ABSTRACT

We present the quantification of cell viability during neutral red (NR) uptake with a compact lens-free system utilizing two light sources. Conventionally, the NR uptake assay determines cell viability based on the accumulation of NR within lysosomes and is quantified spectrophotometrically after a destructive extraction process. Our NR uptake live imaging system offers *in situ* monitoring of cell viability while accentuating 3D morphologies, thus diversifying the assay's functionality. Combining the low-cost NR uptake assay with the compact architecture of lens-free imaging provides high-throughput, point-of-use, live monitoring of cell viability that eliminates extraction steps and preserves the culture.

KEYWORDS: Lens-free imaging, Cell Viability, 3D Culture, Hepatic Cancer Cells

INTRODUCTION

Determining cell viability for *in vitro* tissue culture is crucial for evaluating cell health, toxicity of compounds, and efficacy of therapeutics. NR is a common and inexpensive supravital stain for assessing cytotoxicity. Healthy cells accumulate NR as the nonionic dye diffuses into an acidified lysosome and becomes protonated. In the standard assay, cell viability is quantified spectrophotometrically as an ensemble average of the culture after destructive extraction of the accumulated dye.[1] Lens-free imaging provides real-time culture monitoring at a lower cost, wider field of view, and smaller footprint for high-throughput, point-of-use, quantitative live-cell imaging. In lens-free imaging, a light source directly illuminates the sample that is within immediate proximity of the CMOS sensor array. The result is a shadow image with the size and resolution of the array. We present the use of lens-free imaging to monitor viability of human liver cancer cells during NR uptake, rather than after extraction.

EXPERIMENTAL

Certain commercial equipment, instruments, or materials are identified in this paper to foster understanding. Such identification does not imply recommendation or endorsement by the NIST, nor does it imply that the materials or equipment is necessarily the best available for the purpose.

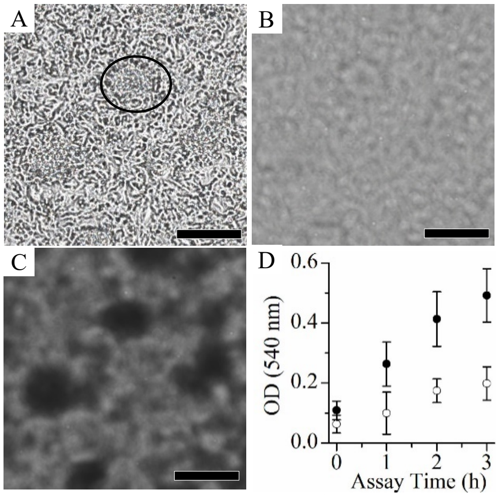

Figure 1. Lens-free analysis of NR uptake by a confluent culture. (A) Pinhole light at 0 h. Collimated light at (B) 0 h and (C) 3 h. (D) NR uptake by clusters (solid) and monolayers (open). Scale bar = 200 µm.

Culture vessels were created by plasma bonding polydimethylsiloxane (PDMS) wells or micropatterns to #1 glass coverslips, then sterilized with 70% ethanol. Flow in microchannels (400 µm wide, 70 µm high, 30 mm long) was controlled with a gentle gravity flow ($\Delta h_{max} = 0.9$ cm). A hybrid cell adhesion matrix (HCAM) was prepared on the surfaces with 50 mg/L fibronectin in Dulbecco's phosphate buffered saline followed by 1 g/L poly(allylamine) in deionized water.

Human hepatoma cells (HepG2) were cultured in Dulbecco's modified eagle medium supplemented with 10% fetal bovine serum (DMEM) at 37 °C and 5% CO_2, harvested at 80% confluency, seeded in culture vessels at a 1:1 vessel:flask surface density and stained within (5 to 6) d. The lens-free system (SOL Inc., KR) has an 8 megapixel CMOS sensor (field-of-view = 10.14 mm^2, spatial resolution = 1.10 µm, pixel size = 1.12 µm). Light sources were filtered at 540±35 nm. The NR uptake assay was performed similar to the standard protocol.[1] After pre-assay imaging, dye-free DMEM was replaced with 40 mg/L NR in DMEM and every hour thereafter for 3 h. Final images were collected with dye-free DMEM. Images were analyzed with

Nablo, Brian; Ahn, Jungjoon; Bhadriraju, Kiran; Lee, Jong; Reyes-Hernandez, Darwin. "Live quantification of cell viability via neutral red uptake using lens-free imaging." Paper presented at The 23rd International Conference on Miniaturized Systems for Chemistry and Life Sciences (µTAS 2019), Basel, CH. October 27, 2019 - October 31, 2019.

Image J[2]. Briefly, pinhole-illuminated images were used to define regions for analysis by subcategorizing cell into “Dense clusters” (circular bodies not in excess of 75 pixels [91 μm^2] or “Spread monolayers” (oblong bodies up to 500 pixels [665 μm^2]). For confluent cultures, areas of consistent cell morphology were marked with circular regions of 1976 pixels (2390 μm^2). Marked regions were transferred to respective collimated-light images to determine the transmittance and calculate absorbance.

RESULTS AND DISCUSSION

The lens-free imaging resolves cells when using a pinhole light source due to cell perimeter scattering light that appear darker and the cell bodies focusing light, frequently saturating the pixel below. This artifact is rendered negligible with a collimated light source (Fig. 1A and B). Thus, imaging occurs in tandem with 1) the pinhole source locating cells and, 2) the collimated source quantifying optical density. Two distinct morphologies are observed herein: 1) spread monolayers, or 2) dense clusters. Under pinhole illumination, dense clusters (Fig. 1A oval) are darker and appear to organize into 3D morphologies similar to multicellular spheroids previously observed on HCAM[3].

