Assumption 1 *The acceleration signal for time intervals of length Δ can be approximated by the following cosine series:*

$$\ddot{y}(t) \approx \sum_{n=0}^{20} A_n(i)\cos(2\pi f_n t) = \sum_{n=0}^{20} A_n(i)\cos(2\pi n t), \quad t \in [t_0 + (i-1)\Delta, t_0 + i\Delta], \tag{4}$$

where $A_n(i)$ is the amplitude of the frequency component corresponding to f_n in the ith time interval. Having the amplitudes of the frequency components in every time interval, the problem reduces to identifying the mapping ϕ such that:

$$\phi : [A_0(i), ..., A_{20}(i)] \rightarrow \tilde{F}_\Delta(i), \tag{5}$$

The ultimate goal is to maximize the harvested mechanical power in equation (2) for time interval i by finding a pseudo-optimal holding force $\tilde{F}_\Delta(i)$. Given the time dependency of the parameters involved, we have divided this problem into two steps:

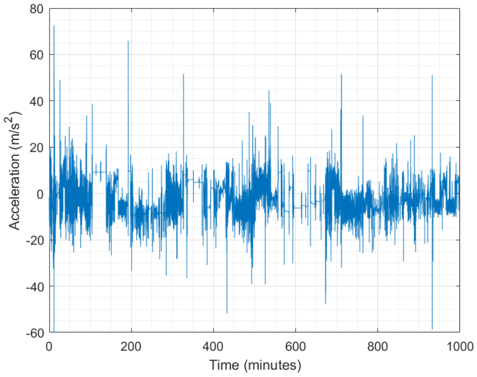


Fig. 2. A 1000-min acceleration sample of human arm motion

1) **Estimation of the pseudo-optimal holding force during time interval i:**
Assuming that we know the $A_n(i)$ coefficients for the acceleration signal in the time interval $[t_0+(i-1)\Delta, t_0+i\Delta]$, what is the pseudo-optimal holding force $\tilde{F}_\Delta(i)$ that maximizes average harvested power for the same time interval i.e. $[t_0 + (i-1)\Delta, t_0 + i\Delta]$?
2) **Estimation of the optimal interval size to maximize the average harvested power for the next time interval i.e. $[t_0 + i\Delta, t_0 + (i+1)\Delta]$:**
In practice, the information about $\tilde{F}_\Delta(i)$ can not be available for the current time interval $[t_0+(i-1)\Delta, t_0+i\Delta]$; and, at best, $\tilde{F}_\Delta(i)$ can be applied to the next time interval i.e. $[t_0+i\Delta, t_0+(i+1)\Delta]$. Therefore, depending on the temporal correlation of the estimated pseudo-optimal holding force, the achieved harvested power will be less than the value obtained in step 1. This step requires further study on optimizing the interval size Δ.

The focus of this paper is on solving the first step through machine learning algorithms. In the next subsection, we will present several methodologies for data classification in order to find a suitable mapping from the frequency spectrum of the acceleration to the electrostatic force F.

B. Acceleration Data Processing

The acceleration data of the human arm motion, as obtained in [10], is used in our analysis. Fig. 2 demonstrates a 1000-min data obtained by attaching an accelerometer to a male subject arm. The data is interpolated with 1ms sampling steps. Then, it is divided into intervals of length equal to one second for approximation with the cosine functions as stated in equation (4). To reduce the size of the action space, the values of the holding force F are divided into 1mN steps. Then, similar to the process outlined in [6] and [7], we choose a value for $\tilde{F}_\Delta(i)$ from the set $\{2, 3, ..., 10\}$.

To label each of the 1-sec intervals with their corresponding holding force which maximizes the harvested power in that

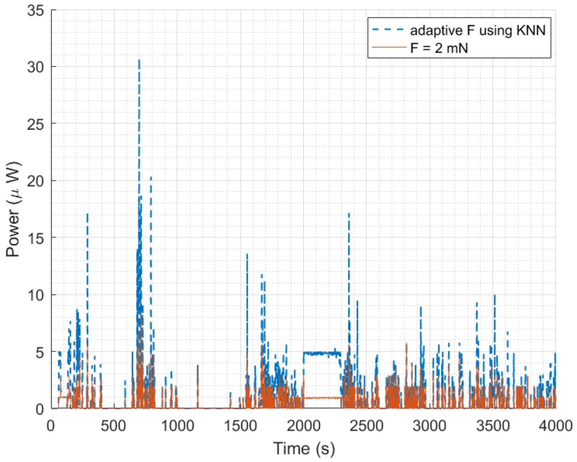

Fig. 3. Comparison of the harvested power for a 4000-sec data for the adaptive holding force with KNN algorithm and a constant holding force

time interval, an algorithm based on the work in [6] is implemented for each of the holding forces and the pseudo-optimal force is obtained accordingly. A set of 1950 labeled data for each of the nine classes (making a total of 17550 vectors) is obtained subsequently.

III. Data Classification

As discussed earlier, the estimation of the electrostatic holding force which maximizes the output power based on the spectral content of the acceleration signal as described in equation (4) can be studied in the context of a classification problem. In what follows, eight different classification schemes are briefly described.

- **Decision Tree Classifier [11]**
A decision tree is a flowchart-like tree structure. An internal node represents a feature (or attribute), each branch represents a decision rule, and each leaf node represents an outcome. The best attribute is selected using an appropriate attribute selection measure (ASM) such as information gain or Gini index. Then, the selected attribute is used as a decision node, the dataset is broken into smaller subsets, and these steps are repeated recursively until a matching condition is satisfied.

- **Random Forest Classifier [12]**
Random forest consists of a large number of individual decision trees that operate as an ensemble. A set of decision trees are created from a randomly selected subset of the training set. Then, the classifier aggregates the votes from different decision trees to decide the final class of the test object. Therefore, a classification is made based on the majority of votes received from each of the decision trees. It is to be noted that a single decision tree may be prone to noise, but aggregating many decision trees reduces the effect of noise, leading to more accurate results.
- **K-Neighbors Classifier [11]**
In this method, an object is classified by a majority vote of its neighbors, with the object being assigned to the most common class among its k nearest neighbors.
- **Support Vector Machine (SVM) [13]**
This is a discriminative classifier which is formally defined by a separating hyperplane. Given labeled training data, the algorithm outputs an optimal hyperplane which categorizes new entries. The hyperplane can be a linear, polynomial or exponential function of the weighted sum of inputs, where the weighting coefficients are optimized in the training process.
- **Multi Layer Perceptron (MLP) [14]**
In this approach, each computational block consists of a weighting matrix that is multiplied by the inputs. The outputs are then passed to a function called *activation function*. These blocks are often repeated several times, and the output of each block is used as the input of the next one. Finally, the output, which is in the form of a vector, classifies the input in the form of an output vector. The elements of the weighting matrices are updated to minimize the error between the estimated vector and a label vector which is associated with the correct class.
- **Stochastic Gradient Descent (SGD) [15]**
This is a linear classifier just like a linear hyperplane in SVM. The only difference is that the optimization technique applied to find the weighting parameters of the hyperplane is stochastic gradient descent. To update the weights, the gradient of loss function is needed. For the computation of the gradient of the cost function, the sum of the cost of each sample is needed, which could be inefficient for large training datasets. On the other hand, when applying SGD, the cost gradient of only one sample is used at each iteration (instead of the sum of the cost gradients of all training datasets) which can significantly reduce the computational complexity of the algorithm.
- **Passive Aggressive Classifier [16]**
In this method, a linear function of the input multiplied by weighting elements is passed to an activation function (often a sign function for binary classifications). Then, a Hinge loss function is used to measure the error between the estimated and true values of labels. The update rule for weighting elements works in such a way that the algorithm is passive when a correct classification occurs (no weight change). For false classification cases, on the other hand, the algorithm becomes aggressive and updates the weights so as to minimize the loss for similar inputs that may occur in other instances.

- **Ridge Classifier [17]**
This method often uses a linear function of the input vector and weighting parameters. The function used for updating the weights is the squared error of the estimated

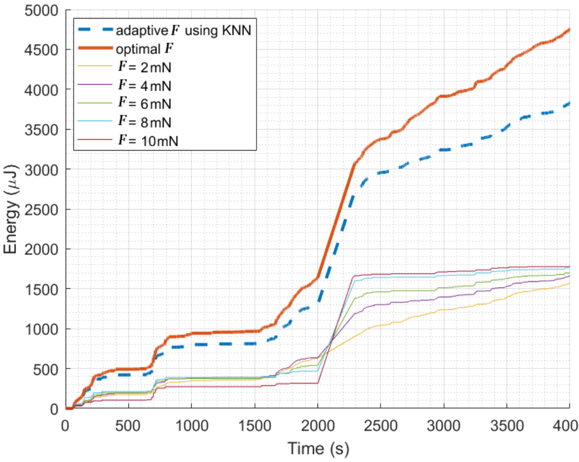

Fig. 4. Comparison of the harvested energy for a 4000-sec time sample for the ideal case with optimal value of F, adaptive holding force with KNN algorithm, and a constant holding force

outputs plus a regularization term which is a function of the weights. The regularization technique tends to reduce overfit in estimation.

IV. Simulation Results

The vectors containing the amplitudes of the cosine approximation for the nine classes of pseudo-optimal force $\tilde{F}_{\Delta}(i)$ are first divided by their maximum magnitude to normalize the vector elements between -1 and 1. Then, 90% of these 17550 vectors are randomly selected from each class in order to be used as the training data set, and the remaining 10% are used as the test data. All of the eight classification techniques described in Section III are compared by simulations, which are performed on a computer with an Intel R processor (Core i5) running at 2.5GHz using 16GB of RAM with Windows 10[1].

For training the classification algorithms and deploying machine learning models, we use the Google TensorFlow[1]platform. The results are given in Table I, indicating the running times for each input vector and accuracy of the learning methods in estimating the pseudo-optimal F. Fig. 3 shows the improvement in the generated power when the electrostatic force is changed using our approach, compared to the case of applying a constant force F=2mN. The amount of gain depends on many factors such as the dimension of the mass-spring-damper inside the CFPG micro-harvester. For these results, the size of the MSD and the distance between the two plates $(2Z_l)$ were chosen as 15×15×1.5mm^3 and 0.5mm, respectively.

TABLE I
Running time and accuracy of eight classification techniques for test data of the acceleration of human arm

	Running Time (s)	Accuracy (%)
Decision Tree	0.0009	45
Random Forest	0.3198	86
KNN	0.032	94
SVM	0.0866	73
MLP	0.0009	86
SGD	0.0010	43
Passive Aggressive	0.1149	50
Ridge	0.0001	43

Fig. 4 displays the gain in the harvested energy for a 4000-sec time interval. The harvested energy for different constant holding forces is also plotted. In addition, for this example, we have included the amount of harvested energy using the optimal value of the holding force as a reference. The curve corresponding to the optimal F serves as an upper bound for the amount of energy that can be generated. Although it is desirable for the adaptive holding force methodology to be as close as possible to the optimal curve, one should also take into consideration the computational complexity of the algorithms used. The higher this complexity is, the more energy it requires to perform, leading to less (or even no) gain in the harvested power. Therefore, a thorough analysis of the implementation complexity and the resulting power consumption of the added hardware is required to justify the addition of the optimization methodology to the micro-harvester circuitry. Our initial investigation shows that algorithms such as MLP can be implemented with reasonable runtime power consumption. Further details of our analysis will be provided in future publications.

V. Conclusion

Efficiency of eight machine learning classification techniques for adaptive estimation of the electrostatic force in a CFPG architecture according to the frequency spectrum of acceleration in human arm was investigated. It was observed that the net energy harvested using a suitable machine learning technique could lead to significant gain in the harvested power. The exact amount of the gain depends on many parameters such as the dimension of the MSD inside the harvester, adaptation time interval Δ, and the classification algorithm. The impact of these parameters will be studied in more details in future research.

Abstract— With the increasing interest in studying Automated Driving System (ADS)-equipped vehicles through simulation, there is a growing need for comprehensive and agile middleware to provide novel Virtual Analysis (VA) functions of ADS-equipped vehicles towards enabling a reliable representation for pre-deployment test. The National Institute of Standards and Technology (NIST) Universal Cyber-physical systems Environment for Federation (UCEF) is such a VA environment. It provides Application Programming Interfaces (APIs) capable of ensuring synchronized interactions across multiple simulation platforms such as LabVIEW, OMNeT++, Ricardo IGNITE, and Internet of Things (IoT) platforms. UCEF can aid engineers and researchers in understanding the impact of different constraints associated with complex cyber-physical systems (CPS). In this work UCEF is used to produce a simulated Operational Domain Design (ODD) for ADS-equipped vehicles where control (drive cycle/speed pattern), sensing (obstacle detection, traffic signs and lights), and threats (unusual signals, hacked sources) are represented as UCEF federates to simulate a drive cycle and to feed it to vehicle dynamics simulators (e.g. OpenModelica or Ricardo IGNITE) through the Functional Mock-up Interface (FMI). In this way we can subject the vehicle to a wide range of scenarios, collect data on the resulting interactions, and analyze those interactions using metrics to understand trustworthiness impact. Trustworthiness is defined here as in the NIST Framework for Cyber-Physical Systems, and is comprised of system reliability, resiliency, safety, security, and privacy. The goal of this work is to provide an example of an experimental design strategy using Fractional Factorial Design for statistically assessing the most important safety metrics in ADS-equipped vehicles.

Keywords— ADS-equipped vehicles, cyber-physical systems, trustworthiness, co-simulation

I. Introduction and related work

The current state of modeling and simulation for vehicles includes proprietary tools, such as IGNITE [1], CANOE [2], and CANALYZER [3], and open-source tools such as OpenModelica [4]. [1] These tools include libraries to simulate vehicle dynamics such as steering, braking, energy conversion and transmission, and power management. Some of these tools allow for communication with external simulators through the FMI [5]. The ability to interface with external simulators widens the range of simulation scenarios that may include interactions with other components through control and sensing functions [6], [7]. In this work we use UCEF [8] to demonstrate that co-simulation can enable innovation in ADS-equipped vehicle research while allowing specialized simulation platforms to independently develop and improve traditional vehicle dynamics simulation.

In Section II we review the testbed functional components, their roles in our co-simulation, and their implementation. In Section III we demonstrate the potential of UCEF to implement the functional components in a co-simulation. In Section IV we propose a strategy for assessing safety metrics by defining an ODD and defining input and output parameters of interest using the Fractional Factorial Experiment Design [9]. The conclusion summarizes our effort and highlights future work.

II. ADS-equipped vehicles Testbed Functional Components and Implementation

In this section we describe the functional components of our ADS-equipped vehicle testbed and its implementation.

A. Functional Components

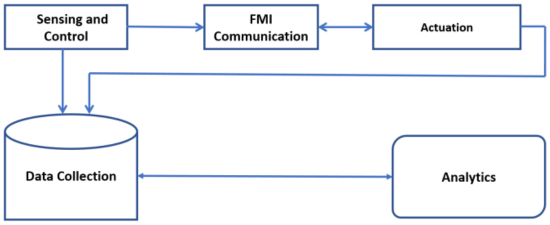

Fig. 1. ADS-Equipped Vehicles Testbed Functional Components

The ADS-equipped vehicle testbed is composed of the functional components described in Figure 1:

a) the Sensing and Control component responsible for receiving input data from the environment such as weather, road condition, traffic infrastructure, and events such as obstacle detection data. The control feature of this component reacts to the data received by

[1] Certain commercial products are identified in this paper to foster understanding. Such identification does not imply recommendation or endorsement by the National Institute of Standards and Technology, nor does it imply that the materials or equipment identified are necessarily the best available for the purpose.

Halba, Khalid; Griffor, Edward; Roth, Thomas; Kamongi, Patrick. "Using Statistical Methods and Co-Simulation to Evaluate ADS-Equipped Vehicle Trustworthiness." Paper presented at Electric Vehicles International Conference (EV) 2019, Bucharest, RO. October 03, 2019 - October 04, 2019.

the sensing feature and generates a corresponding drive cycle, i.e., an acceleration, and braking pattern. Decision support algorithms determine this behavior based on the given ODD;

b) the FMI Communication component plays a bridge role by transmitting the drive cycle produced from the sensing and control component to the actuation component;

c) the Actuation component receives the drive cycle produced by the sensing and control component then performs either acceleration or deceleration functions;

d) the Data Collection component collects data about the interactions between the sensing and control component and the actuation component for further processing and trustworthiness metrics assessment;

e) the Analytics component analyzes the data collected by the data collection component and runs statistical techniques and machine learning algorithms to assess trustworthiness metrics of the ADS-equipped vehicles testbed experiments.

B. *Implementation*

Now we describe the implemented features of the functional components. The implementation uses a NIST co-simulation platform called UCEF that is built using an Ubuntu virtual machine. UCEF relies on the concept of multiple federates that interact using a publish-subscribe message pattern to simulate different functions of a CPS. In the present work, UCEF is used to simulate ADS-equipped vehicle autonomy or decision-making functions focused on acceleration and deceleration.

a) the sensing and control functional component is implemented as two federates: i) a Sensing Federate that simulates a binary obstacle detection notification (vehicle or other obstacle) at a specific simulation time and sends that notification over the HLA bus to the Control Federate. ii) a Control Federate that processes the notification provided by the Sensing Federate and generates corresponding acceleration, and deceleration requests. The Control Federate also implements a User Datagram Protocol (UDP) server that sends drive cycle data to the actuation module over the communication component. Code for the Sensing and Control Federates is available in GitHub [10];

b) the communication component is responsible for communication between the UCEF federates and the Actuation component, built as Functional Mock-Up Unit (FMU). The FMU implements a UDP client that listens on the incoming drive cycle data from the UCEF UDP server implemented in the Control Federate and feeds that information to the Actuation ccomponent. We have built this FMU based on the Q.Tronic FMU Software Development Kit (SDK) and shared its source code in GitHub [11];

c) the Actuation component implementation can be realized using different simulators, including IGNITE, Modelica, and MATLAB that provide both libraries for running traditional vehicle functions and an FMI master algorithm that enables them to interact with other simulators. In this work we use Ricardo IGNITE, a vehicle simulation platform that can be installed on any Microsoft Windows computer, for modeling and simulation of electric and fuel-based vehicle models. IGNITE provides a built-in FMI Master algorithm, and models legacy vehicle functions based on the UCEF generated drive cycle;

d) the Data Collection component is implemented using a MySQL database UCEF federate. Each interaction, or message exchange, is time-stamped and represented in this database as a record that comprises data encoding, the sender, the receiver, the time of transmission, the time of reception, a description of the carried signal, and the payload of the message;

e) the Analytics component will be implemented in a future work as a federate to perform two functions: i) an assessment function using machine learning algorithms and Fractional Factorial Experiment Design scripts. In this work the Fractional Factorial statistical analysis is done using formulas implemented in a standalone excel data form ; ii) a Vert.X-backend [12] / Vue.js-frontend [13] microservice for data visualization was implemented and tested for visualizing post-experiment data collected by the Data Collection component.

III. Co-Simulation of the Functional Components

UCEF enables the co-simulation of a wide variety of CPS using the IEEE High Level Architecture (HLA), including systems at scale such as power grids [14]. Figure 2 shows a federation that will simulate message exchange for the sensing, control, communication, and analytics components using simulated J1939 CAN frames.

These federates were modeled in UCEF using the Web-based Generic Modeling Environment (WebGME), which includes JavaScript extensions to convert the models into Java code.

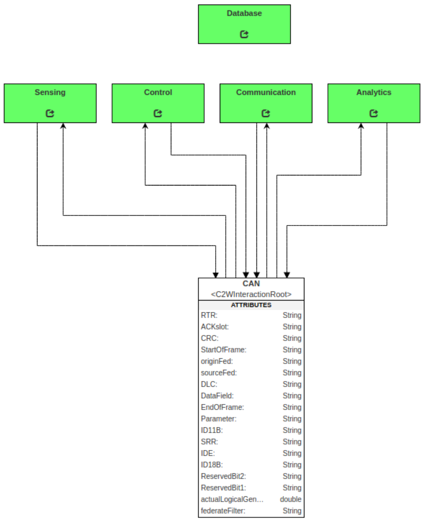

Fig. 2. ADS-equipped vehicles federation where the functional components exchange simulated CAN messages that are logged in a database

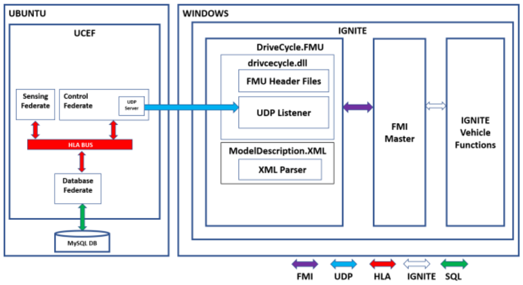

Fig. 3. UCEF implementation of ADS specific functions for an ADS-equipped vehicle testbed

WebGME was used to generate Java code for the model, and that code was implemented with the desired behavior for each federate. Java federates were modeled to represent the features of the functional components. The sensing federate sends obstacle detection data to the control federate over the HLA bus. The control federate adjusts the drive cycle based on the sensing federate input and generates a new drive cycle that will be fed to the actuation module through the FMU. The database federate collects and stores the simulated message exchange between the different federates.

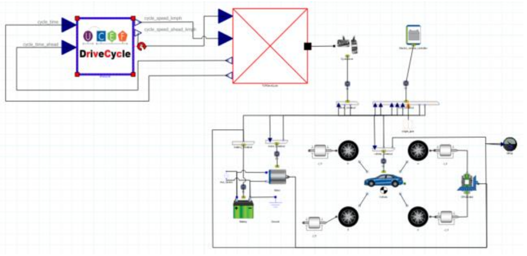

Fig. 4. Custom UCEF drive cycle loaded into IGNITE as an FMU that provides acceleration and braking signals to a simulated Electric SUV

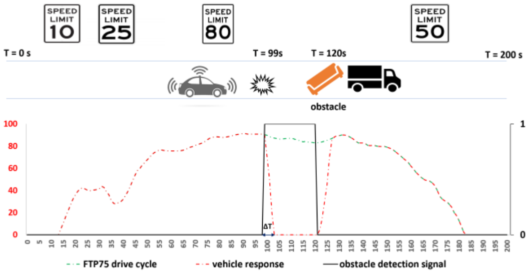

Fig. 5. ODD Overview with the simulated 200s of the FTP 75 drive cycle portion [150-350] fed to the Actuation Module. Stopping Time ΔT is also illustrated.

Other legacy vehicle simulators, such as IGNITE, have a mature implementation of traditional vehicle functions. As such it makes more sense for an ADS-equipped vehicle testbed to focus on extending the capabilities of these simulators by enabling interactions between them and environments like UCEF designed to simulate ADS or non-traditional vehicle functions. Figure 3 shows the integration of IGNITE with the sensing and control federation to produce a co-simulation of the of ADS-equipped vehicle testbed.

We have simulated an exchange of drive cycle data between UCEF and IGNITE. UCEF generates a portion of FTP75 [15] drive cycle data stream. The FMU implements a UDP listener. Figure 4 shows the integration of this external drive cycle data into the IGNITE simulation environment.

IV. Safety Study

In this section we present a scenario that demonstrates the potential of our ADS-equipped vehicles testbed in assessing trustworthiness of ADS-equipped vehicles. According to the National Highway Transportation Safety Administration NHTSA [16] and Waymo's Safety Report [17], an ODD refers to the conditions under which a self-driving system can safely operate. The domain includes geographies, roadway types, speed range, weather, time of day, and state and local traffic laws and regulations. We describe the scenario and the ODD in which our simulated ADS-equipped vehicles safety will be assessed.

A. ODD Description

The vehicle in this ODD is moving along a single lane road and performing a subset of the Federal Test Procedure 75 (FTP75) drive cycle generated by UCEF as shown in Figure 5.

We focus on a subset of the FTP75 drive cycle [150s - 350s] where vehicle speed falls from 90km/h to 0km/h when an obstacle is detected.

We represent this subset on a [0s- 200s] time scale.

At t = T_control, the sensing component in UCEF triggers an alert that indicates an obstacle detection. The vehicle completely stops at t = T_actuation. For a given ODD there is an interval of time ΔT in which the vehicle performs full braking and completely stops when an obstacle is detected. ΔT can be expressed as follows:

$$\Delta T = T\_actuation - T\_control$$

The control component in UCEF generates a drive cycle based on the obstacle detection information it receives.

The Actuation Component (IGNITE-based) receives this drive cycle and simulates the vehicle response. We can compare both input drive cycle and output vehicle response in order to judge whether the vehicle has successfully performed the desired braking time. We assess ΔT once an obstacle is detected. Figure 6 shows vehicle velocity in response to input drive cycle generated by UCEF.

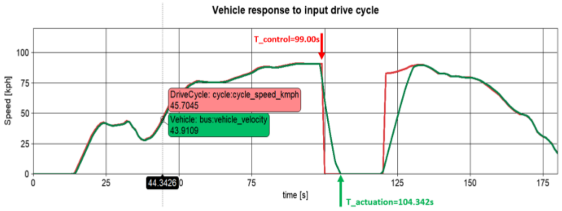

Fig. 6. IGNITE RPOST : Vehicle response to the input drive cycle: the vehicle completely stops 5.342s after the intended theoretical drive cycle control input. T_control and T_actuation are illustrated.

Halba, Khalid; Griffor, Edward; Roth, Thomas; Kamongi, Patrick. "Using Statistical Methods and Co-Simulation to Evaluate ADS-Equipped Vehicle Trustworthiness." Paper presented at Electric Vehicles International Conference (EV) 2019, Bucharest, RO. October 03, 2019 - October 04, 2019.

We have calculated for the default IGNITE parameters a Stopping Time equals to ΔT=5.342s between the drive cycle braking control message (T_control) and vehicle response (T_actuation). This Stopping Time is assessed within the described ODD to determine whether it falls within safe boundaries, i.e.: stopping before hitting the detected obstacle. A safe scenario verifies the following property:

$$0 < \Delta T < \Delta T\_Limit$$

ΔT_Limit is the time the vehicle is predicted to collide, and the Stopping Time will be beyond safe boundaries.

ΔT depends not only on the drive cycle, which is the result of decision support algorithms implemented in UCEF's control component, but it is also influenced by information collected by UCEF's sensing component and IGNITE's vehicle model parameters (vehicle mass for example); changing a single parameter may have a significant impact. Figure 7 is a list of vehicle parameters that could influence ΔT.

	Name	Type	Units	Group	ommer	Case 1	Case 2
Case Title						Case 1	Case 2
Enabled						☑	☑

Fig. 7. A subset of IGNITE's vehicle model parameters. Different ODDs can be defined to assess a trustworthiness metric such as safety. We can define multiple cases each representing a run sequence, where a single or multiple parameters are altered. This figure shows two cases where vehicle mass was the altered parameter.

B. *Trustworthiness metric assessment using Fractional Factorial Experiment Design.*

One of the goals of the UCEF-based ADS-equipped vehicle testbed is to study ADS-equipped vehicles trustworthiness metrics. As in the NIST CPS Framework [18], trustworthiness comprises safety, security, privacy, resilience and reliability. This work has focused on illustrating the potential of co-simulation for assessing ADS-equipped vehicle safety measurement strategies. We have used the Fractional Factorial Experiment Design methodology to run multiple experiments while varying parameters of interests.

Many factors can impact the results of the experiments. Going forward we aim to determine the relative importance of these factors. The sheer number of these factors can present challenges. In this section we use the characteristics of the UCEF-based ADS-equipped vehicle testbed to study these parameters and to design our experiments, using the statistical Design of Experiments (DEX) methodology. Four factors were identified for assessing their influence on the output parameter ΔT (the time required for vehicle speed to go from 90km/h to 0km/h). The identified parameters are vehicle mass, tire rolling resistance coefficient, vehicle aerodynamics resistance surface, and wind speed.

The experiment design we adopt is a 2^k design that takes into consideration 2 levels per factor. This approach is best suited for exploratory experimentation purposes. The outcome of the 2^k factorial experiment helps in identifying the relative importance of factors and offers rapid insight into the interaction effects (Table I). The Fractional design is expressed as follows:

Design expression: $L^{(K-P)}$
L: number of levels of each factor investigated
K: number of factors investigated
P: size of the fraction of the full factorial to be eliminated
L^P: fraction of the full design L^K
M: number of experiments

TABLE I. LIST OF INPUT PARAMETERS CONSIDERED IN THE TWO-LEVEL FRACTIONAL FACTORIAL DESIGN, AND THE VALUES CHOSEN FOR THE TWO LEVELS FOR EACH VARIABLE.

Variable	Description	Low (-1)	High (+1)
X1	Vehicle Mass (Mass)	2000kg	5000kg
X2	Tire Rolling Resistance Coefficient	0.01	0.08
X3	Vehicle Aerodynamics Resistance Surface (Area)	$2m^2$	$5m^2$
X4	Wind Speed	0 mph	45 mph

TABLE II. ΔT IS THE OUTPUT PARAMETER (RESPONSE) MEASURED BASED ON VARIATIONS OF VEHICLE PROPERTIES AND WEATHER CONDITIONS.

Output parameter Y1 = ΔT = F (X1, X2, X3, X4)
Y1: Stopping Time

For a system with K=4 factors, L=2 levels of each factor, and P=1, the number of experiments in a Fractional 2^{K-P} will be $M = 2^{4-1} = 8$ experiments. The half factorial design would reduce M, the number of experiments by half. Table III describes the different sets of experiments with the fractional 2^{K-P} experiment design without replication.

We have explained in this section how the experiment design using statistical fractional factorial techniques can be used to discern which factors yields the most significant response on the output parameters of interest and as a result assess safety related to the specified ODD parameters. By assessing which vehicle characteristics and road conditions have the most influence on ΔT outcomes, we can understand which factors have the most significant impact on the stopping time.

The DEX mean plot [19] is appropriate for analyzing data from a designated experiment, with respect to important factors, where the factors are at two or more levels. The plot shows mean values for two or more levels of each factor plotted by factor. The mean values of a single factor are connected by a straight line. For the given factor levels results shows that "Vehicle Mass" is by far the most important factor in influencing ΔT. "Tire Rolling Resistance" plays the next most critical role. The experimental parameters tested for "Wind speed" and "Vehicle Aerodynamics Resistance Surface" did not indicate a statistically significant effect on stopping time. The average Stopping Time ΔTavg across all experiments is equal to 5.44s. if ΔT_Limit = ΔTavg, we can evaluate safe braking boundaries just by reviewing the DEX mean plot (Figure 8). Raw results can be found in [20].

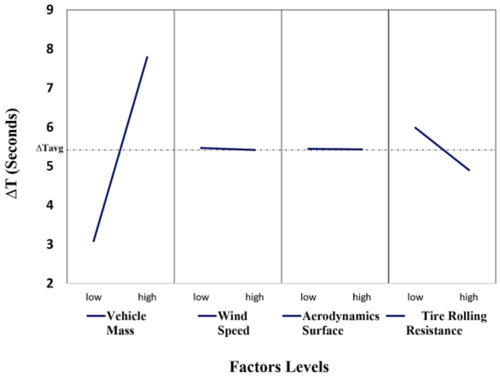

Fig. 8. The DEX mean plot: ΔT respose to 4 factors of interest.

V. CONCLUSIONS AND FUTURE WORK

In this work we have described the NIST UCEF-based-ADS-equipped vehicles testbed and its potential for co-simulation of ADS-equipped vehicle applications.

We have described implementation elements of the testbed and considered an ODD and a metric strategy for assessing safety, one component of trustworthiness.

Finally, we have described an experiment design methodology that can be used to assess trustworthiness metrics. Going forward, we intend to perform additional experiments to further study the safety and other trustworthiness metrics for ADS-equipped vehicles.

We will also design deep learning architectures to explore trustworthiness assessment techniques. For instance, we plan to leverage UCEF to study the safety of ADS functions and synthesize ground truths for training deep learning models. These deep learning models will be used for two purposes: to approximate the safety metric and forecast safety violations. Since many ADS functions are safety critical, we will design learning architectures that are interpretable and explainable.

Residential Application of an Indoor Carbon Dioxide Metric

Andrew Persily, Brian J. Polidoro

ABSTRACT

Indoor carbon dioxide (CO_2) concentrations have been used for decades to evaluate indoor air quality (IAQ) and ventilation. However, many of these applications reflect a lack of understanding of the connection between indoor CO_2, ventilation rates and IAQ. In particular, a concentration of 1800 mg/m^3 (1000 ppm$_v$) has been used as a metric of IAQ and ventilation without an appreciation of its basis or application. After many years of trying to dissuade practitioners and researchers from using CO_2 as a metric of ventilation and IAQ, the first author developed an approach to determine CO_2 levels that can be used as more meaningful indicators. This approach is based on the fact that space types differ in their recommended or required ventilation rates, occupancy and other features that impact indoor CO_2 concentrations. Rather than employ a single CO_2 concentration for all spaces and occupancies, this alternative approach involves the estimation of space-specific CO_2 concentrations. The concept considers the steady-state CO_2 concentration that would be expected in a given space type based on its intended or expected ventilation rate per person, the time to achieve steady-state, the number of occupants as well as the rate at which they generate CO_2, and the occupancy schedule as it pertains to the likelihood that steady-state will be achieved.

This alternative approach was described in a previous AIVC conference paper, with sample calculations presented for several commercial and institutional building spaces. Those calculations yielded potential CO_2 concentration metrics, along with corresponding measurement times after full occupancy. Based on these analyses, it was stressed that reported CO_2 concentrations for comparison to these or other metrics need to be associated with a measurement time relative to the start of occupancy as well as information about the space in question and its occupancy. Since this previous work, an online calculator has been developed to allow users to perform these calculations, and that calculator is described here. In addition, this paper applies the approach to residential buildings, which are more challenging based on their varying configurations and the large fraction of time that occupants spend in bedrooms.

1 INTRODUCTION

Indoor air quality (IAQ) is characterized by the chemical and physical constituents of air that impact occupant health, comfort and productivity. The number of airborne contaminants in most indoor environments is quite large, and their impacts on building occupants are known for only a very small number of contaminants. The large number of contaminants, and their wide variation among and within buildings and over time, makes it extremely challenging to quantify IAQ, let alone to distinguish between good and bad IAQ based on a single metric. There have been efforts to define IAQ metrics, but none have been shown to capture the health and comfort

Persily, Andrew K.; Polidoro, Brian. "40th AIVC - 8th TightVent & 6th Venticool Conference, 2019 Residential Application of an Indoor Carbon Dioxide Metric." Paper presented at Conference 40th AIVC - 8th TightVent - 6th Venticool Conference in Ghent Belgium, Ghent, BE. October 15, 2019 - October 16, 2019.

impacts of IAQ very well or have become accepted in the field (Jackson et al., 2011; Hollick and Sangiovanni, 2000; Moschandreas et al., 2005; Teichman et al., 2015).

The indoor concentration of carbon dioxide (CO_2) has been widely promoted as a metric of IAQ and ventilation, in many cases without a clear explanation of what it is intended to characterize, or a description of its application or its limitations (Persily, 1997). Nevertheless, many practitioners use 1800 mg/m^3 (roughly 1000 ppm$_{v)}$ as a metric, often erroneously basing it on ASHRAE Standard 62.1 (ASHRAE, 2016a). However, that standard has not contained an indoor CO_2 limit for almost 30 years (Persily, 2015a). There have been many papers and presentations that have attempted to clarify the meaning of indoor CO_2 concentrations, some advocating that they not be used at all in IAQ and ventilation evaluations. However, these calls to stop poorly informed applications of indoor CO_2 are not succeeding. Instead, efforts to educate designers, practitioners and others need to continue, and this paper expands on a previously-described approach to using indoor CO_2 concentrations as a metric of ventilation rate per person that thoroughly considers the parameters that determine indoor CO_2 levels (Persily, 2018). That previous discussion presented the approach and outlined its application to a number of commercial and institutional building spaces. This paper expands the consideration to residential buildings and describes an on-line calculator that allows the estimation of indoor CO_2 concentrations in applying this approach.

2 BACKGROUND

Indoor CO_2 concentrations have been prominent in discussions of ventilation and IAQ since the 18th century (Klauss et al., 1970). Since that time, discussions of CO_2 in relation to IAQ and ventilation have evolved, focusing on the impacts of CO_2 concentrations on building occupants, how these concentrations relate to occupant perception of bioeffluents, the use of indoor CO_2 concentrations to estimate ventilation rates, and the control outdoor air ventilation rates based on indoor CO_2 concentrations (Persily, 2015b; Persily, 1997).

Indoor CO_2 concentrations are directly related to the outdoor air ventilation rates per person specified in standards, guidelines and building regulations (ASHRAE, 2016a; ASHRAE, 2016b; CEN, 2007b; CEN, 2009). These outdoor air requirements reflect research on the amount of ventilation needed to control odor associated with the byproducts of human metabolism, as well as other contaminants emitted by building materials and furnishings (Persily, 2015a). This research has found that about 7.5 L/s to 9 L/s per person of ventilation air dilutes body odor to levels judged to be acceptable by individuals entering a room from clean air, i.e., unadapted visitors. This research also supports 1800 mg/m^3 of CO_2 as a reflection of body odor acceptability perceived by unadapted visitors. Of course, there are many other important indoor air contaminants that are not associated with the number of occupants, and CO_2 concentration is not a good indicator of those contaminants.

Indoor CO_2 concentrations are typically well below values of interest based on health concerns (Persily, 2017). Some recent work has shown evidence of impacts on human performance, as well as other health impacts, at levels on the order of 1800 mg/m^3 (Azuma et al., 2018; Snow et al., 2019), while other studies have not shown performance impacts at similar concentrations. It is therefore premature to conclusively link CO_2 concentrations in this range with such occupant impacts until more research is done.

While indoor CO_2 concentrations are not meaningful indicators of overall IAQ, a previous paper describes the use of CO_2 as an indicator or metric of outdoor air ventilation rates per person (Persily, 2018). As discussed in that paper, indoor CO_2 concentrations depend primarily on the rate at which the occupants generate CO_2, the outdoor air ventilation rate of the space, the time since occupancy began, and the outdoor CO_2 concentration. For the purposes of these discussions, outdoor air ventilation refers to the total rate at which outdoor air enters the building or space of interest, including mechanical and natural ventilation as well as infiltration. The cited paper describes the single-zone mass balance theory to calculate indoor CO_2 concentrations from these parameters per the following equation:

$$C(t) = C(0)e^{-\frac{Q}{V}t} + C_{ss}\left(1 - e^{-\frac{Q}{V}t}\right), \tag{1}$$

where C is the CO_2 concentration in the space in mg/m^3, $C(0)$ is the indoor concentration at t = 0, t is time in hours, Q is the volumetric flow of air into the space from outdoors and from the space to the outdoors in m^3/h, and V is the volume of the space being considered in m^3. The steady-state CO_2 concentration C_{ss} is given by:

$$C_{ss} = C_{out} + {}^{G}/_{Q}, \tag{2}$$

where C_{out} is the outdoor CO_2 concentration and G is the CO_2 generation rate in the space in mg/h. Q, C_{out} and G are in general functions of time but are assumed constant in this analysis. Also, air density differences between indoors and out are being ignored by using the same value of Q for the airflow into and out of the space. Finally, this single zone formulation ignores concentration differences within and between building zones and CO_2 transport between zones and assumes there are no other indoor sources of CO_2 other than occupants.

Note that the indoor concentration will only get sufficiently close to steady-state if conditions, specifically Q and G, are constant for a long enough period of time. In particular, a constant value of G requires that the occupancy remain constant, but in many spaces occupancy will be too short or too variable for steady-state to be achieved. A convenient means of assessing whether steady-state is likely to be achieved is by comparing the duration of constant occupancy to the time constant of the space. The time constant is equal to the inverse of Q/V in Equation 1, i.e., the inverse of the air change rate, and the indoor concentration will be about 95 % of steady-state after three time constants. For example, for an air change rate of 1 h^{-1}, steady-state will exist after 3 hours. For an air change rate of 0.5 h^{-1}, it will take 6 hours.

Table 1: Calculated CO_2 concentrations

			CO_2 concentration above outdoors (mg/m^3)		
Space Type	**t_{metric} (h)**	**Time to steady-state (h)***	**Steady-state**	**1 h**	**t_{metric}**
Classroom (5 to 8 y)	2	1.4	1060	940	1040
Classroom (>9 y)	2	1.1	1580	1490	1580
Lecture classroom	1	0.9	1940	1870	1870
Restaurant	2	0.7	1871	1850	1870

Hotel/motel bedroom	6	4.5	1080	520	1060
Office space	2	5.9	985	390	630
Auditorium	1	0.6	2900	2880	2880
Lobby	1	0.6	4467	4430	4430
Retail/Sales	2	2.1	1546	1170	1450

* Time to achieve 95 % of steady-state CO_2 concentration, i.e., three time constants

In the previous work on this CO_2 metric concept, several space types were selected from the commercial/institutional building space types or "Occupancy Categories" in Table 6.2.2.1 of ASHRAE Standard 62.1 (ASHRAE, 2016a). For these spaces, shown in Table 1, CO_2 concentrations above outdoors were calculated at steady-state, after 1 h of occupancy, and at a time t_{metric}, which was selected as a time over which the particular space type may be expected to be fully occupied. That time is in the first column of Table 1, while the time to reach steady-state is in the second column. The assumed occupant densities, occupant characteristics and CO_2 generation rates are described in Persily (2018).

Based on the previous work, including the desire for a CO_2 metric to capture ventilation deficiencies and to be less sensitive to the timing of the concentration measurement, Table 2 summarizes potential CO_2 metric values for these spaces along with the corresponding measurement time. Given the transient nature of indoor CO_2 concentrations, it is critical that a concentration CO_2 metric be linked to a measurement time. Therefore, reported CO_2 concentrations relative to these and any other metrics need to include the time that has passed since the space reached full occupancy. Consideration of additional spaces and different input values would possibly yield other conclusions about potential metrics. Such analyses will be facilitated by the online tool described below.

Table 2: Potential CO_2 concentration metrics

Space Type	CO_2 concentration metric, above outdoors (mg/m^3)	Corresponding time (h after full occupancy)
Classroom (5 to 8 y)	1000	2
Classroom (>9 y)	1500	1
Lecture classroom	2000	1
Restaurant dining room	2000	1
Conference meeting room	2000	1
Hotel/motel bedroom	1000	6
Office space	600	2

Public assembly/Lobby	4500	1
Retail/Sales	1500	2

3 CO_2-BASED VENTILATION METRIC FOR RESIDENTIAL SPACES

This paper extends the concepts discussed above to residential spaces, which can be challenging given the variations in dwelling and family size and in occupant characteristics, as well as the often unpredictable durations of occupancy relative to some commercial and institutional spaces. However, the many hours associated with sleep provide helpful options for these analyses in bedrooms. The approach taken is again to use Equation (1) to calculate the CO_2 concentrations for a given space based on assumptions about the CO_2 generation rates and ventilation rate of the space. In order to explore these dependencies for residential spaces, indoor CO_2 concentrations were calculated for the occupancies listed in Table 3, which describes 3 families: a baseline with 4 members (2 adults and 2 children), a larger family with 2 additional children, and a smaller family with 2 adults and no children. The sex, age, body mass and level of physical activity are described for each family, including the CO_2 generation rate in L/s for each person calculated using the methodology in Persily and de Jonge (2017), as well as the average CO_2 generation rate per person. These generation rates are presented for the whole house during non-sleep hours when occupants are assumed to be more active, and for bedrooms when occupants are sleeping. For occupant characteristics that differ from those considered here, the online tool described below is enables analysis of different occupancies. For each occupancy in Table 3, CO_2 concentrations were calculated for the following ventilation scenarios:

Whole house:

- Ventilation rate requirement from ASHRAE Standard 62.2 (ASHRAE, 2016b)
- Ventilation rate of 0.5 h^{-1}

Bedrooms:

- 62.2/Perfect Distribution: Bedroom ventilation rate is the Standard 62.2 rate divided by the number of house occupants, multiplied by the number of bedroom occupants
- 62.2/Uniform Distribution: Bedroom ventilation rate is the Standard 62.2 rate divided by the whole house floor area, multiplied by the bedroom floor area
- 0.5/Perfect Distribution: Bedroom ventilation rate is 0.5 h^{-1} times the house volume divided by the number of house occupants and then multiplied by the number of occupants in each bedroom
- 0.5/Uniform Distribution: Bedroom ventilation rate is 0.5 h^{-1} times the house volume divided by the whole house floor area, and then multiplied by the bedroom floor area
- 10 L/s per person/Perfect Distribution: Bedroom ventilation rate is 10 L/s multiplied by the number of bedroom occupants

Table 3: Occupancy Assumptions for CO_2 concentration calculations

Case	**Occupants** **(**age, body mass in kg, met level**)**	**CO_2 generation per person (L/s)**	**Average CO_2 generation per person (L/s)**
Baseline family of 4			

Whole house	1 male (40 y, 85 kg, 1.3 met);
	1 female (40 y, 75 kg, 1.3 met);
	1 male (6 y, 23 kg, 2 met);
	1 female (10 y, 40 kg, 1.7 met)
		0.0049
		0.0038
		0.0042
		0.0042
			0.0043

Master Bedroom	1 male (40 y, 85 kg, 1.3 met);
	1 female (40 y, 75 kg, 1.3 met);
		0.0037
		0.0029
			0.0033

Child Bedrooms	1 male (6 y, 23 kg, 2 met); 1 female (10 y, 40 kg, 1.7 met)	0.0021 0.0025	0.0023
Additional occupants in larger family of 6			
Whole house	1 male (8 y, 32 kg, 2 met); 1 female (4 y, 14 kg, 2 met)	0.0050 0.0031	0.0042*
Master Bedroom	No change		0.0033
Child Bedrooms	1 male (8 y, 23 kg, 2 met); 1 female (4 y, 40 kg, 1.7 met)		0.0022*
Smaller family of 2 (no children)			
Whole house	Only adults		0.0043
Master Bedroom	Only adults		0.0033

* Average CO_2 generation rate accounts for all 6 occupants in whole house and all 4 children in child bedrooms.