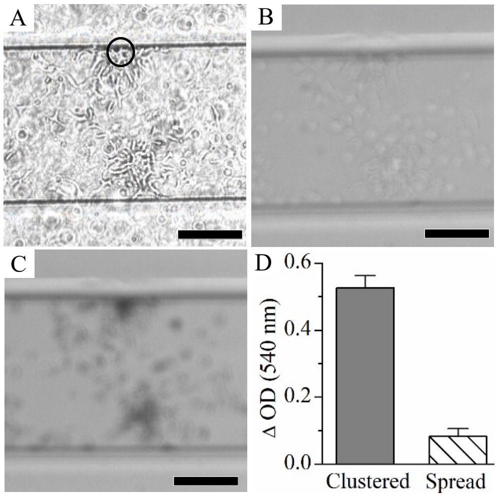

Figure 2. Lens-free analysis of NR uptake by HepG2 cells in a microfluidic channel. (A) Pinhole light at 0 h. Collimated light at (B) 0 h and (C) 3 h. (D) Absorbance of NR in cells. Scale bar 200 μm.

HepG2 cells steadily accumulate NR over the 3 h assay (Fig. 1C and 1D), consistent with the standard NR uptake assay[1]. The dense clusters appear to uptake more NR than spread monolayers. The disparity between morphologies may be due to a difference in pathlength caused by an increase in cell height. Previous work demonstrates that HCAM stimulates HepG2 cells to form 3D cultures[3]. Confocal images of fixed cultures confirm the heights of dense clusters vary from (15 to 35) μm, whereas spread monolayers vary from (4 to 6) μm.

The elimination of the extraction process enables the NR uptake assay to quantify cell viability in microfluidics. Despite the presence of debris within the PDMS, cell perimeters are still identifiable with the pinhole source (Fig. 2A) and NR accumulations is unobstructed with collimated light (Fig. 2B and 2C). Spread cells exhibit a greater cell area while clustering cells (Fig. 2A circle) are more confined and spherical. Clustered cells absorb more light than the spread cells (Fig. 2D), likely due to concentration in lysosomes caused by a reduced cell area.

CONCLUSION

Tandem lens-free imaging with pinhole and collimated light sources enables *in situ* quantification of cell viability and reduces the time to verification for the NR uptake assay. Additionally, NR uptake visually enhances 3D cell morphologies. The reduced footprint of lens-free imaging combined with low-cost supravital stains like NR enables high-throughput assessment of cell viability on a cell-by-cell basis at the point-of-use (e.g., incubator) where traditional microscopes would be disruptive, inhibitory, or costly.

ACKNOWLEDGEMENTS

This work was supported in part by NIST internal funds, NIST grants No. 70NANB17H246 and 70NANB17H292, the N0002519 of the Korea Institute for Advancement of Technology, and the Ministry of Trade, Industry and Energy of the Republic of Korea. This research was performed in part at the NIST CNST.

***Abstract*—The workcell is considered a main building block of various industrial settings. Hence, it is examined as a primary testing environment for studying wireless communication techniques in factory automation processes. A new testbed was recently designed and developed to facilitate such studies in workcells by replicating various data flows in an emulated production environment. In this paper, an approach to storing and analyzing network performance data from a manufacturing factory workcell is introduced. A robotic testbed was constructed using two collaborative grade robot arms, machine emulators, and wireless communication devices. A graph database approach was implemented to capture network and operational event data among the components within the testbed. A schema is proposed, developed, and elaborated; a database is then populated with events from the testbed, and the resulting graph is presented. Query commands are then presented as a means to examine and analyze network performance and relationships within the components of the network. Additionally, we demonstrate how to extract correlations between receive signal power and network delay within the testbed using the graph database query language. Finally, using the inherently interconnected nature of the graph database, we discuss applying the graph database approach toward examining more complex relationships between the wireless communications network and the operational system.**

***Index Terms*—industrial wireless, factory automation, testbed, measurement, instrumentation, graph database.**

I. Introduction

Wireless communication is a key enabling technology for the modernization of factory workcells. Modern factory workcells are highly-interconnected networked control systems in which various devices interact and collaborate to accomplish complex and adaptive production orders. The workcell often contains mobile robots that collaborate with other robots or human beings. Requirements of the workcell include the incorporation of mobile collaborative robotics with real-time coordination of motion and tool actuation. As such, the communication of sensor and control information must be ultra-reliable and of low-latency to assure trustworthy operation [1]. Due to an increased demand for ease of installation, reduced costs of deployment and maintenance, and flexibility, wired networks are being gradually replaced with wireless networks. This presents a real challenge for networks and control systems. Compared with wired connections, wireless links have their unique advantages in connecting field sensors and actuators with reduced cabling costs and natural support of mobility [2]; however, most current communications systems lack the latency and reliability supports [3] mandated by factory owners [4], [5]. New wireless protocols are being designed to address reliability and latency concerns of real-time systems such as those in manufacturing automation. These new protocols include advancements, such as the Institute of Electrical and Electronics Engineers (IEEE) 802.11ax standard and 5G cellular evolution as defined by the International Mobile Telecommunications-2020 (IMT-2020) Standard. Both of these two standards employ improved diversity techniques for multiple access of devices as well as 1 ms latency and greatly improved reliability [6].

Evaluation of such systems used in manufacturing environments requires not only rigorously analyzing network performance, but also studying the impacts of networks on manufacturing systems. Additionally, industry lacks effective and easy-to-use strategies for test and evaluation of such systems in a way that correlates network performance with operational performance. Furthermore, since factory operators desire the ability to control operations within the workcell using wireless technology, we present a novel method to simultaneously capture network and operational event information using a graph database (GDB). The use of a GDB allows for more intuitive inferences to be made through the stored relationships and graph theoretic models [7]. In this paper, we present a GDB approach to the capture and analysis of factory workcell performance utilizing the Neo4j database platform. We present a proposed schema of the database, the process for capturing both network and operational events, and examples of querying the database for cyber-physical performance evaluation of the workcell for our collaborative two-robot machine-tending workcell [8].