The Standard 62.2 whole house ventilation requirement Q_{tot} in L/s is calculated using Equation (4.1b) from the standard, i.e.,

$$Q_{tot} = 0.15A_f + 3.5(N_{br} + 1), \tag{2}$$

where A_f is the floor area in m^2 and N_{br} is the number of bedrooms. The value of Q_{tot} is used in this analysis without any of the adjustments allowed by Standard 62.2, such as the infiltration credit. The whole house air change rate of 0.5 h^{-1} is included as it is recommended in several international standards and guidelines (CEN, 2007a; Concannon, 2002).

For the bedroom cases, two idealized air distribution scenarios are applied to the Standard 62.2 and 0.5 h^{-1} whole house rates. In the first, Perfect Distribution, the whole house rate is divided by the number of occupants in the house. That normalized value is multipled by the number of occupants in each bedroom to determine the ventilation to each bedroom. Perfect Distibution may correspond to a ventlation system that supplies outdoor air directly to each bedroom based on the number of occupants. Under Uniform Distribution, the total ventilaiton rate is normalized by the floor area of the entire house, and the ventilation rate of each bedroom is that normalized rate multiplied by its floor area. Uniform distribution may correspond to a building ventilated by infiltration only, an exhaust-only ventilation system or a mechanical ventilation system that is integrated into a forced-air distribution system. The last bedroom ventilation rate, 10 L/s per person/Perfect Distribution, assumes 10 L/s of outdoor air is supplied for each person in each bedroom. That rate is based on recommendations in CEN (2007a) and (2009).

Table 4 presents the dimensions (ceiling heights and floor areas) for the houses considered.

Table 4: House and bedroom sizes for cases considered

	Ceiling height (m)	**House floor area (m^2)**	**Master bedroom floor area (m^2)**	**Child bedrooms floor area (m^2)**
Large House	2.44	250	30	20
Small house	2.74	200	20	15

Table 5 presents ventilation rates and calculated CO_2 concentrations (above outdoors). The second and third columns contain the outdoor air ventilation rate in L/s per person and h^{-1} for the whole house and bedroom cases. The fourth column is the time to reach a steady-state CO_2 concentration, i.e., three times the inverse of the air change rate. The table does not include t_{metric}, which as described earlier is a time over which a particular space may be expected to be fully occupied. Throughout these analyses, t_{metric} is 2 h for the whole house and 6 h for the bedrooms. The last three columns are the calculated CO_2 concentrations at steady-state, 1 h after occupancy and t_{metric}. The whole house air change rates based on Standard 62.2 are about 0.3 h^{-1} in all but the small house/baseline family case, in which it is about 0.5 h^{-1}. The bedroom air change rates cover a range of almost 10 to 1 for the different cases in the large house/baseline family and the small house/small family. In both of those occupancies, delivering 0.5 h^{-1} directly to the bedrooms under Perfect Distribution results in air change rates above 2 h^{-1} and well over 15 L/s per person. On the other hand, Uniform Distribution to the bedrooms results in less than 5 L/s per person in several cases. These air change rates impact the time required to achieve steady-state, which are 6 h or less for the bedrooms cases other than for 62.2/Uniform. For the whole house, the time to steady-state ranges from 3 h to more than 11 h.

The calculated CO_2 concentrations in Table 5 reflect the differences in ventilation and CO_2 generation for the specific occupancies. It is worth noting that the only steady-state bedroom concentrations greater than 1800 mg/m^3 (assuming an outdoor concentration of 700 mg/m^3) occur in the master bedroom for all 62.2/Uniform cases and for the small house/small family 0.5/Uniform case. Also, for cases with short time constants, 2 h or less, the three CO_2 concentrations are not very different from each other. Much larger differences are seen for larger time constants. In all whole house cases, the concentrations at t_{metric} are at least 200 mg/m^3 above outdoors, which is above the uncertainty typically associated with field measurements of indoor CO_2 concentrations. The bedroom concentrations at t_{metric} are typically even higher, except in the 0.5 h^{-1}/CBR/Perfect case, for which the steady-state concentration is less than 200 mg/m^3. The magnitude of these concentrations relative to typical measurement uncertainties supports the use of such calculated concentrations as a metric, although assuming constant occupancy in a whole house for 2 h could be questionable under some circumstances. It is worth noting that the range of CO_2 concentrations at t_{metric} for each occupancy range by at least 4 to 1 in the small house/baseline family case, to as much as almost 9 to 1 in the large house baseline/family case. These differences demonstrate the importance of considering the target ventilation rate in using calculated CO_2 concentrations as a metric. Also, for the same ventilation case, the differences in calculated CO_2 concentrations at t_{metric} for the different occupancies are not as large as those within the same occupancy for the different ventilation cases. However, they are large enough to be reliably measured and support the need to consider house size and occupancy when using calculated concentrations as a metric.

Table 5: Ventilation rates and calculated CO_2 concentrations for the residential cases

	Outdoor air ventilation		**Time to steady-state (h)**	**CO_2 Concentration above outdoors (mg/m^3)**

Persily, Andrew K.; Polidoro, Brian. "40th AIVC - 8th TightVent & 6th Venticool Conference, 2019 Residential Application of an Indoor Carbon Dioxide Metric." Paper presented at Conference 40th AIVC - 8th TightVent - 6th Venticool Conference in Ghent Belgium, Ghent, BE. October 15, 2019 - October 16, 2019.

To the evaluate the usefulness of calculated CO_2 concentrations as ventilation metrics, the calculations presented in Table 5 were redone with the assumed ventilation rates reduced by 25 %. As in the commercial and institutional occupancies discussed in Persily (2018), these additional calculations were performed to assess how much the concentrations change at lower ventilation rates since a useful metric should capture such changes. The CO_2 concentrations for the reduced ventilation rates are shown in Table 6, as well as the outdoor ventilation rates for each case in L/s per person and h^{-1} and the times to reach steady-state. Values that increase by 100 mg/m^3 or more relative to the corresponding values in Table 5 are noted in bold font. The whole-house, reduced-ventilation concentrations at t_{metric} in Table 6 increase very little relative to the corresponding values in Table 5, often by 30 mg/m^3 or less, which is comparable with the measurement accuracy of many field measurements of CO_2 concentrations. This lack of increase is partly due to the long time constants of the whole-house cases, which allow little time for the concentration to increase after only 2 h. The increases in the bedroom concentrations are more significant, typically at least 100 mg/m^3 and often several hundred mg/m^3 higher for the reduced ventilation cases for a t_{metric} of 6 h. These larger increases for the bedroom support the use of a 6 h value of t_{metric} to capture ventilation deficiencies in bedrooms.

In contrast to the commercial and institutional occupancies discussed by (Persily, 2018), these residential cases are less constrained by space size, occupancy and ventilation, making it difficult to generalize these results to develop CO_2 metrics for residential buildings. Instead, the house, occupancy and air distribution approach need to be accounted for in developing a metric or reference point for evaluating the adequacy of the ventilation rate relative to a target value. The online tool discussed in the next section was developed to implement these concepts.

4 ON-LINE CO_2 METRIC CALCULATOR

In order to support application of the proposed CO_2 concentration metric, an online tool (available at https://pages.nist.gov/CONTAM-apps/webapps/CO2Tool/#/) has been developed. This tool allows the user to estimate indoor CO_2 concentrations in a ventilated space at steady-state, 1 h after occupancy and at a selected value of t_{metric}. These calculated concentrations can then be compared with measured concentrations in a building to evaluate whether the intended or required ventilation rate is actually being achieved. Such a building-specific metric or reference value is far better than using a single value such as 1800 mg/m^3.

Figure 1 shows the first screen encountered when using the tool, where one first selects to analyze a commercial/institutional building or a residential building. Depending on that selection, the user then enters the required inputs. For commercial/institutional buildings, the tool allows one to select from several of the commercial and institutional space types listed in ASHRAE Standard 62.1-2016, and to use the default values in that standard for outdoor ventilation requirements and occupant density, i.e., number of occupants per 100 m^2 of floor area. The tool makes assumptions about the occupants in each space, i.e., sex, body mass, age and activity level in met, needed to calculate the CO_2 generation rate in the space based on Persily and de Jonge (2017). However, these assumptions can be modified by selecting User-Defined Model Type, which brings up an alternative input screen.

The residential building inputs are shown in Figure 2. In this case, the user selects whether they are performing a whole building or bedroom analysis. If whole building is selected, the user can select the ventilation requirement based on Standard 62.2-2016 or enter a whole building air change rate in h^{-1}. If instead they chose to perform a bedroom analysis, they need to select the ventilation requirement from Standard 62.2 or enter a L/s per person ventilation rate. In either case, they also need to define the air distribution as Perfect or Uniform as described above. Under Perfect Distribution, they have the option of having some of the ventilation air bypass the bedrooms entirely, to account for supply vents in other portions of the house. If desired, an Alternate Ventilation per Person input can be input to enable comparison of the results to those obtained with the Primary ventilation rate.

Building Type

● Commercial/Institution ○ Residential

Model Type

● Predefined ○ User-Defined

Predefined Commercial Buildings (from ASHRAE Standard 62.1-2016)

Classroom (5-8 y)

Outdoor CO2 Concentration 0 mg/m³	Initial Indoor CO2 Concentration 0 mg/m³	Ceiling Height 3 m	62.1 Ventilation per Person 5 L/s
62.1 Ventilation per Floor Area 0 L/s˙m²	Occupant Density 25 #/100 m²	Ventilation Rate per Person 7.4 L/s	Time to Metric 2 h

Alternate Ventilation per Person:

5 sL/s

Predefined Occupants

Number of Occupants	Sex	Mass (kg)	Age Group	Activity Level (met)
12	M	23	3 to 9	2
12	F	23	3 to 9	2
1	M	85	30 to 59	3

Figure 1: CO_2 Metric Calculator Default Inputs Screen

Once the user has completed the inputs, they click Get Results on the bottom of the Inputs page. This action brings up the Results screen shown in Figure 3, which summarizes the inputs and displays a plot of the indoor CO_2 concentration versus time, along with concentration values at steady-state, t_{metric} and 1 h after occupancy for both the Primary and Alternate ventilation rates.

The tool is applied by comparing the calculated CO_2 concentrations to measured values, with a measured value that is higher serving as an indication that the actual ventilation rate is below the assumed or desired ventilation rate. For comparisons with a calculated whole house value, the measured CO_2 concentration should be a volume-weighted, whole house average based on the concentrations measured in each room. Since the calculation assumes constant occupancy, the measurement needs to occur while occupancy is constant, which can be limited in duration. Ideally, a constant occupancy period that lasts for t_{metric} occurs for the whole house, and the calculated value at that time are then used for the comparison. If constant occupancy does not last that long (default value of 2 h), the t_{metric} value in the calculator can be modified.

Persily, Andrew K.; Polidoro, Brian. "40th AIVC - 8th TightVent & 6th Venticool Conference, 2019 Residential Application of an Indoor Carbon Dioxide Metric." Paper presented at Conference 40th AIVC - 8th TightVent - 6th Venticool Conference in Ghent Belgium, Ghent, BE. October 15, 2019 - October 16, 2019.

In the case of bedrooms, the calculated CO_2 concentrations can again be compared to measured values in the bedroom. Given the fairly stable bedroom occupancy during sleeping, that comparison should occur several hours after the bedroom is occupied for sleeping. The tool has a default value of t_{metric} for bedrooms of 6 h, which should work well for making the concentration comparisons. On making that comparison, a measured value that is higher serves as an indication that the actual ventilation rate is below the assumed or desired ventilation rate. Note that this comparison neglects the impact of interzone transport on the bedroom CO_2 concentration. Also, the calculation assumes that the CO_2 concentration starts at the outdoor level. However, the initial concentration in the bedroom may be higher than outdoors due to previous occupancy of the house, in which case the calculated concentration will be lower than it would if the actual initial concentration were considered. This situation would result in the calculated metric value being conservative, meaning it would lead to a conclusion that the ventilation rate is lower than it may actually be.

5 SUMMARY AND CONCLUSIONS

This paper expands on a previously-described approach to using indoor CO_2 concentration measurements as a metric for ventilation rates per person, which accounts for the ventilation requirements and occupancies of specific spaces. Calculations of CO_2 concentrations at steady state and other times, are presented for selected residential occupancies based on space-specific inputs of ventilation rate, space geometry and occupancy. Application of this CO_2 metric approach to residences requires one to report, at a minimum, the following: house or bedroom geometry (e.g. floor area and ceiling height), occupant characteristics, time at which full occupancy starts, time of CO_2 concentration measurement, and measured indoor and outdoor CO_2 concentrations. These measurements can then be compared with the values calculated with the online tool as an indication of whether the ventilation rate complies with the value in Standard 62.2 or other ventilation requirement of interest. As additional analyses are performed and the concept discussed with practitioners and researchers, it is anticipated that the approach will become more well-defined and more useful.

Note that all of the input values used in these calculations can be revised to examine the impact of other values on the resulting CO_2 concentrations. An online calculator has been developed to allow users to perform these additional calculations. Based on user feedback, the calculator will be revised in the future. One specific addition being considered is to enable Monte Carlo analyses to quantify the impact of uncertainties in the input values on the calculated CO_2 concentrations, as well as to identify the most important input values, using the methodology described in Jones et al. (2015).

Augmenting Fiat Currency with an Integrated Managed Cryptocurrency

Peter Mell
National Institute of Standards and Technology
Gaithersburg MD, USA
peter.mell@nist.gov

***Abstract*—In this work, we investigate how the governance features of a managed currency (e.g., a fiat currency) can be built into a cryptocurrency in order to leverage potential benefits found in the use of blockchain technology and smart contracts. The resulting managed cryptocurrency can increase transparency and integrity, while potentially enabling the emergence of novel monetary instruments. It has similarities to cash in that it enables the general public to immediately transfer funds to a recipient without intermediary systems being involved. However, our system is account-based, unlike circulating bank notes that are self-contained. Our design would allow one to satisfy know your customer laws and be subject to law enforcement actions following legal due process (e.g., account freezing and fund seizure), while mitigating counterparty risk with checks and balances. Funds can thus be transferred only between approved and authenticated users. Our system has on-chain governance capabilities using smart contracts deployed on a dedicated, permissioned blockchain that has different sets of control mechanisms for who can read data, write data, and publish blocks. To enable the governance features, only authorized identity proofed entities can submit transactions. To enable privacy, only the block publishers can read the blockchain; the publishers maintain dedicated nodes that provide access controlled partial visibility of the blockchain data. Being permissioned, we can use a simple consensus protocol with no transaction fees. A separate security layer prevents denial of service and a balance of power mechanism prevents any small group of entities from having undue control. While permissioned, we ensure that no one entity controls the blockchain data or block publishing capability through a voting system with publicly visible election outcomes.**

***Index Terms*—Blockchain, Cryptocurrency, Digital Cash, Fiat Currency, Smart Contract**

I. Introduction

Bitcoin is a protocol for a permissionless distributed ledger that was designed to provide non-reversible transactions with direct account-to-account fund transfers where no third party needs to be trusted [1]. It leveraged blockchain technology to enable a form of non-sovereign digital currency that was previously not possible. It and subsequent cryptocurrencies introduced smart contracts and new kinds of decentralized governance models that have significant organizational and political implications (e.g., having no relationship with any government). With respect to these systems, [2] points out that cryptocurrencies can enable users to remain anonymous, can have permissionless access, and thus usually do not support know your customer (KYC) and anti-money laundering (AML) laws at the protocol level by design. In this work, we investigate how to leverage some of the novel benefits provided by blockchain technology and smart contracts to enable a new form of managed cryptocurrency that has built-in support for KYC and AML laws with system governance mechanisms along with a balance of power structure. Note that we are not suggesting that such a cryptocurrency should necessarily be issued, as that decision involves policy and economic factors outside of the scope of this work. Instead, we are proposing a technical architecture that could lead towards the technical ability to do so.

We investigate how the governance features of a managed currency (e.g., a fiat currency) can be built into a cryptocurrency in order to leverage potential benefits found in the use of blockchain technology and smart contracts. It is designed to be compatible with and augment a partner managed currency, the users being able to freely exchange one for the other. The resulting managed cryptocurrency can increase transparency and integrity, while potentially enabling the emergence of novel monetary instruments. It has similarities to cash in that it enables the general public to immediately transfer funds to a recipient without intermediary systems being involved and the associated counterparty risks (a single transaction to the system transfers funds). This is accomplished through a distributed multi-party managed cryptocurrency system providing guarantees similar to Bitcoin style cryptocurrencies. However unlike circulating bank notes, our system is account-based and all recipients are identity proofed and authorized. Our design thus supports the satisfaction of KYC and AML laws at the protocol level. Entities distinct from the platform and currency managers can register as identity providers, ensuring fund transfers only to identity proofed and authenticated recipients while maintaining openness to the private sector and competition. Accounts would also be subject to law enforcement actions following legal due process to include the freezing of accounts and fund seizure.

Our system has on-chain governance capabilities using smart contracts deployed on a dedicated, permissioned blockchain that has different sets of control mechanisms for who can read data, write data, and publish blocks. To enable the cryptocurrency to have built-in governance roles along with KYC/AML checks, only authorized identity proofed entities can submit transactions. To support user privacy features, only the miners (referred to henceforth as validators) can read

Mell, Peter. "Augmenting Fiat Currency with an Integrated Managed Cryptocurrency." Paper presented at The Fourteenth International Conference on Software Engineering Advances (ICSEA 2019), Valencia, ES. November 24, 2019 - November 28, 2019.

the blockchain. Validators then maintain dedicated nodes that provide access controlled partial visibility of blockchain data to users (e.g., their account balance, transaction history, and system management transactions). Being permissioned, we can use a lightweight consensus protocol. The protocol could be as simple as the dirty round robin used in Multichain [3]. The use of a security layer that prevents denial of service attacks (which works since all accounts must be pre-authorized and can easily be filtered) can enable a no transaction fee system where the validators are paid by the currency issuer to maintain the currency. Lastly, the architecture contains a balance of power mechanism to prevent any small group of entities from having undue control over the blockchain data or publication of new blocks. While it is a permissioned system, there is not a single entity that decides which accounts can publish blocks. Instead, the existing group of validators vote to determine changes to validator eligibility, with the outcomes being made publicly visible. No one entity controls the blockchain data or block publishing capability.

We implemented our architecture using smart contracts written with the Solidity programming language and made the code open source under a public domain license. It has functions for fund tracking, fiat-to-cryptocurrency fund conversion, transaction logging, account creation, voting scenarios, a bootstrapping mode, role assignment, and the ability of accounts to take special actions given their roles (e.g., law enforcement account freezing and central bank fund creation). A set of initial parameters are used to bootstrap the initial governance options but afterwards a voting system is used for multiple accounts with various roles to collectively manage different aspects of the cryptocurrency.

Research economists seem divided about the effectiveness of central bank issued cryptocurrencies. Some, like in [4], point out the potential economic viability of such assets. Others are more critical: [2] for instance states that there is a 'non-case' for a central bank cryptocurrency; their rationale for this was based on perceived immutable features of cryptocurrencies that would make them useless as alternatives to digital currency. In this work, we want to show that these features, considered immutable, can be altered through changing technical fundamentals about how a cryptocurrency blockchain works; this could enable sovereign cryptocurrencies with fiat currency style governance. Non-sovereign cryptocurrencies started the discussion on how to use blockchain to make the global financial system more stable and distributed; we hope that our work on sovereign cryptocurrencies will further facilitate that discussion.

The remainder of this paper is organized as follows. Section II discusses the foundational technology that underlies the design of our cryptocurrency platform. Section III presents our cryptocurrency architecture while section IV explains the account roles within that architecture. Section V discusses how to instantiate our cryptocurrency to integrate it with a fiat currency. Section VI analyzes the security model of our approach and Section VII discusses our implementation. Section VIII summarizes related efforts and section IX concludes.

II. Foundational Technology

Our managed cryptocurrency leverages existing approaches and borrows concepts from other technologies. This includes the cryptocurrency role system, on-chain governance of validator nodes, on-chain voting, and the decoupling of the validation and execution of transactions.

Our managed currency relies upon each cryptocurrency account being assigned a set of roles; these roles enable the management and use of the currency. Assigning roles to cryptocurrency accounts was initially introduced in [5].

On-chain governance is used to manage the set of validators through the assignment of 'validator' roles to accounts, those allowed to participate in a consensus algorithm to publish blocks. This concept of on-chain validator governance can be found in the Proof of Authority (PoA) consensus model. Here, block creation is distributed among different allowed nodes over time while offering Byzantine fault tolerance. PoA with smart contract based validator governance is implemented in the Ethereum client Parity (through the Aura consensus algorithm [6]) and by POA Network [7]. Another example of a PoA implementation can be found in the Microsoft Azure Blockchain system [8].

To manage the set of validators as well as other system functions, our managed cryptocurrency smart contracts must implement voting mechanisms which add or remove roles, as well as to approve or disapprove system security actions such as fund transfer reversals. Various standards and projects provide blockchain technology for decentralized voting [9]; the Ethereum standard EIP-1202 [10] offers for example an interface for implementing voting within smart contracts. As another example, the open-source project Aragon [11], built on Ethereum, allows token holders to cast a vote on protocol upgrades by signing a specific transaction. The Delegated Proof of Stake (DPoS) consensus algorithm, used for instance in BitShares [12], is another illustration of an on-chain voting structure. In BitShares, users vote by staking tokens into another account (called 'delegate'); the delegate account is then allowed to execute certain actions on behalf of its stakeholders (such as producing blocks and voting on protocol upgrades).

Lastly, our cryptocurrency introduces the concept of a 'Security Gateway'. A list of gateways linked to their associated validators, maintained at the smart contract level, are charged with pre-processing incoming transactions. This decouples the execution and validation of transactions. The Hyperledger Fabric, a permissioned blockchain, also has a similar decoupling [13]. Note that any mention of commercial products in this paper is for information only; it does not imply recommendation or endorsement.

III. Cryptocurrency Architecture

A cryptocurrency platform providing the benefits described in Section I and leveraging technology from Section II can be built using the following architecture. Figure 1 shows the overall architecture from the perspective of a single validator.

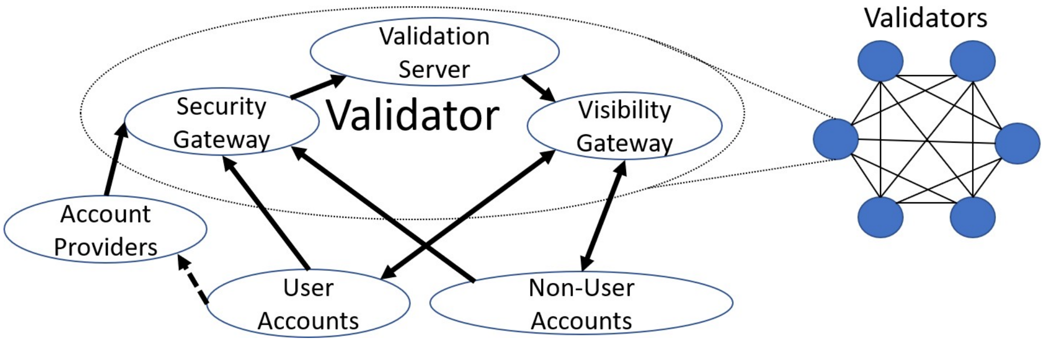

Fig. 1. Interactions of an Individual Validator

A. Platform Architecture

The architecture requires a permissioned smart contract cryptocurrency platform, such as PoA-based Ethereum. It should be configured to not charge transaction fees or gas for sending transactions to the smart contracts. The native cryptocurrency mechanisms of the platform will not be used and instead the cryptocurrency will be stored within the smart contracts (similar to token based ERC-20 [14] compliant smart contract currencies but running on a dedicated platform). Without gas and transaction fees, validators will be rewarded either off-chain or will participate through being inherently motivated to support the cryptocurrency. This is tractable because our use of a lightweight consensus model makes the execution of a validator node less expensive (it is done this way currently by other permissioned blockchain platforms such as Hyperledger Fabric).

The set of smart contracts will be fixed to a small set used to maintain the cryptocurrency. Being a permissioned system, the block publishing software must determine which validators are allowed to participate in the publication of new blocks. This set of permitted validators is managed at the smart contract layer and can be retrieved from the blockchain. In this way our architecture marries what are usually isolated governance layers, the protocol layer which manages the validator node permissions and the smart contract layer which executes code on behalf of system users.

B. Security Gateway

Also managed at the smart contract layer is the list of gateways that each validator maintains to accept proposed transactions from the users of the system. These security gateways pre-process incoming transactions to ascertain their validity. Transactions must be properly formatted and are only accepted from accounts that have roles. Security gateways also keep track of the rate of transactions issued by each account. Accounts with an unusually high rate can be throttled as a form of denial of service protection and to prevent any particular account from taking too large a percentage of system resources. It is possible to white list accounts that have a valid reason to issue a high throughput of transactions.

C. Visibility Gateway

A final platform level resource managed and made visible at the smart contract layer is the set of visibility gateways. Each validator independently maintains a set of such gateways to provide controlled blockchain read access for the account holders. The read access capabilities will be encoded as smart contract view functions (a view function is one that provides read only access and is highly efficient as it is executed locally and not propagated among validators nor included within a block like a normal transaction). However, unlike with typical view function responses, for security reasons (discussed in section VI) the responses will be signed by the associated validator account. The full blockchain is kept private by the validators and user read access is only available through the visibility gateways.

D. Smart Contracts

The smart contract layer, besides managing the authorized platform level resources listed previously, implements the managed cryptocurrency. The smart contracts maintain the list of authorized accounts, the roles granted to each account with associated features, and the balance in each account. We use the account/balance model as opposed to the unspent transaction output (UTXO) model (e.g., in Bitcoin) to avoid the unnecessary complexity (found in [5]) of having to label each unspent transaction with roles. The roles define a set of permissions that enable certain accounts to manage the cryptocurrency and are discussed in the following section.

E. Digital Wallets

Identity proofing results in the participants' identifiers being added to a global on-chain registry controlled by the account providers. As described in [15], the identifiers can be held in custodial, semi-custodial, or non-custodial digital wallets that can be integrated into existing applications, browsers, and operating systems.

IV. Managed Cryptocurrency Roles

The management features and integration with an associated fiat currency are enabled through accounts with various roles. This account and role capability is instantiated on top of the previously described platform and implemented within the fixed set of smart contracts. Section V will describe how these roles can be used in real world systems.

A. Platform Managers

An account with the platform manager role sets the policy for the cryptocurrency system and creates accounts and assigns them non-user roles. Policy can be set to be permanent, temporary, or have a timed expiration. Permanent policies cannot be changed once set (assuming the integrity of the blockchain itself is not compromised). They may be used to instantiate a particular architecture that the cryptocurrency will adopt. Alternately, they may be used to provide confidence to the user base that certain features or settings are guaranteed even though the cryptocurrency is managed by a set of privileged entities. Temporary policies can be changed at any time by a currency manager. Timed expiration policies are considered permanent until a published time at which they become temporary. The system may be set up with only one platform manager, a group of accounts that must vote to make changes, or a hierarchical system where higher priority managers can override policies from lower level managers (as in [5]). This latter design can be used as a security feature in case a currency manager account was compromised; higher priority accounts whose keys are stored in physical vaults could be used to override the compromised account and restore the system.

The policies available to be set can include enabling/disabling features within other roles, setting blockchain parameters such as the size and frequency of blocks, adjusting any fees charged (if any), and setting parameters on how voting will be performed (since the system requires groups to vote to perform certain actions).

During the bootstrapping phase for the cryptocurrency, within some fixed number of blocks, the platform manager defines the initial set of validators. Once the bootstrapping phase is over, the accounts with the platform manager role may not modify the validator roles (thus limiting their authority and creating a balance of power).

B. Account Providers

An account with an account provider role has been authorized by the platform manager(s) to manage user accounts. They identity proof users off-chain, receive a list of the users not yet authorized accounts, and add the user role to those accounts to authorize them. It is important that the users demonstrate ownership of each provided account through proving possession of the associated private key. Each account provider then keeps an internal record of which users are associated with which accounts; this record is not published or shared. This allows KYC and AML laws to be supported at the account provider level (rather than at the entire platform level), which may enhance security and user privacy.

C. System Security

An account with the system security role has the ability to control other accounts for system security purposes. Such accounts can freeze and unfreeze other accounts. They can also move funds between accounts to confiscate funds or reverse transactions. In the latter case we note that the relevant accounts simply need to be debited and credited funds due to our system being account-based (as opposed to following Bitcoin's UTXO model). We also note that since all accounts are identity proofed, system security actions can take place off-chain using existing legal frameworks.

To limit unauthorized actions, policy can be set by the platform manager requiring an on-chain voting mechanism for certain system security transactions. In addition, the platform manager(s) can limit or disable any of the powers of the system security role through policy settings.

D. Users

An account with the user role is one that can be used to receive, store, and send value in the form of tokens maintained by the smart contracts. A single user may have multiple accounts and may use multiple account providers to do so (note that every account must be identity proofed by an account provider).

Each account is labelled within the smart contract with its associated public key. A user maintains use of an account through possession of the associated private key (possibly stored on a hardware token for greater security). If a user loses a private key or suspects that their private key has been stolen, they need a way to retake possession of the account. This is accomplished by swapping out the account's original public key with a new one within the smart contract. When creating their account, users can choose what method they prefer to enable this action; there are at least three options. They can trust their account provider to do this for them and simply re-identity proof to their account provider. They could authorize a set of other accounts to validate the public key swap (using accounts they own or accounts of trusted individuals). Or they could require the involvement of system security along with their account provider, necessitating re-identity proofing with both entities.

E. Currency Managers

An account with the currency manager role has the ability to control the money supply through direct actions or ongoing policy. This includes fund creation, deletion, and the provision of interest. The currency manager accounts vote to set monetary policy or initiate an action (for example the creation of funds to be lent to other entities).

F. Validators

An account with the validator role is an account that represents an authorized block publisher. Validator accounts vote to add/remove the validator role to/from other accounts. Other than block publishing, the validators manage their respective security and visibility gateways. On their visibility gateways, they make visible all cryptocurrency management transactions to provide full transparency to all users.

Each validator account posts on the smart contract the Internet Protocol (IP) addresses of their security and visibility gateways. The visibility gateways then make the security and visibility gateway addresses visible to all users and the validation server addresses visible to other accounts with the validator role. This latter publication facilitates the peer-to-peer permissioned networking between validators used for transaction propagation and block publication.

Each validator account publishes on the blockchain a publicly visible special public key associated with the signed responses from its visibility gateways. This key is different from the public key for the validator account itself. It also publicly publishes contact information (e.g., an email address) for reporting any problems. This is essential for security reasons discussed in Section VI.

V. Integration with Fiat Currencies

The architecture presented in sections III and IV is designed to be integrated with a fiat currency and traditional bank deposits. A government administration could instantiate the cryptocurrency and act as the platform manager. The directors of the government's independent central bank could act as the currency managers. The government law enforcement agencies could act in the system security role. This creates a balance of power where no one organization 'controls' the blockchain. To further promote this, government entities separate from the administration can act as the validators (e.g., a set of states). The national standards body can define the specification for the supporting cryptocurrency software and independent laboratories can test compliance of that software. Note that multiple developers should be used, especially for the validator software, for security purposes and the code should be developed open source and made available publicly. This way a single developer cannot maliciously or unintentionally violate the specification and enable non-protocol compliant blocks to be published and accepted.

Financial institutions (e.g., commercial banks, cryptocurrency exchanges, and other fintech companies) could be made account providers, among other entities, since they already must identity proof their customers. They would keep their mapping of identity proofed users to account numbers private and only reveal select information to fulfill a court order (thus supporting KYC and AML laws while still maintaining user privacy). They can modify their banking software to simultaneously show users their bank deposit balances and cryptocurrency balances (since they established each user's accounts). The financial institution itself would not have access to the user's cryptocurrency balance and transactions but their banking application, on behalf of the user, could retrieve this information from the visibility gateways. These applications could then enable the conversion of bank deposits to cryptocurrency and vice versa (also often referred as on-ramp/off-ramp). The application could send cryptocurrency to the financial institution and have the institution deposit traditional money into the user's bank accounts (and vice versa). The application could also transfer funds between the user's different cryptocurrency accounts using a bank owned account as an intermediary to hide any linkage between the user's accounts from appearing on the blockchain. Note that the financial institution obtains cryptocurrency through its existing fiat accounts with the central bank: the institution sends the central bank fiat currency and the central bank sends it cryptocurrency. If users are allowed to interact directly with the central bank, users can perform this operation themselves.

The central bank, as the currency manager, unifies the fiat and cryptocurrency by enabling the exchange between both. The cryptocurrency could be maintained as a separate line item on the central bank balance sheet. The central bank can create and destroy both currencies and thus can implement a cryptocurrency monetary policy in a similar fashion as when managing solely its fiat currency. Note that offering two forms of currency, with different characteristics and risk profiles, can have significant economic implications that are out of scope for this paper.

VI. Security Analysis

In this section we analyze the security and functionality provided by our architecture using the three traditional computer security pillars of confidentiality, integrity, and availability.

A. *Confidentiality*

Our architecture provides accounts/transactions that are pseudonymous for the validators and confidential to the rest of the users. We note that there is a possibility of user confidentiality being lifted when necessary to support KYC and AML laws (e.g., through a court order for validators to reveal transactions and the respective account providers to divulge account ownership). Users choose which account provider they trust to know which accounts they own. The account provider keeps this private unless required to reveal it. Furthermore, the account provider can distribute user funds between the user's accounts such that there is no linkage on the blockchain between the multiple accounts from the same user.

The transactions on the blockchain are kept private and only shared within the set of validators. The visibility gateways only reveal blockchain transactions to the parties involved in those transactions. A downside of this is that it would appear then that accounts with the platform manager, system security, and currency manager roles can issue transactions without oversight. However, the validators are independent entities that make these transactions publicly visible through their visibility gateways. This offers transparency for all management transactions but confidentiality for user fund transfers.

The IP addresses of the validating servers are stored on the blockchain but the visibility gateways make this information visible only to the validator accounts. Thus, the validation servers themselves are kept confidential. If this information was leaked, a single transaction could be used to update a revealed server to a new IP address (to discourage denial of service (DoS) attacks). The security gateways and visibility gateways' addresses are made public. The visibility gateways operate independently with only a copy of the blockchain and thus can be replicated at scale to counter possible DoS attacks.

Likewise, a validator may have multiple security gateways to provide load balancing and DoS protection.

B. Integrity

The use of a group of independent validators ensures the integrity of the newly published blocks. No validator will accept a block from another validator that does not follow the established protocol. Each block and the transactions therein must be of the proper form and have the necessary digital signatures. As is the norm with blockchains, each block contains a hash of the previous block to enable detection of any changes with previously published blocks. However unlike public blockchain systems, the users themselves cannot verify the retained integrity of the blockchain and so another mechanism must exist to hold individual validators accountable.

For this, user software will query multiple visibility gateways when retrieving user blockchain data. Any discrepancy between the visibility gateways owned by different validators reveals a problem with one of the validators. An exception is for very recent transactions that have not yet been posted by all validators and thus there should thus be an agreed-upon time delay before taking any action. In the case of a discrepancy, an event transaction is triggered and sent to all validators to describe the discrepancy. As long as at least one validator is honest, the discrepancy will be published. Note that this is considered a 'management' type transaction and thus is made publicly visible to all users. Note that since the visibility gateways sign their responses, the user can prove that multiple visibility gateways provided different answers. As long as a majority of the validators remain honest, the honest ones can vote out any validators that provide incorrect results.

If a set of the validators decide to overtly violate the cryptocurrency protocol (e.g., to change a permanent policy or take control away from the platform or currency managers), this will fork the blockchain as happens with other cryptocurrency systems. The non-violating validators would inform participating parties using off-chain methods and, like other cryptocurrency forks, the resolution would take place off-chain. Given that the cryptocurrency will be tied to a fiat currency, investigations and legal action may be taken against the violating validators. Note that only if 100 percent of the validators collude can they make changes without being noticed. Also, note that our cryptocurrency leverages the fact that it is a sovereign currency, existing within an off-chain legal framework.

C. Availability

There are two types of availability that need to be considered: the availability of the cryptocurrency system as a whole and the availability of a particular account to conduct transactions.

The cryptocurrency platform itself has robust availability because it is a distributed system with no central point of failure. Many of the validation servers may fail, even the majority of them, and the system can still continue to function. Note that individual validation servers can be run efficiently due to the use of a lightweight consensus algorithm, permitted by the permissioned blockchain configuration. Also, each security and visibility gateway can be implemented as a cluster of servers to reduce susceptibility to DoS attacks and individual server failures.

Individual accounts are not dependent upon a particular validator and user applications should issue transactions to multiple systems simultaneously (this includes both write transactions to the security gateways and read transactions to the visibility gateways). Using multiple security gateways ensures that no validator could decide to unilaterally block a particular account (note that account ownership is pseudonymous to the validators making this less likely). Using multiple visibility gateways, as discussed above, addresses integrity concerns.

VII. Implementation

We implemented our managed cryptocurrency as smart contracts using the Solidity programming language. It is available as open source software on Github at https://github.com/usnistgov/managed_token under a public domain license. In this proof-of-concept prototype, we implemented the core functions of the managed cryptocurrency. This includes fund tracking, fiat to cryptocurrency fund conversion, transaction logging, account creation, voting scenarios, bootstrapping mode, role assignment, and the ability of accounts to take special actions given their roles (e.g., law enforcement account freezing and central bank fund creation). Certain aspects are simplified, such as monetary policy options, as our goal was not to create a production system but to demonstrate that this managed architecture approach is feasible. We tested our code by deploying it to a local Ethereum test environment.

A couple of money creation schemes are provided in our system as examples. Schemes are provided to vote and carry out money creation in arbitrary accounts (following a top-down approach) as well as in all user accounts in the form of interests (following a bottom-up approach). Furthermore, these schemes can be either push-based or pull-based. In the push-based model, the money creation function creates funds in the recipient(s) account without any action being required from the recipient(s). In the pull-based model, the currency managers set rules through a single transaction to give the right to the recipient(s) to create their own funds according to this set of rules. This can provide scalability gains as users do not have to claim their allowance right away, and instead, may wait until they need it without any risk of not receiving it. In the case of periodic funds creation (e.g. interests, dividends), a user might be able to skip claiming funds between period X and period X + Y, and then, withdraw funds at period X + Y + 1 for all of the periods between X and X + Y + 1 combined. Finally, a set of view functions allows one to selectively control the visibility of monetary creation and other on-chain fund data, both at the user level and at the currency management level (e.g., global supply indicators).

Note that our implementation did not cover the off-chain aspects of our cryptocurrency architecture. In particular, we did not build the security or visibility gateways (although we did write the smart contract view functions to support the latter). We also did not modify the Ethereum mining software to only publish blocks in collaboration with the validators specified by the smart contracts (but we did implement the smart contract code to enable a set of validators to use the on-chain data to manage themselves).

VIII. Related Work

Most of the existing work related to managed cryptocurrencies consists in studies and pilots on blockchain-based central bank digital currencies (CBDC), as well as research and development of protocols for stablecoins, algorithmic currency management, and privacy-preserving KYC/AML checks.

The literature distinguishes two main categories of CBDCs: wholesale and retail. As explained by the Bank for International Settlements (BIS) in their money taxonomy [16], a wholesale CBDC is only available to financial institutions and mainly intended for inter-bank transactions whereas a retail CBDC is globally accessible and usable by the general public. Our managed cryptocurrency architecture is geared towards retail CBDCs, although it could also be launched as a wholesale CBDC, at least initially.

We have developed our architecture to change how cryptocurrencies usually work to enable support for retail CBDCs. As stated earlier, this does not mean that we are necessarily claiming that one should be created; we are simply providing some of the technical capability to do so. That said, the subject of state or central bank issued cryptocurrencies has been one of considerable interest. A BIS poll in 2018 showed that more than 70 percent of central banks worldwide were already engaged in CBDC work [17]. Some central banks, such as the central bank of Canada (project Jasper [18]), the Monetary Authority of Singapore (project Ubin [19]), or the Bank of Thailand [20] have focused their research on wholesale CBDC. Also, the European Central Bank and the Bank of Japan are conducting joint research on wholesale CBDCs with Project Stella [21]. Others, such as the Ecuadorian Central Bank ('Dinero Electronico' [22]), the People's Bank of China [23], and the Government of Venezuela (Petro [24]) aim at developing a CBDC for retail use. It should be noted, however, that many central bank efforts do not use (nor plan to use in the future) distributed ledger technologies (DLT); for example the Sveriges Riksbank from Sweden [25] stated that they currently deemed DLT too inefficient for use in a retail CBDC. An example of a non-DLT retail electronic currency is the e-Peso [26]. This is a pilot from the Central Bank of Uruguay that was launched as complement to physical cash but relied on a central registry for ownership recording.

Aside from efforts from governments and central banks, several other blockchain-based research projects have entered the field of managed cryptocurrencies. For example, RScoin [27] provides a cryptocurrency framework using a UTXO model where generation of the monetary supply is controlled by a central authority and transaction processing is handled by dedicated institutions, called 'mintettes'; ultimately, the central authority handles the creation and posting of new blocks. Our system differs from this approach in that currency managers do not influence the block creation process nor benefit from special viewing rights over the content of the blockchain. Another example of a managed cryptocurrency system can be found in Fedcoin [28], which builds upon RScoin's framework by providing a Node.js implementation, KYC rules that enable a central bank to blacklist users, and improved anonymity features. However, unlike our proposal, it does not natively offer the ability for accounts to be assigned roles; this leaves the central bank as the sole entity involved in the identity provider, management, and system security functions (e.g., identity-proofing new accounts, freezing unlawful users, and coin production).

'Decentralized Finance' projects, many of which are currently built with smart contracts deployed on the public Ethereum blockchain or as second layer solutions atop Bitcoin, are also being developed for stablecoins and decentralized currency management where money supply is governed algorithmically (such as Dai [29]). In our system, unlike reserve-backed stablecoins (such as Libra [30], USD Coin [31], and J.P. Morgan Coin [32]) that are pegged one-to-one with the asset(s) that they represent, there is a built-in currency manager role that can develop monetary instruments and vote for monetary policies to increase and decrease the currency supply. Since it is programmable, novel, potentially more flexible monetary instruments may be implemented.

From a security point of view, efforts are being made to offer security standards, toolsets, and services for cryptocurrencies. For example, EIP-1080 [33] is an Ethereum standard that offers an interface geared towards charge back and theft prevention/resolution for ERC-20 tokens [14]. Also, more loosely related is that the Enterprise Ethereum Alliance (EEA) Legal Industry Working Group [34] intends to standardize law-compliant smart contract designs.

Our system provides user privacy through use of a permissioned blockchain that supports roles with different responsibilities and data visibility (e.g., block publishers cannot see account owners' identities). However, cash transactions offer an ideal for anonymity and attempts to achieve this ideal for electronic currencies have been the subject of much research. The development of some privacy-preserving technologies, such as zero-knowledge protocols, has assisted in this objective. For example, Chaum introduced eCash [35] in 1983, one of the first attempts at anonymizing electronic money transactions via the use of blind signatures; Zcash [36] is an example of cryptocurrency that relies on a type of zero-knowledge proof called zk-SNARKs for keeping transactions private; and ChainAnchor [37] offers a method based on the 'Enhanced Privacy ID' zero-knowledge protocol for controlling access to a permissioned blockchain while allowing users to transact pseudonymously and maintain transaction unlinkability.