II. Graph Databases

A GDB is the type of databases that uses nodes, edges, and properties to store and present data. A GDB is a part of a family of databases known as NoSQL databases that are used often to represent complex interrelated structures of data and their relationships. This can be very difficult with traditional relational databases. The GDB places a high priority on the relationships (edges) between units of information. In addition, the GDB does not enforce any particular schema or structure, and, therefore, provides greater flexibility in storing and representing information in which the parts of information

Candell, Rick; Hany, Mohamed; Liu, Yongkang; Montgomery, Karl; Foufou, Sebti. "A Graph Database Approach to Wireless IIoT Work-cell Performance Evaluation." Paper presented at 2020 IEEE International Conference on Industrial Technology, Buenos Aires, AR. February 26, 2020 - February 28, 2020.

may vary among units. The relationships within a GDB are efficiently queried because they are persistently stored within the database. In a GDB, queries can be made based on relationships. This, in particular, presents an advantage when storing information regarding systems with correlations that are apparent but difficult to visualize or quantify. The GDB approach was chosen for this specific purpose—to quantify and visualize relationships between non-ideal communications within a workcell and its impact on the physical system.

III. Related Work

Multiple surveys about GDBs have been presented to describe the associated models, tools, and their features in [7], [9], [10]. Also, examples of applications and implementations of GDBs are presented in [11] to show their use on enterprise data, social networks, and determining security and access rights. It was found that GDBs provide the much needed structure for storing data and incorporating a dynamic schema. On the other hand, query languages are used to extract data including traversing the database, comparing nodes properties, and subgraph matching [12]. The performance of different GDB tools and methodologies is analyzed and compared in [13], [14]. Multiple comparisons in these articles have shown improved performance of Neo4j in the general features for data storing and querying, and data modeling features such as data structures, query languages and integrity constraints.

Furthermore, industrial data analytics play an essential role in achieving the smart factory vision and improving decision-making in various industrial applications. Five main industrial data methodologies are studied including highly distributed data ingestion, data repository, large-scale data management, data analytics, and data governance [15]. Industrial data processing offers valuable information about various sections of industrial applications including inefficiencies in industrial processes, costly failures and down-times, and effective maintenance decisions [16]. In [17], a platform for performing industrial big data analysis is presented where the performance requirements are introduced to achieve a cost-effective operation. Various other frameworks for industrial data analysis can be found in [18], [19], where the importance of using data analysis in decision making is emphasized.

Due to its advantages including scalability, efficiency, and flexibility, NoSQL databases are a popular alternative to relational databases in the case of large amounts of data in various applications [20]. The GDB is a kind of NoSQL database approaches that additionally handles complex relationships [21]. GDBs are widely adopted in various industry-related applications and use cases such as network operations, fraud detection, and asset and data management [22]. Relationships in social networks have been modeled using a GDB for structural information mining and marketing [23]. On the other hand, business solutions for scenarios with multiple large data sources require distributed processing in decision making for various problems such as fraud detection, trend prediction, and product recommendation [24].

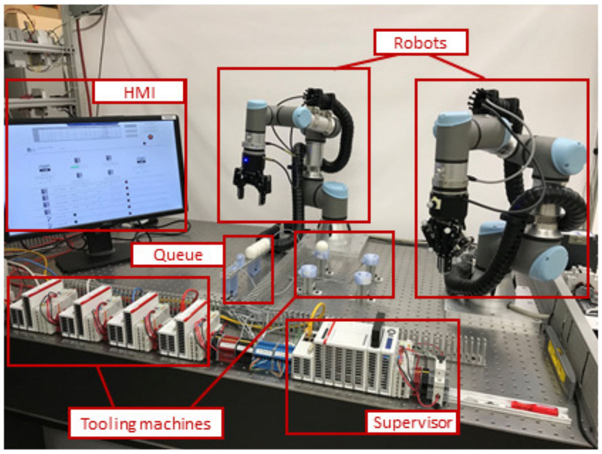

Fig. 1: Collaborative work cell testbed

IV. Case Study: Robotic Machine-tending

In this section, we present a two-robot machine tending workcell case study. We first present the design of the workcell followed by an elaboration of the database design called a schema. The information work-flow, i.e., the process for collecting, processing, and analyzing the network event data is presented. We then provide examples of the resulting graph and results of targeted queries that demonstrate the purpose of the database.

A. Workcell Design

To facilitate wireless network research and showcase the power of wireless technologies in industrial practices, a testbed shown in Fig. 1 has been developed at the National Institute of Standards and Technology (NIST) as described in [8]. The testbed is composed of two collaboration-grade robots, a supervisory programmable logic controller (PLC) used for the control of the workcell, four smaller PLCs serving as computer numerical control (CNC) machine emulators, and a human-machine interface (HMI). Each robot is equipped with a six-degrees-of-freedom (DOF) force-torque (FT) sensor and a two-finger gripper. A Modbus/TCP server is included within the supervisor PLC and is used for communication between the supervisor and the robots. The PLCs themselves communicate to each other using the Beckhoff Automation Device Specification (ADS) protocol. All elements within the workcell are synchronized to a stable and accurate grand-master clock. Therefore, as described in [8], the operational, network, and measurement elements are all synchronized to the grand-master clock through a precision time protocol (PTP)-capable switch.

Work-orders for the workcell are submitted through the supervisor. Each work-order consists of a work-plan for a part, and the work-plan determines how each part moves through the workcell until it is completed. The inspection of each part is conducted at each machining station, and after the final inspection, the part is placed back into the input queue. Under normal operating conditions, the work continues until all work-orders have been processed. This continuous form of operation provides ample opportunity to collect statistically significant metrics of both the network and the operation of the workcell.