IX. Conclusion

Most cryptocurrencies and cryptocurrency research efforts focus on providing cryptocurrencies with strong anonymity and privacy guarantees in a robust distributed system that is not owned or managed by any single entity or group. We do not dispute the importance of such efforts and the emergence of the associated new social constructs, but point out that research in managed cryptocurrencies integrated with our current institutions has been sorely lacking. This is unfortunate as all people live under the laws of their respective countries and it is thus important to research cryptocurrencies that can explicitly support those laws.

In recent years, central banks have been interested in this area, but some of their researchers have discounted cryptocurrency solutions because the foundational technology appears incompatible with central bank goals, especially the support for KYC and AML laws. In this work, we showed how the foundational elements of a cryptocurrency can be rethought to support central bank goals and to explicitly support the laws that apply to electronic fiat currencies. We hope to convince the reader that this type of approach is technically feasible and that cryptocurrencies can be developed that integrate with an associated fiat currency and explicitly support the laws of the respective government.

Estimating the Parameters of Circles and Ellipses Using Orthogonal Distance Regression and Bayesian Errors-in-Variables Regression

Jolene Splett* Amanda Koepke* Felix Jimenez†

Abstract
In ordinary least-squares regression, independent variables are assumed to be known without error. However, in many real-life situations this assumption is not valid. Both orthogonal distance regression and Bayesian errors-in-variables regression can be used to estimate model parameters when there are errors in the dependent and independent variables.

To illustrate the use of the maximum-likelihood and Bayesian approaches, we use both methods to estimate the parameters of a circle. The data used for circle fitting were taken from the cross section of an optical fiber. The shape of optical fibers is important when joining two fibers, so accurate dimensional measurements are critical to minimizing coupling loss. We then compare the results of the two techniques when fitting an ellipse to simulated data.

Circle and ellipse fitting using maximum-likelihood methods have been well documented; however, Bayesian methods for these tasks are less developed. As expected, we found that the Bayesian approach for circle fitting is more intuitive and easier to implement than the maximum-likelihood approach, but generalizing the Bayesian approach to ellipse fitting was surprisingly difficult.

Key Words: Bayesian statistics, errors-in-variables regression, orthogonal distance regression, circle fitting, ellipse fitting

1. Introduction

In many real-life regression problems, errors are present in both the independent and dependent variables. Circles and ellipses are classic examples of data that have errors in both the x and y variables.

We examine two methods of fitting circle and ellipse data. The first method is orthogonal distance regression (ODR). In ODR, maximum-likelihood estimates are obtained by minimizing distances between data points and the fitted curve. The second method is Bayesian errors-in-variables regression (EIV). In general, the Bayesian technique allows for easy and intuitive explicit modeling of errors in both the x and y variables for simple models. In this paper, we seek to extend the Bayesian EIV method for the purpose of estimating the parameters of circles and ellipses. While maximum-likelihood based approaches to the circle-fitting problem are well documented (Boggs et al. [1992], Chernov [2011]), very little has been written about a Bayesian approach to this classic errors-in-variables problem.

Data representing the cross section of an optical fiber (Wang et al. [1997], Mamileti et al. [1992]) are used to demonstrate the ODR and EIV methods for estimating the parameters of a circle. We then use both methods to fit an ellipse to simulated data.

Sections 2 and 3 describe the data being fit and detail our circle fitting and ellipse fitting techniques. Results are provided in Section 4, and Section 5 summarizes our findings.

2. Circle Fitting

2.1 Optical Fiber Data

Dimensional measurements of an optical fiber cross section are obtained by circle fitting. Accurate dimensional measurements are critical to providing the best possible transmission of light through the fiber; as much as 1 μm offset in joining two fibers will result in about 5 % loss of signal (Wang et al. [1997]).

The data were obtained by first generating a gray-scale image of a fiber cross section (Figure 1). Next, an edge-detection algorithm was applied to the image to define the outside edge of the fiber, producing the (x, y) coordinate pairs required for the analysis.

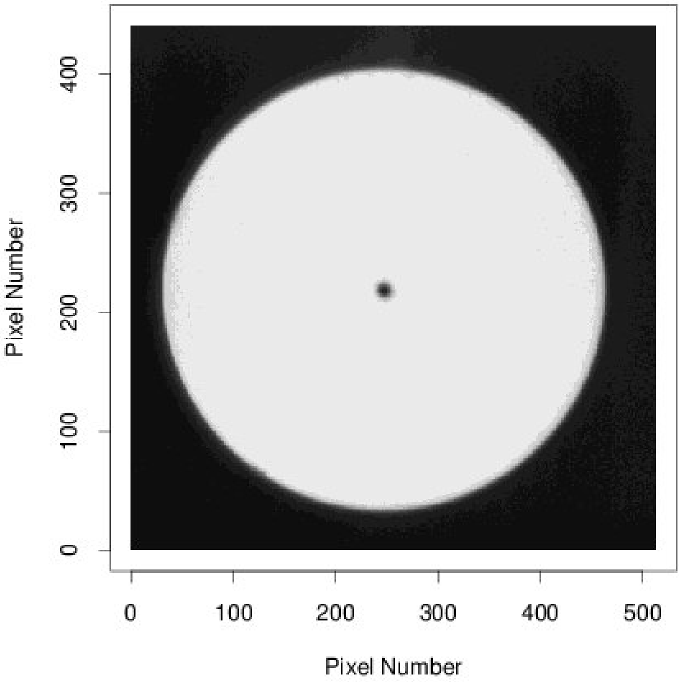

Figure 1: Gray-scale image of an optical-fiber cross section. Data and figure from Wang et al. [1997].

For reasons discussed in 2.2.1, two different representations of a circle are used to perform model fitting. For ODR, we use the general equation of a circle, $r^2 = (x_i - x_c)^2 + (y_i - y_c)^2$. The parameters of interest are the radius (r), the x-coordinate of the center (x_c), and the y-coordinate of the center (y_c).

For EIV, we define a general circle in terms of (x, y) coordinates. Consider a unit circle, centered at $(0, 0)$ with radius $r = 1$. We denote points on the unit circle as $(\tilde{x}_i, \tilde{y}_i)$, where $\tilde{x}_i = \cos(\theta_i)$, $\tilde{y}_i = \sin(\theta_i)$, and $\theta_i \in (-\pi, \pi]$. From the unit circle, we can obtain points on a standard circle (x'_i, y'_i) by multiplying by a constant r, so $x'_i = r\cos(\theta_i)$ and $y'_i = r\sin(\theta_i)$. This standard circle is centered at zero and has radius r. We can move this circle to a new center (x_c, y_c), which gives us the general form for points on a circle

$$(X_i = x_c + r\cos(\theta_i),\ \ Y_i = y_c + r\sin(\theta_i))\,. \tag{1}$$

2.2 Bayesian Estimates

2.2.1 *The model*

To obtain parameter estimates in the frequentist framework, the sum-of-squared residuals is minimized subject to the constraint from the general equation of a circle; creating a similar framework for Bayesian EIV regression is not obvious. Keksel et al. [2018] modeled a circle using Bayesian methods by defining their likelihood using $(x_i - x_c)^2 + (y_i - y_c)^2 - r^2$, assigning this a normal distribution with zero mean and some variance, but the approach does not allow the errors in the x and y variables to be modeled separately. The method used by Werman and Keren [2001] also has this limitation. Since the ODR circle parameterization makes it difficult to determine the likelihood for the Bayesian EIV regression approach, we propose a more intuitive parameterization, rewriting the model in terms of x and y coordinates.

We use the general form of a circle (1) to model our observed data. First, for notational and computational convenience, we roughly center our observed circle by subtracting the means, so our new data are represented as $x_{i,new} = x_i - \bar{x}$ and $y_{i,new} = y_i - \bar{y}$, where $\bar{x} = \frac{1}{n}\sum_{i=1}^{n} x_i$ and $\bar{y} = \frac{1}{n}\sum_{i=1}^{n} y_i$. The center of the new circle is then $x_0 = x_c - \bar{x}$ and $y_0 = y_c - \bar{y}$, where (x_c, y_c) is the center of the observed circle data as defined in Section 2.1. Thus for the EIV model, (1) becomes

$$(X_i^* = x_0 + r\cos(\theta_i), \;\; Y_i^* = y_0 + r\sin(\theta_i))\,. \tag{2}$$

We assume $x_{i,new}$ and $y_{i,new}$ are normally distributed about the points of some true circle defined by (2) with variances σ_x^2 and σ_y^2, so

$$x_{i,new} \sim N(X_i^*, \sigma_x^2) \qquad y_{i,new} \sim N(Y_i^*, \sigma_y^2). \tag{3}$$

Now we must assign prior distributions to all of the parameters in our model. We know that the deviations of the points about the circle are small, encouraging us to use relatively concentrated prior distributions for σ_x and σ_y. We assume tight gamma prior distributions for σ_x and σ_y,

$$\sigma_x \sim \text{Gamma}(\text{shape} = 2, \text{rate} = 50) \qquad \sigma_y \sim \text{Gamma}(\text{shape} = 2, \text{rate} = 50).$$

Since we center our data, x_0 and y_0 should be close to zero, so we assume *a priori*

$$x_0 \sim N(0, 1) \qquad y_0 \sim N(0, 1).$$

The radius is required to be positive, and we assume *a priori*

$$r \sim N(60, 10^2) I_{r \geq 0}.$$

This prior distribution is centered about a realistic value of r, but has large variance.

We use a von Mises prior distribution for the θ_i, bounded between $-\pi$ and π, with location equal to zero and concentration, κ, equal to 0.1. This distribution is plotted for various concentration values in Figure 2. The concentration determines how concentrated the distribution is about the location. The distribution becomes uniform over the interval as κ goes to zero. However, in practice the concentration is restricted to be greater than zero for computational reasons, so we give κ a small value. The von Mises distribution is a common circular distribution that has desirable inferential properties (Mardia and Jupp [2000]).

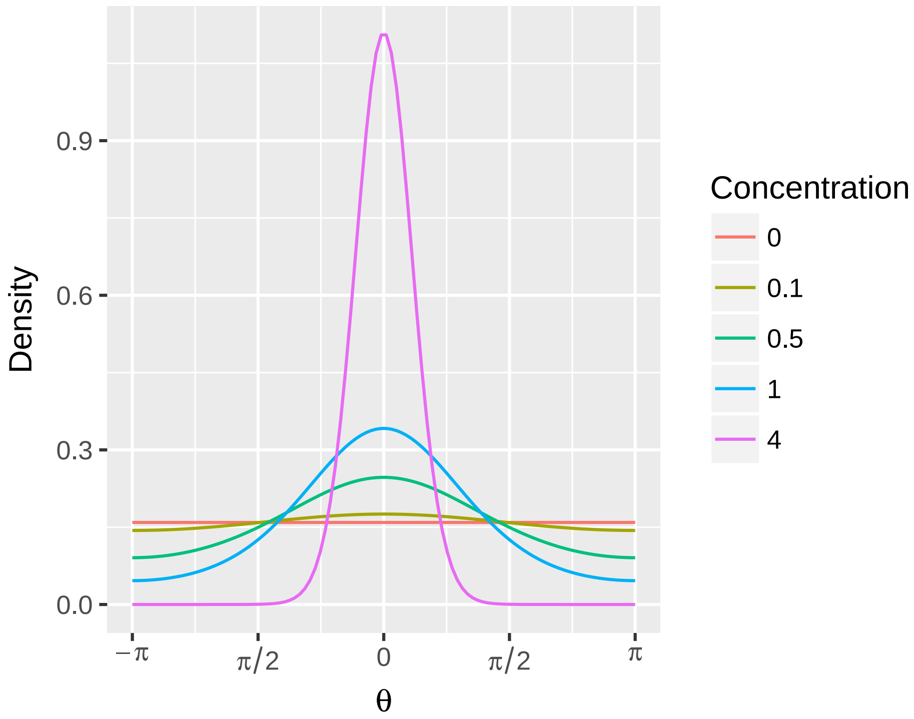

Figure 2: Probability density functions for von Mises distributions on θ, bounded between $-\pi$ and π, with different values for the concentration. As the concentration approaches zero, the distribution becomes more uniform.

2.2.2 MCMC

Now that a model, a set of priors, and the observed data have been defined, we turn our attention to estimating the parameters. To accomplish this, we use Hamiltonian Monte Carlo (HMC), implemented via `Stan` using the `R` package `rstan` [Carpenter et al., 2017, Stan Development Team, 2018], to sample from the posterior distribution of the parameters given the observed data. In particular, we run three chains, each with a burn in of 500 samples and a total of 1000 iterations.

The large number of parameters make this model difficult to fit without reasonable initial values for HMC. We initialize all three chains as follows. The initial radius value is $r_{init} = 60$, the standard deviations (σ_x, σ_y) are both initialized at 0.01, and the center is $(x_{0,init}, y_{0,init}) = (0, 0)$. To initialize the θ_i, we relate them to the data $(x_{i,new}, y_{i,new})$ and the other initial values, so

$$\theta_{i,init} = \arctan\left(\frac{\tilde{y_i}}{\tilde{x_i}}\right) = \arctan\left(\frac{(y_{i,new} - y_{0,init})/r_{init}}{(x_{i,new} - x_{0,init})/r_{init}}\right),$$

which reduces to $\theta_{i,init} = \arctan\left(\frac{y_{i,new}}{x_{i,new}}\right)$.

2.3 Maximum-Likelihood Estimates

We obtain maximum-likelihood estimates of the parameters for the circle model using the Fortran package, ODRPACK (Boggs et al. [1992]). The model for circle fitting,

$$0 = (x_i - x_c)^2 + (y_i - y_c)^2 - r^2, \tag{4}$$

is an implicit model because there is no explicit independent variable. For implicit multivariate orthogonal distance regression using ODRPACK, define $z_i = (x_i, y_i)$ and $\delta_i = (\delta_{x_i}, \delta_{y_i})$, where δ_{x_i} and δ_{y_i} represent the errors in x_i and y_i, respectively. Parameters are estimated using

$$\min_{\beta,\delta} \sum_{i=1}^{n} w_{\delta_i} {\delta_i}^2 \tag{5}$$

subject to the constraint

$$f_i(z_i + \delta_i; \beta) = ((x_i - \delta_{x_i}) - x_c)^2 + ((y_i - \delta_{y_i}) - y_c)^2 - r^2 = 0, \qquad i = 1, \ldots, n,$$

where w_{δ_i} are weights and $\beta = (x_c,\, y_c,\, r)$. For our problem, $w_{\delta_i} = 1$ for all i.

3. Ellipse Fitting

3.1 Simulated Data

To understand the models for fitting the ellipse, we review some geometry. An ellipse can be defined in terms of two circles with radii r_x and r_y, with $r_x > r_y$. This is depicted in Figure 3. As with the circle model, we first consider the unit circle (green circle in the figure). In the figure, A denotes a point on the unit circle, and $A = (\tilde{x_i}, \tilde{y_i}) = (\text{cos}(\theta_i), \text{sin}(\theta_i))$, where $\theta_i \in [0, 2\pi)$. Using points on the unit circle, we obtain points on the red circle by multiplying by r_y, so point B in the figure equals $(r_y\text{cos}(\theta_i), r_y\text{sin}(\theta_i))$. Similarly, we obtain points on the blue circle by multiplying by r_x, so point C in the figure equals $(r_x\text{cos}(\theta_i), r_x\text{sin}(\theta_i))$. Using these two circles, we obtain a point (D) on the standard ellipse as $(x_i', y_i') = (r_x\text{cos}(\theta_i), r_y\text{sin}(\theta_i))$. The standard ellipse is centered at zero, has major axis r_x, and has minor axis r_y.

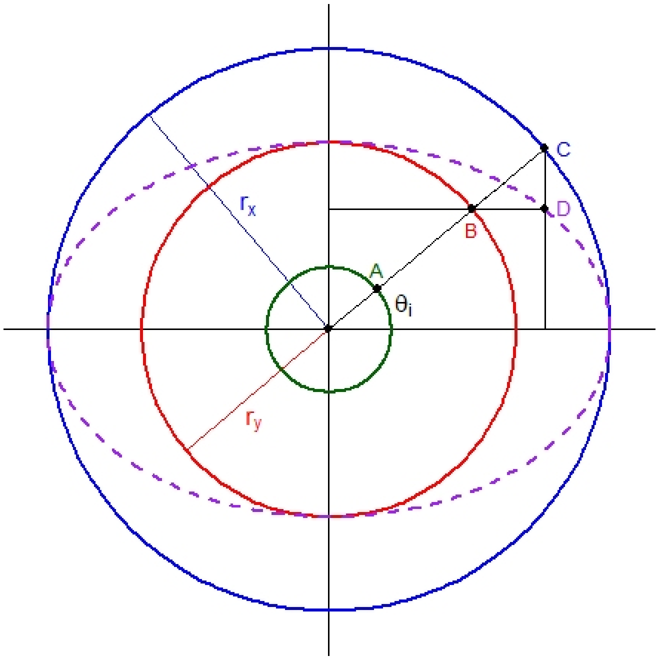

Figure 3: Geometric interpretation of an ellipse based on two circles with different radii.

The standard ellipse can be rotated by angle α and moved to a new center (x_c, y_c), which gives us the general form for points on an ellipse

$$\begin{aligned} X_i &= x_c + r_x \cdot \cos(\theta_i) \cdot \cos(\alpha) - r_y \cdot \sin(\theta_i) \cdot \sin(\alpha) \\ Y_i &= y_c + r_y \cdot \sin(\theta_i) \cdot \cos(\alpha) + r_x \cdot \cos(\theta_i) \cdot \sin(\alpha). \end{aligned} \tag{6}$$

For ellipse fitting, we simulate 1000 noisy data pairs as $x_i \sim N(X_i, \sigma_x^2)$ and $y_i \sim N(Y_i, \sigma_y^2)$ using the values shown in Table 1. The $\theta_1, \ldots, \theta_{1000}$ are an evenly spaced sequence from $-\pi + \epsilon$ to $\pi - \epsilon$, with $\epsilon = 0.00001$. Figure 4 displays the data points used in the analysis.

Table 1: Parameters used to generate simulated ellipse data.

Parameter	Value
x_c	71
y_c	74
r_x	62
r_y	50
α	-0.55 rad
σ_x	0.05
σ_y	0.07

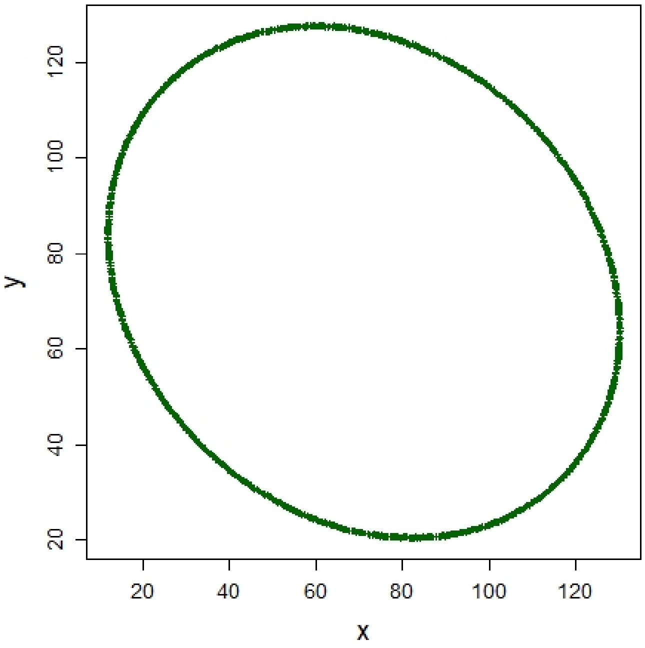

Figure 4: Simulated ellipse data (n=1000) generated using (6) and the parameters listed in Table 1.

3.2 Bayesian Estimates

3.2.1 The Model

As before, we use the general form of the ellipse (6) to model our observed data. We again roughly center our observed ellipse by subtracting the means, so our new data are represented as $x_{i,new} = x_i - \bar{x}$ and $y_{i,new} = y_i - \bar{y}$, and the center of the new ellipse is $x_0 = x_c - \bar{x}$ and $y_0 = y_c - \bar{y}$, where (x_c, y_c) is the center of the observed ellipse data as defined in Section 3.1. Thus for the EIV model, (6) becomes

$$\begin{aligned} X_i^* &= x_0 + r_x \cdot \cos(\theta_i) \cdot \cos(\alpha) - r_y \cdot \sin(\theta_i) \cdot \sin(\alpha) \\ Y_i^* &= y_0 + r_y \cdot \sin(\theta_i) \cdot \cos(\alpha) + r_x \cdot \cos(\theta_i) \cdot \sin(\alpha). \end{aligned} \tag{7}$$

As with the circle model, we assume $x_{i,new}$ and $y_{i,new}$ are normally distributed about the points of some true ellipse defined by X_i^* and Y_i^*, so

$$x_{i,new} \sim N(X_i^*, \sigma_x^2) \qquad y_{i,new} \sim N(Y_i^*, \sigma_y^2). \tag{8}$$

We use many of the same prior distributions assumed in Section 2.2. Since we center our data, we assume *a priori* that the center of our ellipse should be close to (0,0), so

$$x_0 \sim N(0,1) \qquad y_0 \sim N(0,1).$$

The standard deviations of x_i and y_i, both of which are positive, are defined by

$$\sigma_x \sim \text{Gamma}(\text{shape} = 2, \text{rate} = 50) \qquad \sigma_y \sim \text{Gamma}(\text{shape} = 2, \text{rate} = 50).$$

Both the x radius (r_x) and y radius (r_y) must be positive. We assume

$$r_x \sim N(60, 10^2) I_{[r_x>0]} \qquad r_y \sim N(60, 10^2) I_{[r_y>0]}.$$

Again, this prior distribution expresses a lot of uncertainty about these parameter values, even though we think they should be around 60. The larger of the r_x and r_x values corresponds to the major axis (M) and the smaller value corresponds to the minor axis (m).

The rotation of the ellipse, α, is constrained to cover a 90 degree range to ensure a unique solution for the parameter estimates. This restriction on α allows us to avoid imposing a restriction on the relative sizes of r_x and r_y due to the fact that the major axis must be greater than the minor axis. If α covered an entire 180 degree range, then two different values of α could be used to describe the same ellipse if the major and minor axes are switched. *A priori* we assume α has a uniform distribution between $-\pi/2$ and zero.

Finally, we again use a von Mises prior distribution for the θ_i, bounded between $-\pi$ and π, with location equal to zero and concentration equal to 0.1.