B. Database Schema

GDBs are NoSQL databases such that the database does not contain any predefined structure or rules to enforce such structure. This is a major difference between relational databases and GDBs. Nevertheless, it was necessary to sketch a pseudo-schema to capture the intended nodes and relationships that would be stored within the database (the terms pseudo-schema and schema will be used interchangeably). Before describing the schema itself, it is necessary to first explain the requirements of the schema. Therefore, the requirements for our schema are as follows:

Time Any manufacturing automation system is indeed a time-varying control system with network and operational events. The database schema must necessarily support time-based queries and, specifically, time-windowed queries.

Operational Events The schema must represent operational events such as the movement of a robot arm or the movement of a part.

Network Events The schema must represent network events such as the transmission of packets.

Message Grouping The schema must support grouping of logically related events such that those events can be correlated to a specific occurrence within the testbed.

Wireless Support The schema must support the capture of both wired and wireless network traffic without special provisions within queries for either.

QoS Support The schema must allow for the capture of quality of service (QoS) data when available.

Spectrum Monitoring The schema must support the capture and association of network events with observations from a spectrum monitoring system (SMS) if that information is available.

1) Node Design: Given the fore-mentioned requirements, a sample pseudo-schema is shown in Fig. 2, which represents the intended structure of the information within the GDB. It is important to remember that since GDB schemas are not really schemas, such as those found in relational databases, but representations of intent, the schema represented here should be considered a notional example of the final product. Within the graphs, nodes represent logical elements, and edges represent the relationships between those elements. Both nodes and edges may contain properties providing more description and labels that define categories or classes of the said nodes or edges. Our schema is designed such that the data within the graph is intuitive to understand and allows for time-based queries to occur. The facilitation of time-based queries was an essential requirement of our database design. Our schema is represented using the following node labels:

Actor A physical component within the factory workcell such as a robot, PLC, or other networked item.

NtwkID A network address item for an actor such as an Internet Protocol (IP) address.

Transaction A complete information exchange between two or more actors (multiple actors may participate in a transaction).

Message A network transmission event that occurs between two actors (messages are essentially packet transmissions captured at the transport layer; multiple messages support a transaction).

Physical Action A physical occurrence within a factory workcell associated with actors through multiple time based relationships.

SMS An SMS observes and records significant spectral events within the workcell and may report those events to actors within the workcell.

Sniffer Measurement device that records all transmissions conducted over the wireless medium and includes wireless header information for each wireless transmission detected.

Adapter Device that serves to connect an actor to a network (adapters are divided into sub-categories depending on the type of interface to a network).

Adapter:Ethernet A subcategory of adapter representing an Ethernet interface.

Adapter:Wireless A subcategory of adapter representing a wireless interface.

Adapter:Wireless:AP A subcategory of adapter representing a wireless access point interface.

Adapter:Wireless:UE A subcategory of adapter representing a wireless user equipment interface.

QoS Report Quality of service report of a message (not all messages will have a QoS report).

It is important to note that most network infrastructure components are not captured within the graph, but, instead, only basic interfaces between actors and the network are captured. Our intent when designing the graph was to make the graph network and protocol agnostic, such that the network is viewed as a black-box. Accordingly, the captured events of the physical system and the network are considered useful for the analysis of performance.

2) Relationships (Graph Edges): Relationships are edges within the graph that capture the informational interactions between nodes. Relationships, like nodes, can contain labels and properties. As shown in Fig. 2, nodes are connected through defined relationships. A subset of the relationships are defined as follows:

PARTICIPATED_IN Actors will participate in transactions. A transaction exists for each logical set of messages between actors such as the setting of a Modbus register or the sending of a command to a robot. Therefore, actors will participate in many transactions, and multiple actors may participate in a single transaction.

SUPPORTED Messages (i.e., packets between actors) are associated with transactions through the SUPPORTED relationship. Depending on the protocol and the quality

Fig. 2: The intended schema (i.e., pseudo-schema) of the graph database used for each operational run of the NIST wireless factory testbed. The graph is organized into nodes and edges, where the edges signify relationships among network elements and physical operational elements.

of the channel, a single transaction could have one or many messages connected through this relationship.

TX/RX An actor may either transmit (TX) or receive (RX) a message. Both the TX and RX relationships contain a timestamp in the format of an epoch time which is a floating point number in seconds since January 1, 1970, with a resolution of microseconds.

PERFORMED When an actor performs a physical action, a relationship is created between the actor and the physical action node. This relationship contains start and stop time properties as well as the source of the observation such as a networked camera.

REPORTED_TO An SMS may be a passive or active listener within a workcell. When an SMS operates as an active listener, spectral reports from the SMS may be sent to an actor such that the actor can respond intelligently to the spectral event. Reports from an SMS to an actor are captured within this relationship.

Other relationships shown in the schema of Fig. 2 but not explained above are considered self-explanatory.

3) Closer Examination: Examining the sample schema more closely, two actor nodes are represented. In this case, Actor A is the supervisory controller, and Actor B is a robot arm. Both nodes participate in a transaction, which, in this example, is a Modbus/TCP exchange. The transaction itself is associated with one or more messages (i.e., packets). Each message associated with a transaction manifests itself as a node in the graph. Multiple message nodes will exist for each transaction. Additionally, QoS reports may be associated with each actor node through a collocated sniffer node. By keeping QoS reports separate, we have the flexibility of supporting different wired and wireless protocols within the same graph. Recall, that a graph database has no enforceable structure and thus affords this type of flexibility. Each actor node may have network identities associated with it through the use of network identifier nodes. Each network identifier node may contain address information such as a hardware address or a network address; however, this is dependent on the protocols and addressing schemes being used, and a node could have many different identification nodes.

4) Physical Actions: Finally, each actor in the graph may associate with physical actions. These actions exist in the database as automatons such that every time a new action occurs, a new edge would be added between the actor and the physical action. Timestamps within the graph represent “measurement time” denoting that all timestamps are accurately synchronized to the grand-master clock. The method of synchronization is outside the scope of this paper and is explained fully in [8]. This paper describes the database structure and the process for preparing and inserting the data into the database, which is described in the following subsection.

C. Information Workflow

The workflow for collecting, processing, and inserting measurement data into the graph database is multi-pronged, as shown in Fig. 3. The workcell, which in our case study is a two-robot workcell with four CNC machines, is instrumented with network probes that capture transmitted and received packets as well as probes to capture operational movements

Database Insertion
Metrics Queries Visualization

Fig. 3: Data processing flow from factory workcell to database

such as arm robot position and the state of the supervisor PLC. Network data is stored in packet capture (PCAP) files, while operational data is stored in comma separated value (CSV) files. We developed bash scripts to extract relevant information and prepare the data for insertion into the database. The scripts also contain rules for grouping packets together as transactions based on the application protocol and time. The scripts produce CSV files that are ready for insertion into the Neo4j database. Once the data resides within the database, we apply queries to extract information for the evaluation of workcell performance and visualization of network and operational events within the workcell. By tracking paths through the relationships within the graph, discerning how a network event such as interference is related to physical events such as position uncertainty or part throughput is possible. Various impairments may be introduced as a part of workcell operation. Examples of such impairments include competing wireless traffic, radio interference, and reflections and diffraction due to the multi-path environment [25]. We have shown that it is feasible to implement such impairments and measure the resulting physical performance manifestation [8]. This is accomplished through the use of a radio channel emulator as demonstrated in [26].

D. Sample of a Resulting Graph

In the following, we show results from a trial run of the NIST industrial wireless testbed. In this trial run, a single physical wireless link is used between a wireless adapter connected directly to the supervisor and a wireless access point connected to all the other actors in the testbed. The wireless nodes represent IEEE 802.11b/g/n devices and are connected through a variable radio frequency (RF) attenuator that allows us to vary the channel quality. During the trial run, the production of 10 parts was emulated, which resulted in 10 minutes of network activity.

After populating the database with data captured from the trial run, the resulting realized schema is shown in Fig. 4. The schema visualization is produced by invoking the command

```
call db.schema.visualization()
```

in Neo4j. It is important to note that a realized schema shows only one representation of each node and relationship whereas the intended pseudo-schema shown in Fig. 2 was developed to exemplify the relationships between types of nodes, labels, and relationships. Where label inheritance is employed, such as the case for different adapter types, relationships are reproduced; however, this is a result of the visualization tool rather than the schema itself. Fig. 4 serves, therefore, to validate that the intended schema was indeed realized by the insertion of event data from the testbed. In the realized schema, inherited labels are shown as separate nodes.

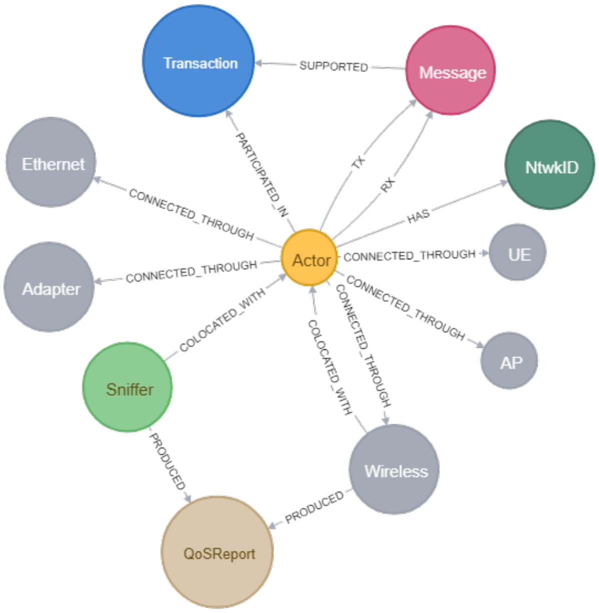

Fig. 4: Realized schema of the graph database fully populated after capturing network and operational data from the NIST industrial wireless testbed.

As described in Section IV-B, the database includes every network transaction that occurs during the operation of the testbed. This includes any logical transaction nodes inserted into the database and any associated packets that happened to traverse the network. Therefore, for a short duration of time depending on packet transmission rates, the amount of data stored in the database can grow quickly. This presents a visualization challenge that graphs are designed to handle. A sample graph is shown in Fig. 5, which represents only 1 second of wired and wireless network data captured from

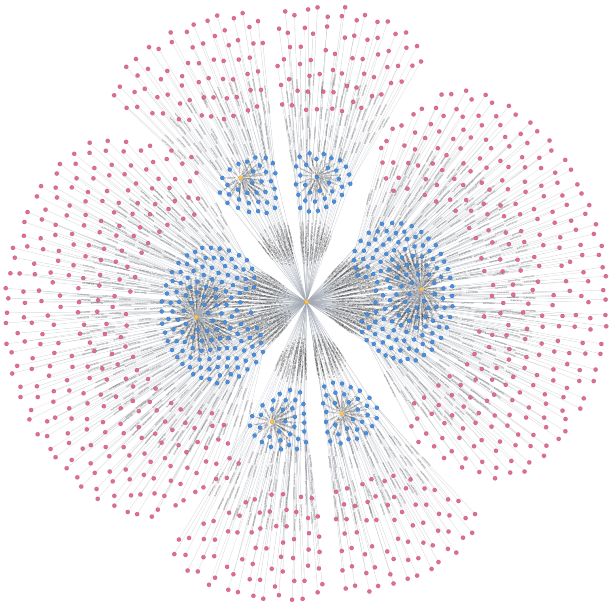

Fig. 5: Visualization of a node graph resulting from a testbed experiment.

the NIST two-robot pick-and-place wireless testbed described in [8].