3.2.2 MCMC

Our results are very sensitive to initial values, particularly for the angle of rotation. Thus, we use the data to estimate a rough angle of rotation to initialize the model. Using the roughly centered data $(x_{i,new}, y_{i,new})$, we calculate $r_i = \sqrt{x_{i,new}^2 + y_{i,new}^2}$. The maximum r_i should correspond to a point close to the major axis, so the angle that corresponds to that point, constrained to be between $-\pi$ and zero, is a good initial value for the angle of rotation of our ellipse. Specifically, $\alpha_{init} = \text{arctan}\left(\frac{y_{j,new}}{x_{j,new}}\right)$, where j is the index for the maximum value of the r_i. If this is not between $-\pi/2$ and zero, we find the corresponding angle that is in this range.

For the center, we use $(x_{0,init}, y_{0,init}) = (0, 0)$. Given $(x_{i,new}, y_{i,new})$, we obtain a standard ellipse roughly centered at $(0, 0)$ and rotated by angle, $-\alpha_{init}$, using

$$\begin{aligned} x_i' &= (x_{i,new} - x_{0,init}) \cdot \text{cos}(-\alpha_{init}) - (y_{i,new} - y_{0,init}) \cdot \text{sin}(-\alpha_{init}) \\ y_i' &= (y_{i,new} - y_{0,init}) \cdot \text{cos}(-\alpha_{init}) + (x_{i,new} - x_{0,init}) \cdot \text{sin}(-\alpha_{init}). \end{aligned} \tag{9}$$

From the standard ellipse (9), we can initialize r_x and r_y as

$$\begin{aligned} r_{x,init} &= \frac{|\text{min}(x_i')| + |\text{max}(x_i')|}{2} \\ r_{y,init} &= \frac{|\text{min}(y_i')| + |\text{max}(y_i')|}{2}. \end{aligned}$$

To initialize the θ_i, we set

$$\theta_{i,init} = \text{arctan}\left(\frac{y_i'/r_{y,init}}{x_i'/r_{x,init}}\right).$$

The standard deviations σ_x and σ_y are both initialized at 0.01. We use these values to initialize three chains, each with a burn in of 300 and a total of 600 iterations, again using HMC to sample from the posterior distribution.

3.3 Maximum-Likelihood Estimates

A general formula for an ellipse that is translated and rotated in the x, y plane (Fuller [1987]) is

$$\beta_1(y_i - y_c)^2 + 2\beta_2(y_i - y_c)(x_i - x_c) + \beta_3(x_i - x_c)^2 - 1 = 0. \tag{10}$$

The center of the ellipse is $(x_c,\, y_c)$; however, the remaining parameters, $(\beta_1,\, \beta_2,\, \beta_3)$, have no geometric interpretation. Thus, we compute the angle of rotation, the major axis, and minor axis, $(\alpha,\, M,\, m)$, from the estimated model parameters $(\hat{x}_c,\, \hat{y}_c,\, \hat{\beta}_1,\, \hat{\beta}_2,\, \hat{\beta}_3)$.

We use ODRPACK to obtain the maximum-likelihood estimates of the ellipse model parameters by the same procedure described in Section 2.3. As in circle fitting for an implicit model (10), ODRPACK minimizes (5) subject to

$$\begin{aligned} g_i(z_i + \delta_i; \beta) &= \beta_1((y_i - \delta_{y_i}) - y_c)^2 + 2\beta_2((y_i - \delta_{y_i}) - y_c)((x_i - \delta_{x_i}) - x_c) \\ &+ \beta_3((x_i - \delta_{x_i}) - x_c)^2 - 1 = 0, \;\; i = 1, \ldots, n, \end{aligned}$$

where $z_i = (x_i,\, y_i)$ and $\beta = (x_c,\, y_c,\, \beta_1,\, \beta_2,\, \beta_3)$.

The standard errors of $(\hat{x}_c,\, \hat{y}_c)$ are obtained directly from ODRPACK. However, the standard errors of the additional parameters of interest, $(\hat{\alpha},\, \hat{M},\, \hat{m})$, are computed from Monte Carlo simulations (Lafarge and Possolo [2015]) based on $\hat{\beta}$ and the estimated variance-covariance matrix of $\hat{\beta}$.

4. Results

Parameter and interval estimates determined by maximum-likelihood and Bayesian methods are shown in Tables 2 and 3 for the circle and ellipse models, respectively. There is very little difference between estimated parameters for maximum-likelihood and Bayesian methods for both circle and ellipse models. Plots of the parameter estimates and their 95 % confidence intervals and 95 % credible intervals are shown in Figures 5 and 6.

Table 2: Circle parameters estimated by ODR and Bayesian EIV.

Parameter	ODR Estimate (95 % Confidence Interval)	Bayesian EIV Estimate (95 % Credible Interval)
x_0, μm	71.89 (71.89, 71.90)	71.90 (71.89, 71.90)
y_0, μm	74.26 (74.26, 74.27)	74.27 (74.26, 74.27)
r, μm	62.47 (62.47, 62.47)	62.48 (62.47, 62.48)

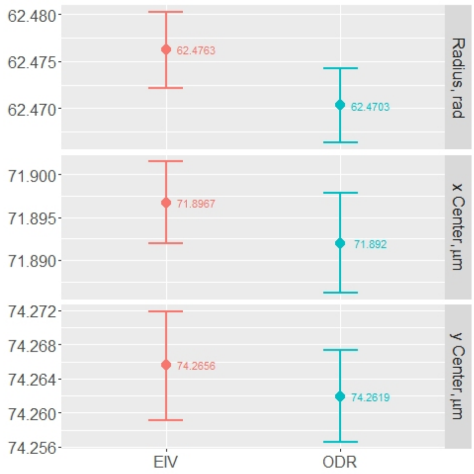

Figure 5: Bayesian and maximum-likelihood interval estimates for circle parameters.

Splett, Jolene D.; Jimenez, Felix; Koepke, Amanda. "Estimating the Parameters of Circles and Ellipses Using Orthogonal Distance Regression and Bayesian Errors-in-Variables Regression." Paper presented at 2019 Joint Statistical Meetings, Denver, CO, US. July 28, 2019 - August 01, 2019.

Figure 7 displays a portion of the measurement data and the circle fitting results for both methods. Plotted on the scale of the raw data, the two methods produce nearly identical circles. The plot shows how the raw data deviates from a circle due to imperfections in the optical fiber.

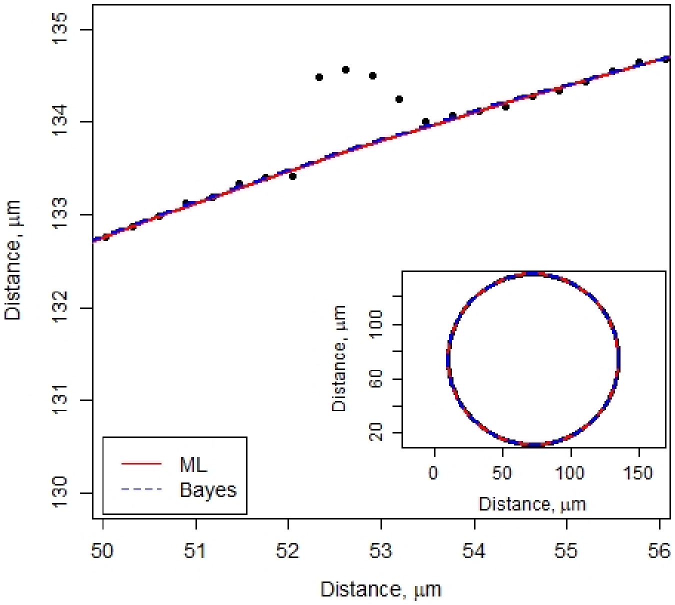

Figure 7: Maximum likelihood and Bayesian circle fitting results.

5. Discussion

We fit a circle model to a real data set and an ellipse model to a simulated data set using both maximum-likelihood and Bayesian approaches. The two methods produced similar parameter and interval estimates. The Bayesian approach is more intuitive for the error-in-variables problem than the maximum-likelihood method. Although we expected the Bayesian approach to be easier to implement than the maximum-likelihood method, we encountered many issues in practice when fitting an ellipse model to the simulated data using Bayesian EIV regression. For instance, the credible interval for the angle of rotation, α, does not cover the true value.

The two methods were further tested when we fit an ellipse to the optical fiber data. The maximum-likelihood method was able to produce parameter estimates, but the Bayesian EIV regression approach could not due to lack of convergence of the chains sampled using HMC. However, parameter estimates were obtained using Bayesian EIV regression when the angle of rotation was fixed at -0.55 rad. The failure of the Bayesian method stems from an inability to estimate α given the current model framework. The angle of rotation and the angles θ_i that correspond to each data point are likely not separable in this model formulation, especially when the data are very circular as is the case for the optical fiber data. Thus, a different model formulation is likely required. The maximum-likelihood method proceeds in a different fashion, minimizing the objective function subject to the constraint of the circle model. Imposing a constraint in an intuitive way, while maintaining the error-in-variables structure of the problem, seems much more difficult in a Bayesian framework. More work is needed to develop new models for Bayesian EIV regression.

Another assumption that should be examined in future Bayesian models is the independence of the errors in the x and y values. For most Bayesian EIV regression problems, this assumption makes sense, but for optical fiber data these errors are likely correlated. It is plausible that a large error in the x coordinate suggests a deformation in the fiber at that point, and would likely have a corresponding y value with a large error as well. The model for the data will depend on how the data are acquired. Future work will include formulating a more accurate model of the error structure for our data. Additionally, in the future we will try using more prior distributions that do not assume independence between the center, radius, and angles.

HOW TO USE AND HOW NOT TO USE CERTIFIED REFERENCE MATERIALS IN INDUSTRIAL CHEMICAL METROLOGY LABORATORIES

John R. Sieber
Chemical Sciences Division, National Institute of Standards and Technology
Gaithersburg, Maryland

ABSTRACT

As a producer of certified reference materials (CRMs), NIST faces high demand for Standard Reference Materials (SRMs). The demand is exacerbated by wide spread misuse of CRMs. When should one use CRMs? When should one not use CRMs? Must labs always use NIST SRMs? How can labs demonstrate analytical capabilities for their accreditation scopes? Why so many questions? Standards developers, laboratory accreditors, and laboratory staff must be able to understand these topics with respect to quality systems in compliance with ISO/IEC 17025. They must calibrate and validate test methods and document traceability to the International System of Units (SI). Many people working in laboratory accreditation and under the umbrella of a quality system don't fully understand what these things are, let alone the language of chemical metrology. On average, they have little training in analytical chemistry, elemental analysis, and reference material development. It is hoped this paper will impress upon the reader the need for understanding of how CRMs can be best used in the laboratory. This paper provides a brief background on the above problems and then looks at some of the support and reference information provided by NIST to metals and mining industries labs, commercial CRM producers, and accrediting bodies. The concepts and guidance apply broadly to chemical metrology and fundamental analytical chemistry. The paper includes examples (some from XRF) to illustrate concepts.

STATE OF AFFAIRS IN APPLIED CHEMICAL METROLOGY

To put the uses of certified reference materials into a modern perspective, consider that accreditation is now a *de facto* requirement to do business. For business purposes, it began with ISO 9001 more than 30 years ago. ISO is the International Organization for Standardization, which is one of the leading organizations for development of voluntary consensus standards for a wide range of topics, including laboratory organization practices and standard test methods. Laboratories find compelling business reasons to adopt an ISO/IEC 17025 (2017) quality system. ISO/IEC 17034 (2016) and the ISO Guide 30 series are required for organizations that produce certified reference materials, who may also need to comply with ISO/IEC 17025. However, these

Sieber, John. "How to Use and How Not to Use Certified Reference Materials in Industrial Chemical Metrology Laboratories." Paper presented at Denver X-Ray Conference, Lombard, IL, US. August 05, 2019 - August 09, 2019.

documents are difficult to digest, especially when there is little experience within the analytical community. The difficulty is compounded when there is little or no experience or guidance in how and when to best use certified reference materials. During two ASTM International/National Institute of Standards and Technology workshops in 2004 and 2014, it was shown that roughly four of five auditors from accrediting bodies came from the world of physical metrology, not chemical metrology. Unfortunately, these quality system auditors were not equipped to work with laboratories doing analytical chemistry.

With the combination of a low level of analytical chemistry expertise by auditors and management of accrediting bodies and by quality assurance officers at industrial companies, some audit requirements have been implemented that are incorrect for chemistry labs. The staff of labs undergoing audits typically do not know how and when to challenge requirements. They may also be dissuaded from doing so by their quality officer, because there is a desire to avoid jeopardizing the accreditation.

In seeking guidance, lab staff may look to the organizations from which they obtain certified reference materials (CRMs). After all, CRMs are an important and visible tool in the maintenance of quality performance of test methods. Commercial CRM producers are not necessarily equipped to help customers, because they may have a relatively low level of knowledge of the aspects of chemical metrology that apply to laboratory quality systems and uses of CRMs. A recent, informal survey of certificates of analysis issued by commercial reference materials producers uncovered shortcomings including incorrect treatments of uncertainty, mixing of certified and non-certified values in a single reporting table, lack of rigorous statistical approaches, and lack of indications of overall understanding of the fundamental concepts of CRM development: measurand, traceability, uncertainty, and validation.

Empirical observations appear to show that organizations involved in industrial chemical metrology and the support of industry labs are weak in the expertise needed to perform method validation and to utilize the statistical tools that support demonstration of the quality of test results. Consequently, unnecessary and expensive work is done in the name of quality. As a direct result, NIST SRMs have come to be seen as a panacea to satisfy accreditors and clients. If a lab uses NIST SRMs in calibrations, they are likely to get fewer questions and challenges from auditors, because auditors and the manufacturers' clients believe that is the way to get a quality calibration and to ensure the entire lab operation obtains quality results. This is simply not true, nor is it possible in all cases, because NIST cannot provide SRMs for all analytical needs.

PURPOSES FOR CERTIFIED REFERENCE MATERIALS

At NIST, CRMs are seen as providing higher order references with values for the true amounts of constituents and properties. Certified values are estimates of the true values, because the values are determined based on testing sufficient to elucidate biases in individual test methods, or at least among the methods (May, et al., 2000). Typically, that involves using multiple, independent test methods and examining how well the results from those methods agree. Independent test methods do not share the measurement method, and preferably, they do not share methods of sample preparation. In addition, quality assurance materials are analyzed by each method to critically evaluate the individual method.

In the ISO/IEC 17034 system, it is allowed to certify values for method-dependent definitions of a measurand. The measurand is simply what has been measured. For example, an analytical instrument may measure X-ray photons, for the example of X-ray fluorescence spectrometry (XRF), but the test method determines the mass fraction of an element, which is the measurand. A method-dependent value for a measurand would be obtained if only one test method is used for the assignment of the certified value for the reference material. Using a single test method, it is not possible to test for bias in a way that ensures the test result is an estimate of the true value.

Certified reference materials are primarily tools for validation of test methods, the idea is to use a CRM as if it is a typical sample. See the right side of Figure 1, which maps out how a laboratory result can be traced back to the SI. The test results are evaluated to see if they agree with the certified value. It is recognized that CRMs are also frequently used as calibration standards. See the left side of Figure 1. CRM use is unavoidable, and even necessary when using test methods such as XRF and spark optical emission spectrometry (Spark-OES). These methods are frequently used with solid form materials, e.g. alloys. Both techniques are typically used to determine 10 elements or more in alloys, and both typically require tens of calibration standards to fully calibrate such a method.

CRMs provide values with traceability links to units of the International System (SI), including the kilogram, the mole, and other common units. The SI is not the only standards system that may be used, but it is the world standard system for chemical metrology.

CRMs are often artifacts, that is they are exemplars of real materials with extraordinary homogeneity, often much better than is typically produced for the normal, industrial use of a material. However, many materials do have as-manufactured homogeneity that is fit for the purpose of certification.

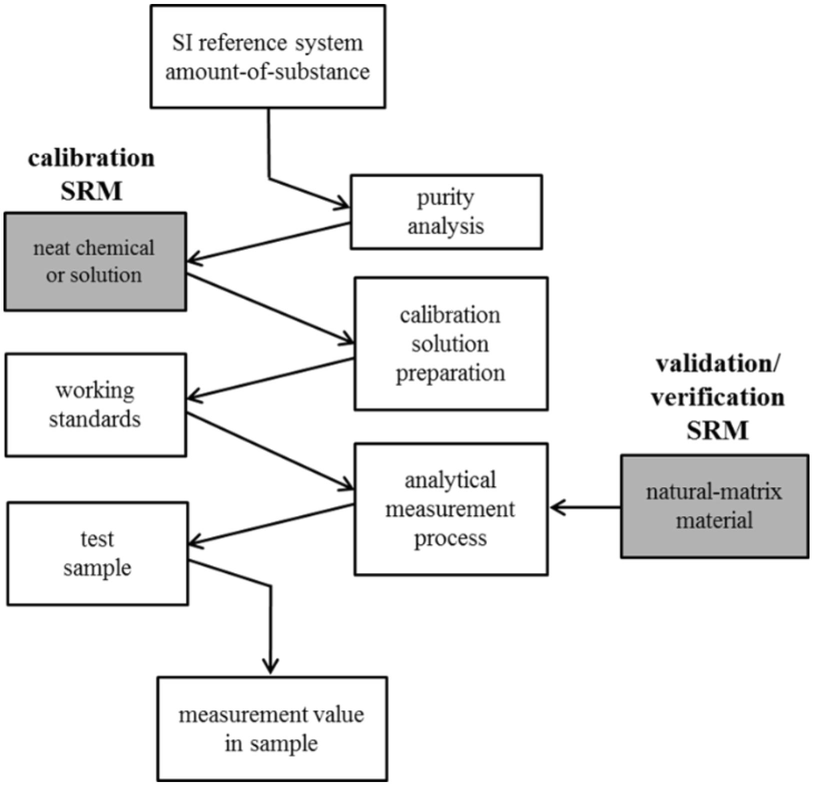

Figure 1. Traceability chain in chemical metrology showing points at which CRMs are used for calibration or validation. The SI is the International System of Units for metrology.

For reasons that will be explained below, one should know that CRMs are rare, expensive, and require long development times. NIST cannot guarantee the continued or continuous supply of any SRM. It may go out of stock with no notice to customers, and it may not be renewed. It may be put on sales restriction due to technical issues, e.g. stability testing, which may result in withdrawal of the material. NIST has a complex system for evaluation of the fitness of materials for their purpose and for the needs and potential impacts for SRMs. SRM users are a critical source of feedback to the NIST Quality System for Measurement Services. Their feedback helps define the needs for reference materials and reference methods in areas of both existing and emerging technologies.

PURPOSES FOR REFERENCE MATERIALS OF OTHER TYPES

The term reference material, in the global lexicon, covers all types of reference materials with CRMs being a subset. At NIST, the two categories are separate and are called Standard Reference Materials (SRMs) and reference materials (RMs). SRMs have at least one certified value based on the NIST criteria for certification and RMs are materials that have no certified values. When there are certified and non-certified values in the same COA, it is required by ISO Guide 31 (2015) to keep them separate. The goal is to prevent confusion by users of the CRM.

Note that in-house RMs can be developed in a single lab or developed by a third party under contract to the lab needing them. There are a number of reasons to use a RM instead of a CRM. Most reasons are based on the amount of information necessary for the intended use and the lower investment needed to develop an RM compared to a CRM.

The first use for an RM may be in process control, that is for use of control charts or control limits to maintain statistical control of a measurement process, i.e. a test method. For this purpose, the RM need not have a certified value. One can simply obtain a value for the measurand from a freshly implemented and validated calibration of the process to be controlled. Multiple measurements provide a mean value as the nominal target value, and the repeatability standard deviation is used to calculate warning and control limits. The primary need is to have a material in good supply and with a high level of homogeneity fit for the purpose, meaning the standard deviation from measurement to measurement, day to day and piece to piece is low enough to provide the required statistical control and not inflate the contribution of process control to the overall uncertainty of test results.

The same requirements apply to using a RM for drift correction. The need is for a homogeneous material that provides a stable signal measurable with high precision. Drift correction options may use more than one material to control drift of sensitivity and baseline. There is no need to certify the material. Simply obtain a value for the signal at time zero and compare that to future measurements to perform drift correction, if it is necessary.

A third use for an RM is instrument conditioning, that is measurements of a material to warm up and to stabilize the instrument response for a particular matrix. It is surprising how often labs will use expensive CRMs for this purpose. An excellent example comes from inert gas fusion and combustion test methods. People have been known to take a $1,000 bottle of an SRM and run six, eight, or even 10 samples just for this purpose. That is a great waste, because they don't need a certified material. They only need something with sufficient homogeneity to demonstrate the instrument is working correctly with the repeatability precision necessary for quantitative determinations of the species being measured. In the metals industry, ASTM International Committee E01 on Analytical Chemistry of Metals, Ores and Related Materials has made progress toward ending this behavior by including statements in the standard test methods that this should not be done.

Calibration is another common use for RMs. There is some debate about that, especially among quality system accreditors and advisory panels, who subscribe to the idea that the only way to get accurate calibrations is to use CRMs as the calibration standards. Many of them also believe the valid range of a calibration extends just from the lowest value from a CRM used as a calibrant to the highest value from a CRM used as a calibrant, and no farther in either direction. Of course, these beliefs ignore basic analytical chemistry and the concepts of limit of quantification at the low end and acceptable levels of uncertainty at the high end of a calibration curve.

One important part of calibration is evaluation of matrix influence and spectral interferences. Reference materials developed for this purpose may be the only viable tools for evaluating the magnitudes of such effects and calculating correction factors, in the absence of fundamental parameters modeling, such as with XRF methods. It may be difficult, if not impossible, to find CRMs that have the levels and variety of compositions necessary for empirical estimation of corrections for any given material matrix. Perhaps the most expedient way to obtain such materials is development of in-house reference materials. It may also be possible to commission a private sector CRM producer to develop a set of RMs.

ASTM Committee E01 published ASTM E2972 Standard Guide for Production, Testing, and Value Assignment of In-House Reference Materials for Metals, Ores, and Other Related Materials (2015). This standard guide was developed to provide explanations of the types and amounts of information necessary to create an in-house RM.

WHAT TO LOOK FOR IN A CERTIFICATE OF ANALYSIS

This discussion below covers just five categories of information required in a certificate of analysis. A complete list is found in ISO Guide 31. The first category is a description of the material. It is up to the CRM user to decide which materials are the best for their intended purpose. The description explains the composition of the material and gives the unit form and size. The form may be a bottle of chips of metal or powder, or it may be a disk of metal or glass. For bottled material, the mass of the bottle contents is given. For solid forms, the shape and dimensions are given.