This visualization is produced by calling the following query in the Neo4j.

```
MATCH p=(a:Actor {name:'Supervisor'})--(t:
    ↪ Transaction)--(b:Actor) ,p2=(m:
    ↪ Message)-->(t) WHERE t.timeStart>T
    ↪ AND t.timeStop<T+1
RETURN p,p2
```

The colors of the resulting nodes follow the realized schema in Fig. 4 while only the actors, transactions, and messages are visualized in 5. The relationships between the messages and transactions are shown where a single transaction is connected to at least two messages to represent the communications between any two actors. The variable T in the query represents an arbitrary time variable in seconds within the trial run to capture the data within 1 second only.

We then show a more detailed visualization for all the nodes and relationships corresponding to a single transaction. This visualization is produced by calling the following query where Ts is an arbitrary time variable to specify the timeStart value for the single transaction.

```
MATCH p=(a:Actor {name:'Supervisor'})-->(t
    ↪ :Transaction {timeStart:Ts})<--(b:
    ↪ Actor {name:"CNC-1"})
WITH p, a, b, t
MATCH p1=(a)-->(m:Message)<--(b), p2=(m)
    ↪ -->(t), p3=(a)-[:HAS]-(),p4=(a)<-[:
    ↪ COLOCATED_WITH]-()-[:PRODUCED]->(q:
    ↪ QoSReport), p5=(a)-[:
    ↪ CONNECTED_THROUGH]-(),p6=(b)-[:HAS
    ↪ ]-(), p7=(b)-[:CONNECTED_THROUGH]-()
WHERE q.time>t.timeStart AND q.time<t.
    ↪ timeStop
RETURN p,p1,p2,p3,p4,p5,p6,p7
```

In Fig. 6, the actor nodes are labeled by their names *CNC-1* and *Supervisor*, the transaction is labeled by its type *ADS*, the messages are labeled by their transmission role *Request* and *Response*, the NtwkIDs are labeled by their IP addresses, the Ethernet adapters are labeled by their names *eth0*, the wireless adapters are labeled by their names *Moxa* and *TP-Link*, the sniffer is labeled by its name *WLS1*, and the QoS reports are labeled by the received signal strength indicator (RSSI) value in dBm. This visualization includes only the QoS reports generated within the duration of the corresponding transaction.

E. Calculation of Metrics

We now present an example of deploying the proposed GDB approach in industrial wireless analysis. During the trial run time, we varied an RF attenuator value in the single wireless link. The attenuation can take the values {0, 10, 20, 30, 40, 50, 60} dB. We evaluate the message latency as the difference between the receive and transmit times of a message including transmission, processing, and retransmission times. Each message has been coupled to a QoS report that is the one reported at the closest time instant before the message transmit time. One of the parameters in the QoS report is the RSSI value captured by the Sniffer colocated with the supervisor's wireless adapter.

In Fig. 7, we present a scatter plot showing the correlation between the message latency in seconds to the measured RSSI values by the sniffer in dBm. The figure shows that the latency is higher at the lower RSSI values due to the increased number of retransmissions. Generally, an IEEE 802.11 transmission can occur using different IEEE 802.11 mode and modulation and coding scheme (MCS) based on the channel quality. At the RSSI of -90 dBm, the receiver should operate at the most robust communications mode and the lowest MCS index. However, retransmissions still occur due to having the received power near the sensitivity of the supervisor's wireless adapter. As shown in Fig. 7, retransmissions may occur at other RSSI values as well when the transmitter selects a higher mode of transmission and a higher MCS index. In this case, we assert that the receiver is operating close to the marginal sensitivity for a given mode (e.g., 802.11n) and MCS index. We observed that the transmitter switches to a lower MCS index for the retransmitted messages, which supports our supposition. Therefore, latency can in fact be high for better RSSI values. This effect is illustrated in Fig. 7 where certain messages can have latency values at -43 dBm, which are comparable to those in the case of -90 dBm.

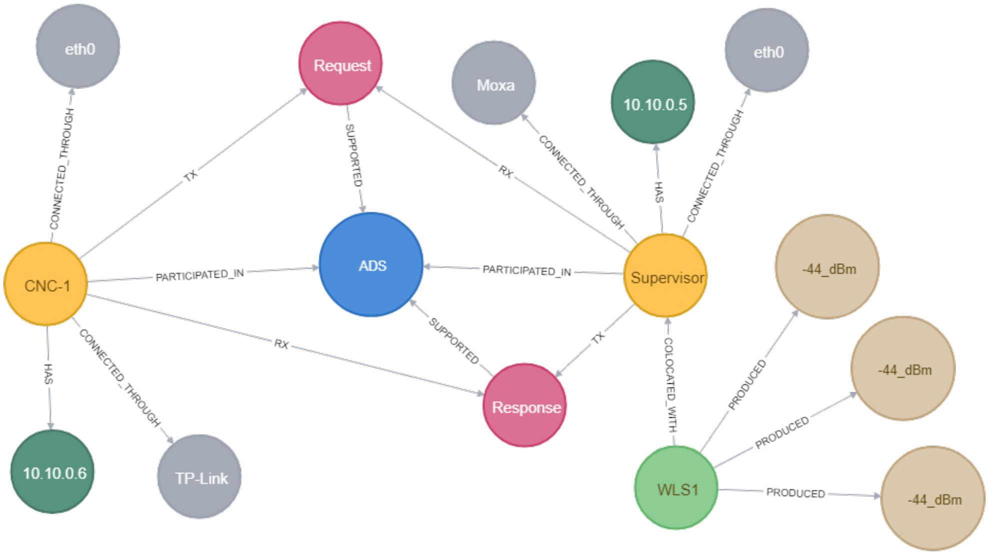

Fig. 6: A detailed visualization resulting from a testbed experiment for all the nodes and relationships corresponding to a single transaction.