The next category is a description of the intended uses of the material. For NIST SRMs designed for chemical metrology, the intended uses are summarized by the following sentence. This SRM is intended primarily for evaluation of methods of analysis for similar materials and for validation of value assignment of in-house RMs. There may be specialized uses, possibly related to specific test methods, validation of results for regulatory purposes, or calibration of special equipment.

Next, and perhaps most important is an explanation of the certified values. There are three topics which must be addressed: (1) definition of measurands, (2) explanation of metrological traceability, and (3) definitions of uncertainty estimates. For the definition of measurands, a typical statement is as follows. The measurands are the mass fractions of the total amounts of the elements in a steel matrix. Other possibilities include measurands that are chemical compounds or chemical states of elements. The matrix may be any type of material from steel and other alloys to plastics, foodstuffs, water, fuel oils, and many more. Metrological traceability states the units system for the certified values, which is discussed further below. Uncertainty estimates are typically defined as expanded uncertainty estimates expressed at a coverage level of approximately 95 % and a more detailed discussion of uncertainty follows the details on traceability.

The period of validity of certification is relatively simple in that it can be an expiration date or indefinitely, which means the assigned values and uncertainty estimates for the material are expected to remain valid for a very long period of time. This option is used when a material is known to be highly stable, for example most metals and alloys, when stored correctly. Because CRM producers must perform stability testing and respond to customer inquiries, all CRMs are monitored for their stability.

The last category of information on this top five list is instructions for storage, handling and use. Users need to know how much of a unit is certified. Perhaps the material is a disk of chill-cast metal, and it may be certified for only the first 10 mm deep from the original test surface. The user will also need to know any instructions for sample preparation. If the assigned values are given in a dry basis, instructions for drying are given. Another example is a warning about potential contamination of a disk of metal when a fresh surface is prepared by grinding. Bottles of powder and liquids must be carefully mixed prior to sampling. Every certificate of analysis should provide a minimum recommended sample quantity for an analysis. This will be explained later under the heading of heterogeneity. Finally, the instructions may explain how to use the uncertainty estimates for comparisons of values and for propagation of uncertainty, for which there is more information later in this paper.

METROLOGICAL TRACEABILITY

It is the responsibility of the CRM issuer to establish metrological traceability (traceability for short) of assigned values to a higher-order reference system such as the SI. Traceability is the association of units with an assigned value. In Figure 1, the measured value at the bottom has units from the SI at the top, when the two are connected by calibrations with uncertainty estimates. In the figure, the traceability chain is the assemblage of actions in the boxes and the arrows connecting those boxes. Here is an example SRM statement: “The certified values are metrologically traceable to the SI derived unit of mass fraction expressed as percent”. For NIST SRMs, this is usually sufficient wording to ensure SRM customers that NIST has done the work needed to establish traceability. Many CRMs from commercial producers have no statement of this kind. Instead, they list CRMs and chemicals used in the certification process, without an explicit statement that traceability was established to a specific SI unit. It is an indication they need more training in this area.

For a testing lab to discuss traceability, they must have first dealt with uncertainty estimates for their results, and then they may wish to state something like the following: “The result value is traceable to the SI unit as realized by NIST through the value for element Xx in Standard Reference Material YYY”. While there may be value in being able to show a link to NIST, the traceability link can be through values provided by any CRM producer as long as that producer can demonstrate traceability to the SI units system.

It is also possible for a lab to achieve metrological traceability to an SI unit without a Certified Reference Material. The simplest way is to use a high-purity material having an assay with stated uncertainty and a balance calibrated to establish traceability to the kilogram. There are discussions and demonstrations of this concept in the published papers of Gotthard Staats (1988,1990,1993).

Traceability can be established by using a CRM as a quality assurance material. A comparison between measurement results may be viewed as a calibration, if the comparison to a reference material is used to check and, if necessary, correct the quantity value and measurement uncertainty attributed to the measured material (JCGM 200:2012).

HETEROGENEITY

Composition variance is a part of the overall uncertainty of the value of a measurand. Heterogeneity of a material is evaluated based on the purposes for which the material is intended. With that knowledge, the decision can be made as to whether the material is fit for the intended purpose. To test heterogeneity, choose a method or methods based on considerations of minimal sample preparation, small quantity tested, low counting uncertainty, instrument stability, and testing *within-unit* variance versus *among-units* variance. In most cases, this testing must be done after the candidate material has been prepared and packaged as units for sale.

One or more quantitative analysis methods may adequately account for material heterogeneity as an effect contributing to one of its components of variance. The CRM developer should plan quantitative analyses with that in mind and balance it against the amount of work requested of analysts. In the final assessment of overall uncertainty, it may or may not be necessary to have a component of uncertainty explicitly stated to inform a user of the material heterogeneity. The decision must be made for every CRM development project. Some CRM producers believe a standard uncertainty component for heterogeneity must be published for every measurand in every certificate of analysis. This is not true; however, the COA should contain a statement about heterogeneity, especially when sampling is strongly affected. For example, the heterogeneity and structure of a material may be such that certain portions should not be sampled or that for a particular test method multiple portions should be tested, and the results averaged.

On the concept of minimum sample quantity, think of choosing small aliquots like using a more powerful microscope. At some magnification, it becomes apparent the material is very heterogeneous. Users of CRMs need to know how small a sample can be taken that still allows the analyst to expect to obtain a single result with a value and an uncertainty estimate comparable to the certified value and its uncertainty estimate. If smaller specimens than the recommended minimum must be used, the user must take multiple samples and calculate the mean for comparison to the certified value.

When heterogeneity among units of a CRM is large, the difference between the true value for amount of measurand in one unit and the certified value may be large, or the difference between any two units may be large. Comparisons among units and of a unit to the certified value become more difficult. Figure 2 represents this concept, where the top, black curve shows the range of values for individual bottles as the width of the superimposed (blue) rectangle. This is an exaggerated case of high unit-to-unit variance. The central point of the upper curve represents the overall certified value with the width of the curve representing the uncertainty interval estimated for the certified value. The bottom (red) curve represents the composition of a single unit of the material with the central point being the true value of the amount of substance in that one unit. The (green) rectangle superimposed on the lower curve represents composition variance within the single unit as being smaller that the upper (blue) *among-units* variance. Greater heterogeneity among CRM units causes more units to be shifted farther from the overall certified value. Some units may have their (red) curve shifted way to the left, and some may be shifted way to the right. Therefore, comparisons between any two units must allow for the probability of larger differences, which makes the CRM *less* useful for high precision comparisons. The overall composition variance must be minimized with the contribution of *among-units* variability being less significant than *within-unit* variability. That is, the lower (green) rectangle for a single unit should be wider than the upper (blue) rectangle, but not so wide as to cause the problem of excessive heterogeneity within each unit. When heterogeneity is sufficiently low overall, a material is described as having homogeneity fit for purpose.

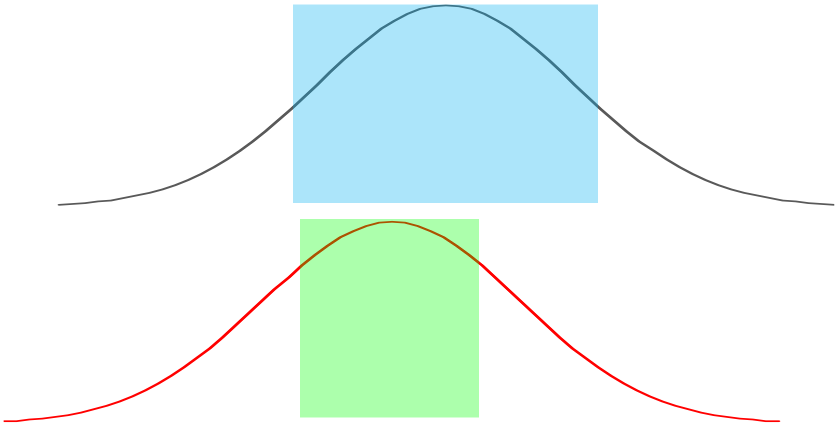

Figure 2. Conceptualization of uncertainty with the top curve representing the certified value for a CRM as the central point of the Gauss curve, the width of the Gauss curve representing 95 % coverage interval, and the top (blue) rectangle representing an exaggerated contribution by overall material heterogeneity. The bottom curve represents the true value for a single CRM unit as the central point of the (red) curve with the curve and (green) rectangle representing the overall and *within-unit* heterogeneity for that unit respectively.

UNCERTAINTY

NIST consensus values and uncertainty estimates for measurands are calculated using statistical methods with many different approaches available, and they can be tailored to each CRM project. Examples of the tools can be seen in the NIST Consensus Builder at https://consensus.nist.gov/, which provides three different approaches for exploration. For those interested in general purpose, statistical tools for evaluation of uncertainty, NIST offers the Uncertainty Machine at https://uncertainty.nist.gov/. Both web tools have online manuals with examples.

In most cases, certified values are accompanied by a symmetric uncertainty interval, expressed as a half-interval, U, with approximately 95 % coverage. That means the full interval, $2U$, is a range within which the true value is expected to be with 95 % confidence. Propagate uncertainty using the combined standard uncertainty, $u_c = U/k$., where k is a coverage factor chosen for the effective degrees of freedom in the evaluation of the certified value. Values for k are given in the certificate of analysis. If for some reason, there is no k value given, the user is advised to set $k = 2$ and to assume the effective degrees of freedom are high enough for that approximation. Older NIST COAs may give just u_c based on variance among collaborator mean results and expert judgement of other components of uncertainty.

In some cases, the uncertainty estimate may be given as an asymmetric interval. Then, the COA will show the certified value accompanied by the range of the interval having approximately 95 % coverage. The decision to provide an asymmetric interval may result from the distributions of values from individual test methods having markedly different widths on either side of the consensus value. In some cases, the consensus value may be so close to either zero or 100 % that the statistics indicate values < 0 or > 100 % are possible. Then, the uncertainty interval will be truncated at zero or 100, making the interval asymmetric. Users can approximate u_c by dividing the range of the coverage interval by four. A conservative alternative is division of the wider side of the range by two. An approach recommended by statisticians is to use a Monte Carlo method for propagation of error, using the actual error distributions representing the uncertainties of the certified values. This method requires fewer assumptions and approximations. To make it possible, the CRM producer must supply files containing the error distributions for the assigned values. NIST SRM 2780a Hard Rock Mine Waste provides that information through a link to the NIST SRM Online Request System:
(https://www-s.nist.gov/srmors/view_datafiles.cfm?srm=2780a).

CRM users must be aware of the great variety of uncertainty definitions to be found in commercial CRM certificates. When in doubt, ask the issuing body to explain their approach and the components of uncertainty included in the estimate. At a bare minimum, the components must include an estimate of repeatability standard deviation from analyses of the material and a standard uncertainty estimate based on the uncertainty of calibration. There may be additional uncertainty components, but without these two things, an uncertainty budget is incomplete.

COMPARING YOUR RESULT TO A CERTIFIED VALUE

The primary purpose of a comparison between a found result and a certified value is to test for bias in the analytical method. ISO Guide 33 (2015) provides an equation for a bias detection limit as shown in Equation 1, where x is the value from each source, u is the combined standard uncertainty for each value, and k is a coverage factor. Most experts agree that $k = 2$ is the most reasonable and convenient choice to approximate 95 % confidence. When the difference between the found result and the certified value is less than this detection limit, there is no evidence for bias in the found result.

$$\left|x_{found} - x_{CRM}\right| \leq k\sqrt{u_{found}^2 + u_{CRM}^2} \qquad (1)$$

The first thing needed for this calculation is an estimate of the uncertainty of the found result. Again, a complete uncertainty budget providing an overall estimate similar in definition to the certificate estimate would be ideal. However, one can begin with repeatability standard deviation and add components for other sources of uncertainty, including calibration, to improve the coverage of the uncertainty of the found result. The more inclusive the uncertainty estimate, the better the information to be gained from the comparison.

The concepts explained above can be illustrated as in Figure 3 in which the four cases are designated: 1) Found result (indicated by X) with no uncertainty either falls outside the certified value uncertainty interval (vertical error bar) (1a), or if the analyst is lucky, it falls inside the interval (1b); 2) Certified value falls within the found value uncertainty interval; 3) Found and Certified intervals overlap and either both values fall inside each other's interval (3a) or both values fall outside each other's interval (3b); and 4) the two intervals do not overlap. For case 1a, there is no evidence the found and certified values agree. For case 4, there is evidence of a bias between the values. For all other cases, there is evidence providing some level of confidence there is agreement. Please note that Eq. 1 may indicate a detected bias in contradiction to Figure 3b, because the standard uncertainty estimates are added in quadrature. It should also be understood that case 1b was referred to as luck, because at NIST the goal is to make the uncertainty estimate as small as possible to show the level of confidence that the certified value is a good estimate of the true value. This goal is in opposition to the goal of including the material heterogeneity variance in the uncertainty estimate, which tends to broaden the coverage interval. In other words, a compromise must be struck to improve confidence in the certified value without hindering the practical utility of the CRM.

EQUIVALENCE OF CRMs AND RMs

The last topic for discussion addresses an example of a faulty accreditation requirement. One well-known requirement in the metals industry is that all CRMs must have been developed under an ISO/IEC 17034 accredited system. While such a situation would be ideal, it causes significant problems in practice. It may be that this requirement resulted from an attempt at universal application of the relatively new ISO/IEC 17034 to all accreditations. Because ISO/IEC 17034 (and its predecessor ISO Guide 34) is a relatively recent phenomenon, there are relatively few CRMs that are compliant out of the hundreds of extant CRMs. The implementation of Guide 34 did not automatically invalidate all existing CRMs at that time. To do that would be to try to argue that none of the CRM producers and national metrology institutes knew how to develop certified reference materials prior to sometime in the 1990s. That simply isn't true. In fact, Guide 34 grew out of efforts by qualified organizations to codify the processes in CRM development for the general benefit of all.

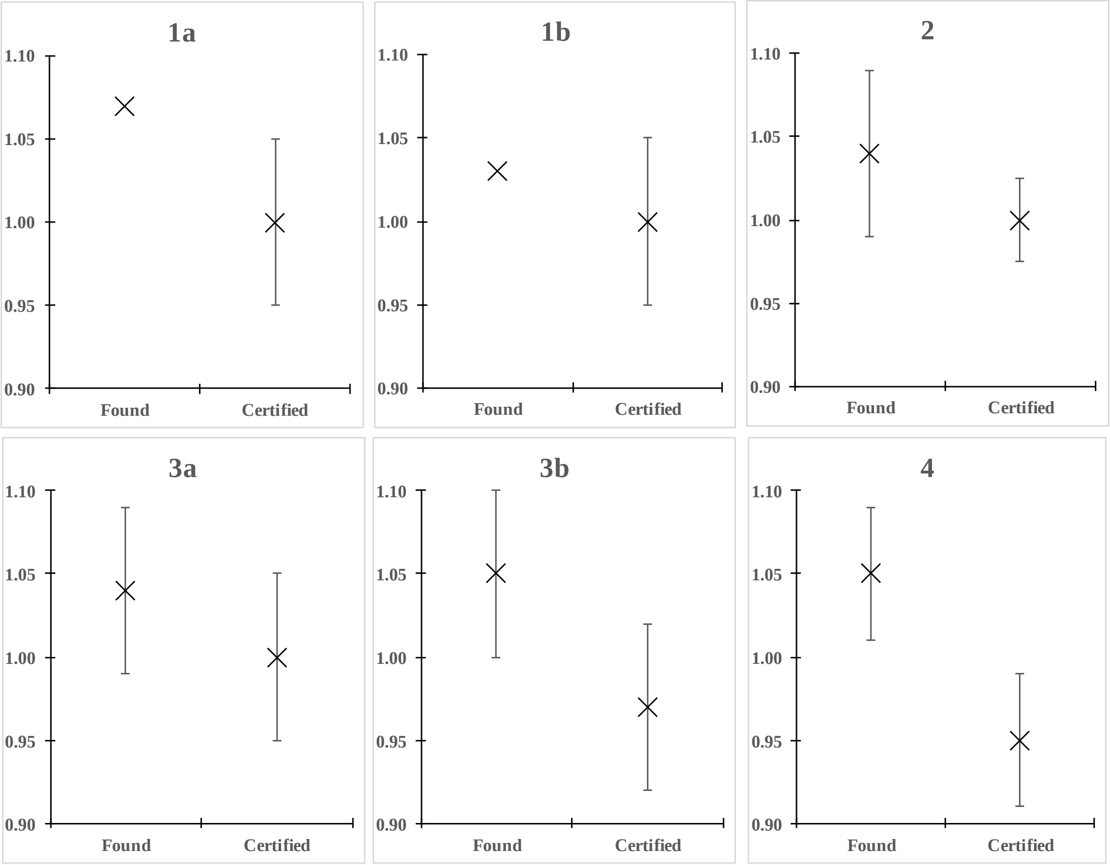

Figure 3. Example cases for comparisons of found results to a certified value and accompanying uncertainty estimate. Case 1a: bias indicated, found value without uncertainty outside certified value coverage interval; Case 1b: no evidence of bias, found value without uncertainty falls inside certified value interval; Case 2: no evidence of bias, uncertainty of found value overlaps certified value; Case 3a: no evidence of bias, found coverage interval overlaps certified value and certified value interval overlaps found value; Case 3b: may or may not be bias, two coverage intervals overlap, but do not cover the values; and Case 4: bias indicated, no overlap of coverage intervals.

A good way to demonstrate that many CRMs in existence prior to the advent of ISO Guide 34 are still good even after the conversion to ISO/IEC 17034 is through the concept of equivalence. Equivalence means the CRMs, test methods or test results from different sources are all fit for the same purpose. The example shown in Figure 4 is calibration of copper in low alloy steel, using CRMs developed from 1965 through 1993. There are 36 CRMs with 33 developed by NIST. The other three were issued by Bureau of Analysed Samples Ltd. (Middlesbrough, England). In the graph, the calibration curve passes through every set of horizontal error bars. That fact and the relatively narrow sizes of the error bars indicate that all 36 CRMs are fit for the purpose of calibration of Cu in steel. In other words, they are all equivalent for that application. Consequently, a subset of the CRMs would be sufficient for the calibration task, and no biases would be expected among results from different subsets of these CRMs.

The concept of demonstration of equivalence has a practical application in testing laboratories. Perhaps a lab has a small collection of CRMs and RMs with two or three each from multiple CRM producers and a number of RMs included. When it can be demonstrated that all of them fit on the same calibration curve within their respective uncertainty estimates, the lab has validation evidence to show to auditors, who may challenge the lab's practices, their choices of CRMs and their inclusion of RMs as calibration standards. Of course, the RMs must have defensible uncertainty estimates that can be used as part of the equivalence comparisons. However, they need not all be certified under an ISO/IEC 17034 compliant quality system.

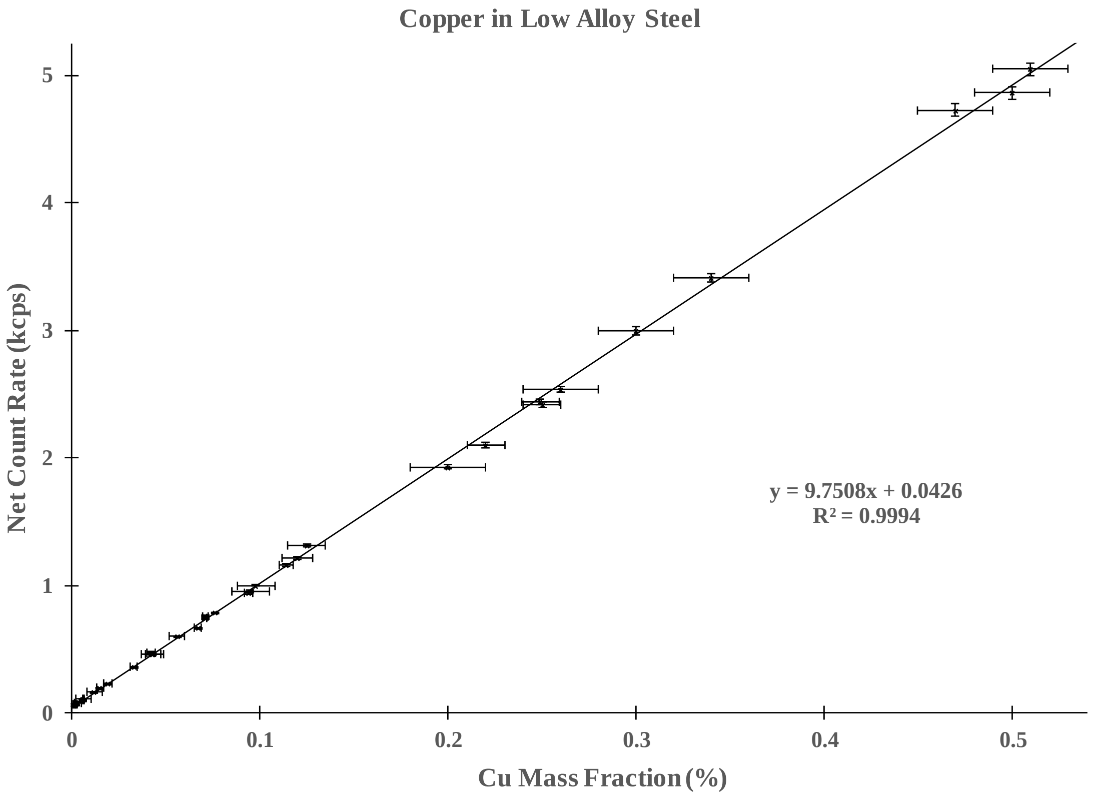

Figure 4. Calibration of a wavelength dispersive XRF spectrometer for copper in low alloy steel, using 33 NIST SRMs and three materials from Bureau of Analysed Samples. Horizontal error bars equal the published uncertainty estimate from each certificate of analysis. Vertical error bars are X-ray counting standard uncertainty.

CONCLUSION

This manuscript is intended to teach a broad audience some fundamentals of certified reference material development, documentation, and use. It began by setting the stage with a description of the state of affairs in industrial chemical metrology in which there is a strong need for education in basic analytical chemistry and in method validation. The discussion covered the primary purposes for CRMs and contrasted them to uses better suited to non-certified RMs. Then, fundamentals of CRM documentation were described to explain what a CRM user needs to ascertain from a certificate of analysis. Of those fundamentals, metrological traceability, heterogeneity and uncertainty were explained in greater detail from the NIST perspective. The paper finished with two examples of how to interpret measured results for CRMs, including testing for bias between found results and certified values and demonstration of equivalence of reference materials. Following the references list below, the reader will find a list of recommended reading on some of the topics discussed herein.

SRM development and other support provided by NIST is done with user needs in mind. NIST welcomes feedback and requests for support. The most direct way to provide feedback is by contacting the NIST Technical Contact for the individual SRM of interest, or one that is similar to the composition needed. For example, see SRM 8k (NIST, 2017) for which this author is Technical Contact. Questions of a more general nature can be sent to srms@nist.gov, or one may visit the Standard Reference Materials website at www.nist.gov/srm/.

Techniques to Estimate Commercial Building Infiltration Rates

Andrew Persily*, Lisa Ng, W. Stuart Dols, and Steven Emmerich

National Institute of Standards and Technology
100 Bureau Drive MS8600
Gaithersburg, Maryland USA
andyp@nist.gov

ABSTRACT

The estimation of low-rise, residential building infiltration rates using envelope airtightness values from whole building fan pressurization tests has been the subject of much interest and research for several decades, constituting a major topic of discussion during the early years of the AIVC. A number of empirical and model-based methods were developed, with their predictive accuracy evaluated in field studies around the world. Infiltration estimation methods for residences are now commonly available in guidance documents and employed in whole building energy and indoor air quality modeling. However, the greater complexity of many commercial buildings, including their size, multizone airflow dynamics and the influence of mechanical ventilation systems, makes the estimation of infiltration rates from fan pressurization test results more challenging. As a result, progress on infiltration estimation methods for commercial buildings has been slower than in low-rise residential. This paper reviews methods for estimating commercial building infiltration rates going back to the 1970s. More recent approaches using correlations based on a large number of multizone airflow model simulations are presented as a more feasible approach. Particular attention is given to how energy models have dealt with infiltration estimation in commercial buildings, with a detailed discussion of how the energy analysis program EnergyPlus has considered infiltration. More complex and presumably more accurate methods of accounting for the energy impacts of infiltration in commercial buildings, based on coupled airflow and energy analysis models, are also discussed as they have become more accessible in recent years given the increasing power of personal computing.

KEYWORDS

airflow; commercial buildings; infiltration; modeling

1 INTRODUCTION

Building infiltration rates have important impacts on energy use, indoor air quality (IAQ), and moisture management, and these rates have been studied for more than 80 years (Coleman and Heald, 1940). The importance of infiltration was demonstrated by the creation of the Air Infiltration Centre (AIC), which held its first conference in 1980 focusing on infiltration measurement (Air Infiltration Centre, 1980), and subsequently evolved into the Air Infiltration and Ventilation Centre (AIVC). The term infiltration is used in this paper to describe the airflow into and out of buildings through unintentional leakage in the exterior building envelope due to pressure differences induced by wind, indoor-outdoor temperature differences and the operation of ventilation and other building systems. It is interesting to compare this with the definition promulgated by the AIVC in 1992, i.e., “The uncontrolled inward leakage of outdoor air through cracks, interstices, and other unintentional openings of a building, caused by the pressure effects of the wind and/or the stack effect” (Limb, 1992). This earlier definition mentions only inward flow, although many discussions of infiltration implicitly include outward flow or exfiltration. It doesn’t mention pressure differences induced by building systems, such as exhaust fans, atmospherically-vented combustion appliances and unbalanced ventilation systems. In addition to these pressures, infiltration rates also depend on building envelope airtightness, airtightness of interior partitions and air temperatures within individual

Persily, Andrew K. "40th AIVC - 8th Tight Vent & 6th Venticool Conference, 2019 Techniques to Estimate Commercial Building Infiltration Rates." Paper presented at 40th AIVC - 8th TightVent - 6th Venticool Conference, 2019, Ghent, BE. October 15, 2019 - October 16, 2019.

building zones. The physics of infiltration are well-understood and have been documented in a variety of places, including Dols and Polidoro (2015) and Etheridge and Sandberg (1996).

Much of the early work on infiltration focused on low-rise residential buildings based in part on their relative simplicity compared with commercial and institutional buildings, which are often larger and more complex, and have more zones and more elaborate ventilation systems. For the purposes of this paper, the term commercial building is used to describe commercial and institutional buildings that are used for a variety of purposes (e.g. work, education, healthcare, retail, public assembly) but not as residential living spaces. Multi-family residential buildings are also not included in this discussion. This description of commercial buildings is admittedly quite broad, and it includes buildings of the same size as single-family residences; the key point is that these commercial buildings include many large, complex, and mechanically ventilated buildings. In general, infiltration rates are more challenging to measure in commercial buildings than low-rise residential, again given their multizone layout, larger size and variations in ventilation system layout and operation. These factors often make it difficult to apply single-zone tracer gas measurement techniques as they complicate achieving uniform tracer gas concentration, which is required in using these techniques (ASTM, 2011). Multi-zone tracer methods exist, which can overcome these challenges, but they are much more difficult to apply (Etheridge and Sandberg, 1996) .

Given that infiltration rates in commercial buildings vary with weather and system operation, they need to be measured many times to characterize infiltration in a given building. Such long-term infiltration measurements have only been done in a small number of large commercial buildings (Grot and Persily, 1986). Therefore, in lieu of extensive measurement efforts, methods to estimate commercial building infiltration are needed to support design, energy calculation, IAQ analysis, retrofit planning and other applications. There is a long history of infiltration estimation methods in low-rise residential buildings, going back to the first AIC conference (Kronvall, 1980; Warren and Webb, 1980; Sherman and Grimsrud, 1980). This earlier work focused on methods to estimate infiltration rates from blower door measurements of envelope airtightness and weather conditions. These techniques evolved over time and are widely used and described in practical guidance (ASHRAE, 2017).

In contrast to low-rise residential buildings, the development of infiltration estimation methods for commercial buildings has progressed more slowly. Due to the often greater complexity of commercial buildings, there have been fewer measurements of envelope airtightness and infiltration rates in commercial buildings to support the testing of estimation methods, also contributing to slower advancement. Nevertheless, infiltration estimation methods in commercial buildings have progressed, and this paper outlines their development and summarizes tools currently available to designers, building scientists and other practitioners.

2 EARLY ESTIMATION METHODS

The earliest description of a large building infiltration estimation method known to the present authors was published before the first AIC conference (Shaw and Tamura, 1977). In that work, separate equations developed specifically for tall buildings are presented for infiltration flow rates due to wind and stack effect. The inputs to the wind infiltration component include building height and width, an envelope air leakage coefficient (that could come from a building pressurization test), wind speed and a wind direction adjustment factor. In addition to the leakage coefficient, the stack infiltration equation requires the length of the building perimeter, the indoor and outdoor air temperatures, the height of the neutral pressure level, and a thermal draft coefficient. The authors do not provide guidance on the neutral pressure level, but it can be measured in conjunction with a fan pressurization test. The thermal draft coefficient depends on the airtightness of the exterior walls relative to the interior partitions and captures how the static pressure decreases with height within the building interior, i.e., whether it is linear with height, which would reflect a relatively open interior, or whether there are pressure drops across floors and other interior partitions. The authors note that the value of this coefficient is around 0.8 in office buildings based on the small number they had studied but note the lack of measured values for apartment buildings. The reference also includes an equation to combine the wind and stack infiltration components to estimate the total infiltration rate. In the 42 years since its publishing, Shaw and Tamura (1977) is only cited 34 times in Google Scholar, most of which are publications on infiltration modeling. None of these references appear to have employed the model to predict infiltration rates and compare them with measured values.

The other means of calculating infiltration rates in commercial buildings is multizone airflow modeling, i.e., CONTAM or other software (Dols and Polidoro, 2015; Walton, 1989b; ESRU, 2002; IES, 2019). These models involve a multizone representation of a building and use mass balance analysis to solve for the airflows between all building zones including the outdoors, from which building infiltration rates can be calculated. These models account for all relevant building airflow physics, though their neglect of the conservation of momentum and energy limits their applicability in buildings that are naturally ventilated and with interior air that is not quiescent. Given the need to for many inputs to describe multizone building airflow systems, such models are generally not considered to be readily accessible to practitioners, though they are widely used in the design of smoke control systems (Klote et al., 2012).

3 INFILTRATION ESTIMATION IN ENERGY ANALYSIS

While commercial buildings have always experienced air infiltration through envelope leaks, and early studies showed that the rates were significant (Grot and Persily, 1986), infiltration was often neglected in energy analysis in part due to its perceived complexity. Rather than take this important phenomenon seriously, many simply assumed infiltration was equal to zero. In some cases, at least in the U.S., this assumption was justified by claiming that mechanically ventilated buildings are pressurized, thus eliminating infiltration. This justification was based on the common practice of providing more supply air than return air. In reality, the complexity of multizone building airflow systems results in indoor-outdoor pressure differences being localized phenomena that depend on outdoor wind patterns, building height, and differences between the rate at which ventilation air is delivered to and removed from individual building zones. As a result, infiltration will occur even when more ventilation air is supplied to a building than removed by exhaust unless detailed analyses and control strategies are implemented to control pressure differences across the entire envelope.

Another approach, embodied in the EnergyPlus energy analysis software and other tools, is to use empirical equations for estimating infiltration. These empirical equations were developed from analysis and testing of low-rise residential buildings as noted below, and do not capture the airflow physics of large, multizone or mechanically ventilated buildings. In the case of EnergyPlus, the following equation is available for calculating infiltration rates:

$$\text{Infiltration} = I_{\text{design}} \bullet F_{\text{schedule}} \left[A + B|\Delta T| + C \bullet W_{\text{s}} + D \bullet W_{\text{s}}^2\right] \qquad (1)$$

where I_{design} is defined by EnergyPlus as the "design infiltration rate", which is the airflow through the building envelope under design conditions. Its units are selected by the user and can be h^{-1}, $m^3/s \bullet m^2$ or m^3/s. To apply this infiltration approach in EnergyPlus, a value of I_{design} is assigned to each zone. F_{schedule} is a factor between 0.0 and 1.0 that can be scheduled, typically to account for the impacts of fan operation on infiltration. $|\Delta T|$ is the indoor-outdoor temperature difference in °C, and W_{s} is the wind speed in m/s. A, B, C and D are constants, for which values are suggested in the EnergyPlus Engineering Reference (DOE, 2019). As noted in that reference, this equation is based on measurements in 10 one- and two-story houses, for which 30 infiltration rates were fit to the equation (Coblentz and Achenbach, 1963). The default strategy in EnergyPlus is to assume a constant infiltration rate, i.e., A=1 and B=C=D=0. However, this approach does not reflect known dependencies of infiltration on outdoor weather and HVAC system operation. The EnergyPlus Engineering Reference provides values of A, B, C and D based on two energy analysis programs that preceded EnergyPlus, BLAST and DOE-2. No references are provided for these values, but they are presumably based on studies in low-rise, residential building as there were no studies of infiltration in commercial buildings available when these two predecessor programs were developed. The EnergyPlus Engineering Reference also includes two other empirical infiltration models developed for low-rise residential buildings, i.e., the Sherman-Grimsrud and the AIM-2 models described in Chapter 16 of the ASHRAE Fundamentals Handbook (ASHRAE, 2017). While these approaches account for weather effects, they are also based on low-rise residential buildings and do not account for the airflow physics in larger buildings and in buildings with the more complex mechanical ventilation systems typical of commercial buildings.

Gowri et al. (2009) proposed a method to account for infiltration in commercial buildings that was developed using a square medium-size office building and a building envelope airtightness value, such as can be obtained through pressurization testing. Assuming a constant indoor-outdoor pressure difference of 4 Pa, Gowri calculated an infiltration rate using an approach that accounts for wind but not temperature effects, despite their known importance in taller buildings and colder climates. Gowri recommends that this infiltration rate be multiplied by a wind speed adjustment and by a factor of 0.25 when the HVAC system is on and 1.0 when the system is off. Overall, the method greatly oversimplifies the dependence of infiltration on building envelope airtightness, weather, and HVAC system operation.

EnergyPlus also has the ability to perform multizone airflow analysis, as embodied in the CONTAM model discussed above, using the EnergyPlus Airflow Network model (DOE, 2019). This model is based on a predecessor to CONTAM referred to as AIRNET (Walton, 1989a) and an earlier version of CONTAM (Walton and Dols, 2003). It is worth noting that while CONTAM has evolved considerably in the intervening years, the EnergyPlus Airflow Network model does not incorporate all of those improvements.

Han et al. (2015) compared the use of various infiltration estimation methods in improving the accuracy of building energy simulations. One method used the EnergyPlus Airflow Network model with three infiltration levels (leaky, medium and tight) as defined via DesignBuilder, which is a graphical front-end to EnergyPlus. The other methods utilized various means to establish monthly and annually averaged wind pressures including the use of an AIVC database of wind tunnel measurements and the use of computational fluid dynamics (CFD) to model the building exterior. For this case study, the CFD-based methods resulted in energy predictions that more closely matched utility bills.

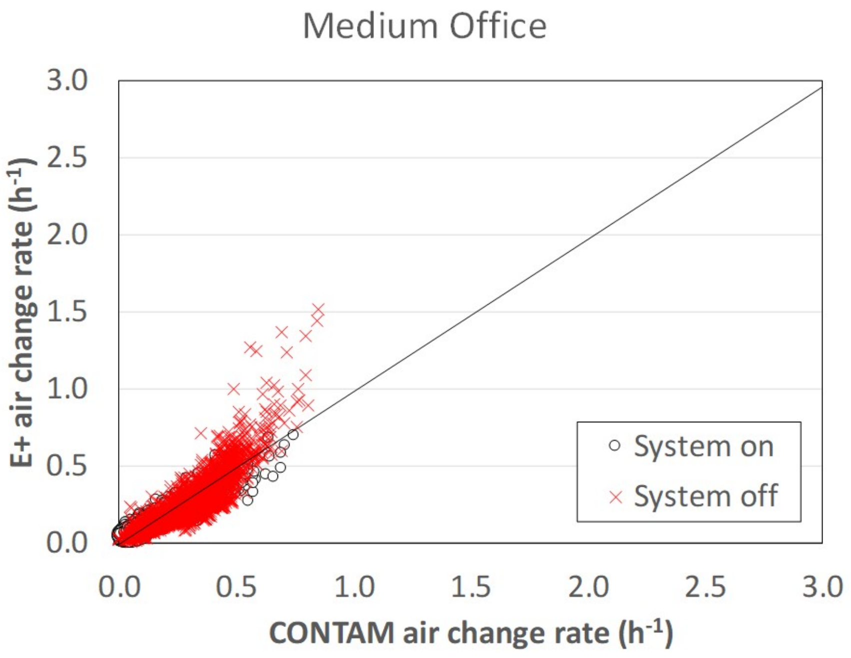
4 MORE RECENT ADVANCES

As building energy use has become of increasing interest over the years and as envelope insulation levels have increased, there has been more recognition of the importance of infiltration, including the need to control air leakage and to reliably estimate infiltration rates. These changes were reflected in the inclusion of requirements for continuous air barriers and envelope airtightness testing in energy efficiency standards such as ANSI/ASHRAE/IES Standard 90.1 (ASHRAE, 2016). As a result, new approaches to estimating infiltration were developed and are becoming more widely applied. This section describes one such approach, which uses values of the coefficients in Equation (1) developed specifically for commercial buildings, as well as a second approach using coupled energy and airflow analysis methods.

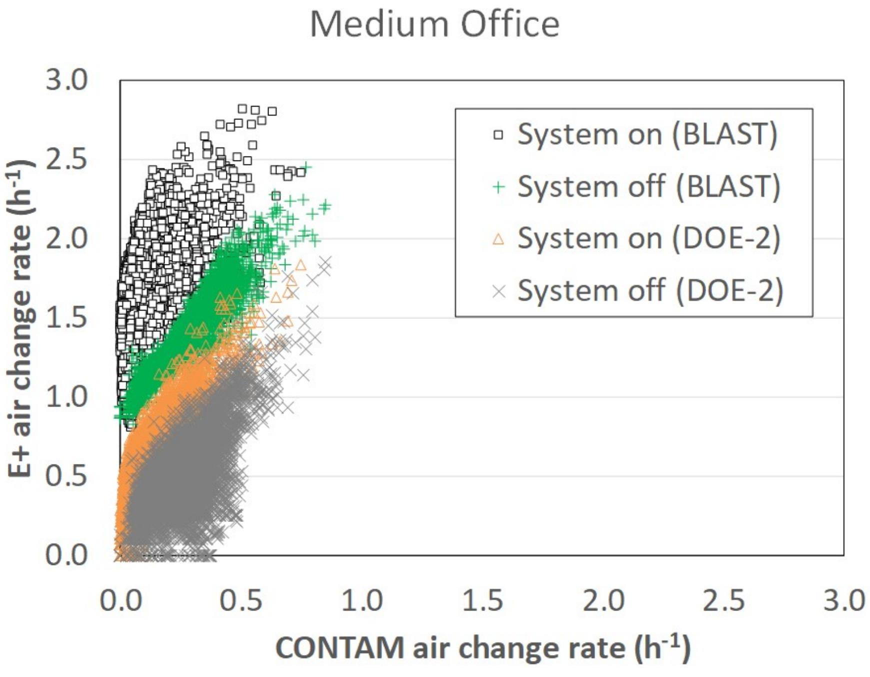
4.1 Large Building Infiltration Correlations

Values of the coefficients in Equation (1) for commercial buildings were recently developed by NIST. These coefficients were identified from investigations of the relationships between infiltration rates calculated using multizone airflow models, weather conditions, and building characteristics, including envelope airtightness and HVAC system operation. These relationships were developed using CONTAM models of the EnergyPlus models of 16 DOE commercial reference buildings (DOE, 2011; Goel et al., 2014). For each of these 16 buildings, different versions of the EnergyPlus models exist that correspond to different versions of ASHRAE Standard 90.1. In the ASHRAE 90.1-2004 versions, infiltration was modeled as 100 % of the design value when the HVAC system was off and 25 % (or 50 %) of that value when the HVAC system was on using the F_{schedule} term in Equation (1). Further, A=1 and B=C=D=0 in Equation (1), which means the weather dependence of infiltration was ignored. In the ASHRAE 90.1-2013 versions of the prototype building models, infiltration was modeled with the same F_{schedule} values but with C=0.224 based on a study by Gowri et al. (2009), which as noted earlier ignores the dependence of infiltration on indoor-outdoor temperature differences. These estimation methods are limited in that they do not fully account for weather effects and greatly oversimplify the impacts of system operation on infiltration.

In NIST's effort to develop coefficients for Equation (1), simulations were performed using NIST-developed CONTAM models of the DOE reference buildings to generate whole building infiltrations rates for a range of weather conditions with the ventilation fans on and off. Correlations were performed to fit these predicted infiltration rates to weather data, i.e., outdoor temperature and wind speed, to estimate the constants in Equation (1). For the ASHRAE 90.1-2004 versions of the building models, correlations were performed for 7 of the 16 reference models using Chicago weather (Ng et al., 2015). Compared with the assumption of constant infiltration in the reference building models, the correlation-based infiltration estimates agreed 60 % better on average with the CONTAM predictions. An example of the agreement between these infiltration correlations and the CONTAM predictions is shown for the Medium Office in Fig. 1a. The values for A, B and D for these 7 buildings were then correlated with building height, exterior surface area to volume ratio, and net system flow (i.e., design supply air minus design return air minus mechanical exhaust air) normalized by exterior surface area in order to predict these coefficients for any given building based on these three parameters (height, surface to volume ratio and net system flow). This generalized method resulted in an average improvement of 50 % when compared to the constant infiltration rates in the reference building models. Figure 1b compares the predictions using the suggested constants from DOE-2 and BLAST in the EnergyPlus Engineering Reference document, which results in much poorer agreement with the CONTAM predictions than seen using the correlation approach.



(a)



(b)

Fig. 1 EnergyPlus infiltration rates vs. CONTAM infiltration rates for Medium Office building using (a) NIST correlations and (b) DOE-2 and BLAST coefficients

In order to make these correlation-based estimation methods more accessible, they were incorporated into an Open Studio Measure called “Adding infiltration correlated for weather and building characteristics” (https://bcl.nrel.gov/node/83101). When the ASHRAE 90.1-2013 versions of the prototype building models were released, NIST updated the corresponding CONTAM models and expanded the infiltration correlations to eight cities (Ng et al., 2018). This work is continuing with the inclusion of more building types.

4.2 Energy-Airflow Model Coupling

Airflow and heat transfer are closely coupled processes in buildings, particularly in multizone buildings and in applications of natural ventilation. Basically, airflow models need zonal air temperatures to calculate airflows, and energy models need these airflows to calculate zonal temperatures. These calculations have historically been handled by separate software tools, with the inputs of each tool entered by the user “manually.” However, increased computer power and more widespread application of building simulation in design is making both building energy analysis and airflow modeling more accessible, as well as enabling more direct coupling between these two types of modeling tools. The CONTAM-based methods employed by Han et al. (2015) utilized loose coupling between the energy and airflow analysis software, i.e., the outputs from one program were used as inputs to another but not during runtime. More recent advancements have enabled tight coupling or co-simulation between CONTAM and energy modeling tools, i.e., EnergyPlus and TRNSYS (Dols et al., 2015; Dols et al., 2016). Co-simulation allows for the runtime exchange of simulation results between energy and airflow programs at each time step. Currently available coupling allows the complex interaction between building-specific thermal, wind and system effects to be addressed simultaneously.

5 SUMMARY AND CONCLUSIONS

The estimation of infiltration rates in commercial and institutional buildings is more complex than in low-rise residential buildings given the larger size and multi-zone configuration of these buildings, the complexity of their HVAC systems and the lack of infiltration and airtightness measurements to validate estimation methods. As a result, there has been slower progress in infiltration estimation compared with low-rise residential buildings. This paper described the history of infiltration estimation in commercial buildings, with a focus on how energy analysis tools (i.e., EnergyPlus) treat infiltration. At this time, there are basically three options for estimating infiltration rates in commercial buildings: multizone modeling, empirical formulas (i.e., Equation 1) in which the coefficients are all non-zero and have a sound technical basis, and coupled energy-airflow modeling (which is essential an application of multizone modeling). While there has been progress in these estimation methods, it is unclear how simple such methods can be given the complexity of airflow and pressure in large, multizone buildings. Nevertheless, infiltration rates are needed for commercial building energy and IAQ analyses or other applications, and if an estimated rate is to be used it must be based on a sound technical approach and data, which need to be reported along with the estimate.

6 ACKNOWLEDGEMENTS

The authors express their appreciation to Sara Persily of BCER Engineering for her helpful review.