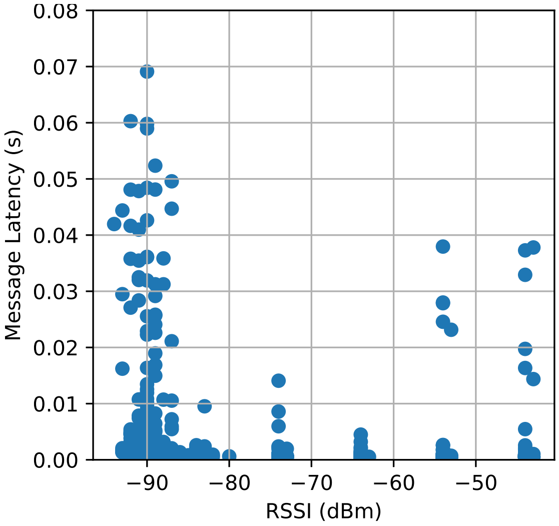

Fig. 7: Correlation between the message latency and the RSSI values by the sniffer.

V. Future Direction

We have presented the general architecture of a performance evaluation database. Future work will include developing query algorithms for the calculation of performance metrics as well as correlation of network events to the physical performance of the manufacturing system. Algorithms will be developed to indicate locations in time of lost information making more direct performance correlations possible. Beyond performance evaluation of the manufacturing system, we believe that the graph database approach enables anomaly detection because relationships within the data are intrinsically stored and thus efficiently queried. The structure of the information is important within a graph database, and defining the relationships such that the paths through nodes may be discovered is essential to efficient queries and discovery of hidden correlations. Therefore, more research will be done in the modification of the presented schema. Machine learning will be applied for the detection of anomalies, performance degradation, signal quality, and network performance enhancement through more efficient resource allocation. Our plans also include online database insertions to enable the demonstration of online operation of the database. We also intend to examine the development of better control system strategies that mitigate network losses and delays. Since this approach is indifferent to the communications protocols used, we intend to extend our database approach to include various protocols, radio bands such as millimeter wave bands for 5G communications, and different use cases to include mobile robotic platforms and safety critical systems.

VI. Conclusions

We have presented in this paper a novel approach to capturing network and operational event information from a factory workcell with the purposes of 1) capturing and storing of network and operational events, 2) calculating performance metrics of the network, and 3) discovering performance dependencies between the network and the physical assembly of the workcell. Using a graph database, we have demonstrated that it is possible to construct such a database, compute network performance metrics and discover correlations. We have also developed the capability of examining the correlation between network events and the performance of physical actions. This will be a source of further research.

Future progress and measurement data will be deposited in the NIST public domain repository as a reference for industrial traffic modeling efforts and comparative studies on industrial wireless technologies [27].

***Abstract*— We have recently created a 4 V rms cryocooled JAWS (Josephson Arbitrary Waveform Synthesizer) using 204,960 nearly identical Josephson junctions (JJs) that are embedded in coplanar-wave guides. The JJs are pulse-biased at repetition rates up to 16×10^9 pulses per second to create quantum-accurate, calculable AC waveforms at frequencies from DC to greater than 1 MHz. This system has metrological applications including in precision ac voltage calibrations, comparisons of arbitrary impedances, and ac power measurements.**

Keywords*— *Metrology, digital-to-analog conversion, Josephson junction arrays, measurement standards, signal synthesis, superconducting integrated circuits, voltage measurement.

I. Introduction

Over the past thirty years, electrical metrology has been revolutionized by superconducting Josephson-junction (JJ) circuits' ability to generate quantum-accurate voltages. Circuits and systems with higher output voltage have enabled these advances in metrology. We recently doubled the output voltage of the JAWS (Josephson Arbitrary Waveform Synthesizer) system compared to previous systems [1] by developing a JAWS chip that generates dc and ac voltages up to 1 MHz with rms amplitudes up to 2 V. This performance improvement has enabled the direct calibration of new instrument ranges and has opened new applications in impedance and ac power metrology.

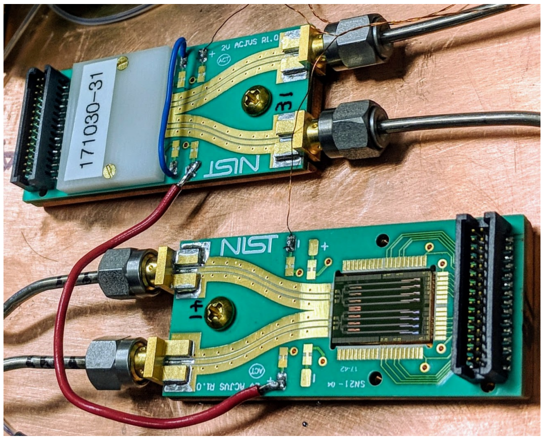

Fig. 2. Picture of two 2 V rms JAWS chips on a 4 K cryocooler

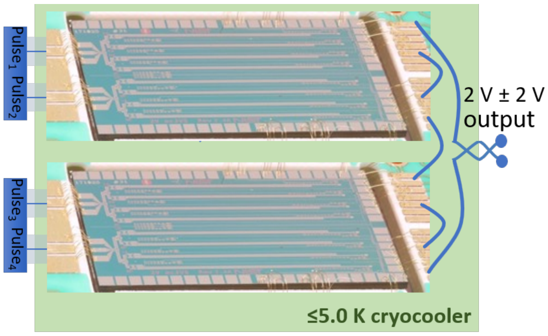

Fig. 1. Simplified system diagram of a 4 V rms cryocooled JAWS

II. Recent Progress

We created a 4 V rms cryocooled system (see Figure 1) by using two of the 2 V JAWS chips containing a combined total of 204,960 nearly identical JJs [2]. The JJs are arranged in 16 series arrays that are embedded in separate coplanar-wave guides (see Figure 2). The quantum-accurate JAWS waveforms are based on a delta-sigma encoding of the JJ voltage pulses which have an integrated area *h/2e*. The voltage pulse timing is controlled by current biasing the JJs with a programmable series of fast current pulses at up to 16×10^9 pulses per second. Each 2 V chip has two high-speed pulse inputs, each of which use two layers of superconducting Wilkinson dividers to split their respective inputs into four signals that each bias one series JJ array. To generate a quantum-accurate output voltage, each input bias pulse must induce every JJ to create a single quantized output pulse.

The 4 V rms output voltage of the new JAWS system has allowed us to calibrate precision ac instruments on higher voltage ranges. Other applications require the ability of these 2 V JAWS chips to generate two separate independent arbitrary waveforms that each have an amplitude up to 1 V rms. For example, we have used these dual 1 V quantum-accurate signals for impedance metrology. The two independently programable JAWS signals are combined with a digital bridge to replace the transformer-based sources typically used in precision impedance bridges. The new JAWS-digital bridge impedance systems have simplified and improved the uncertainty of comparisons between arbitrary impedances [3]. Another new application for JAWS circuits is ac power metrology, where dual quantum-accurate programmable signals with defined harmonic content having specified amplitudes and phases will provide direct quantum-based reference signals for calibrating electric power meters [4].

Abstract: To calibrate near-field scanning microwave microscopes (NSMM) for defect detection and characterization in semiconductors, it is common to develop a parametric finite element analysis (FEA) code to guide the microscope user on how to optimize the settings of the instrument to improve its performance. Two problems arise that make the application of the FEA code difficult if not impossible. The first problem is due to the approximate nature of the FEA method and the critical requirement that the accuracy of the FEA solutions be mathematically verified during the entire calibration process. The second problem is a prerequisite that the user's computer be licensed with the specific FEA software at a sizable cost and training time to the user. In this paper, we solve both problems by designing an intelligent PYTHON code that manages the seamless running of two license-free codes, namely, a compiled parametric COMSOL AC/DC-Module-based code that yields a series of solutions at various finite element mesh densities as input to a FEA-verification code written in a statistical analysis software named DATAPLOT that uses a nonlinear least squares method to check and verify the FEA solution of the COMSOL code. An example of a generic NSMM calibration code running a coupled and license-free finite element and statistical analysis software is presented and discussed.

1. Introduction

To calibrate near-field scanning microwave microscopes (NSMM), as shown schematically in Fig. 1, for detection, sizing, and depth estimation of surface and subsurface defects in semiconductors, it is common to develop a parametric finite element

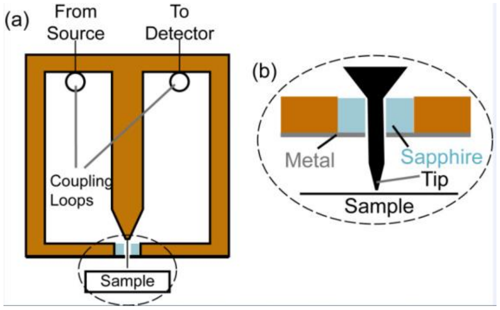

Figure 1. A near-field scanning microwave microscope (NSMM) design based on a coaxial resonator. (a) A schematic of the coaxial resonator, which is operated in transmission mode. (b) A closer view of the prober tip, which is connected to the center conductor of the resonator and extends toward the sample through an opening at the bottom of the resonator (after Gao and Xiang [2] as reproduced in Fig. 7.6, p.115 of a book by Wallis and Kabos [1]).

Fong, Jeffrey T.; Heckert, N. Alan; Filliben, James J.; Marcal, Pedro; Berweger, Samuel; Wallis, Thomas Mitchell (Mitch); Kabos, Pavel. "Design of an intelligent PYTHON code to run coupled and license-free finite-element and statistical analysis software for calibration of near-field scanning microwave microscopes." Paper presented at COMSOL Users Conference, Boston, MA, US. October 02, 2019 - October 04, 2019.

analysis (FEA) code to guide the microscope user on how to optimize the settings of the instrument to improve its performance.

Two problems arise that make the application of the FEA methodology difficult if not impossible. The first problem is due to the approximate nature of the FEA method and the critical requirement that the accuracy of the FEA solutions be mathematically verified during the entire calibration process (see, e.g., refs. [3] through [7]). The second problem is a pre-requisite that the user's computer be licensed with a specific FEA software capable of solving the calibration problem (such as COMSOL [8]) at a sizable cost and training time to the user.

In this paper, we solve both problems by formulating the conceptual design of an intelligent PYTHON code that manages, as shown by Chollet [9] and Fong, et al [10], the seamless running of two license-free[6] codes, namely, a compiled [11] parametric COMSOL AC/DC-Module-based code that yields a series of solutions at various finite element mesh densities as input to a FEA-verification code written in a statistical analysis software named DATAPLOT [12] that uses a nonlinear least squares logistic function fit method [6, 7] to verify the FEA solution of the COMSOL code.

To present the design concept of an intelligent PYTHON code for NSMM calibration, we choose to use an example problem with a very simple sample geometry, namely, a small spherical inclusion in a semiconductor block of 2 um length, 1 um width, and 0.5 um thickness. The diameter of the inclusion is 25 nm, and the clear distance from the top of the sphere to the top surface of the block is 33.3 nm.

In addition, we prescribe that the electrode radius is 10 nm, the electrode voltage is 0.1 v, and the operating frequency is 5 GHz.

To simplify the problem further, we also prescribe the material properties of the block and the inclusion without an estimate of uncertainty, namely,

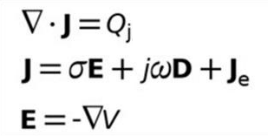
The block electric conductivity = 1e-12 S/m.
The block dielectric constant = 11.7.
The inclusion electric conductivity = 0.01 S/m.
The inclusion relative permittivity = 20.

In Section 2, we develop a parametric finite element analysis (FEA) code using the AC/DC module of the COMSOL code [8] and the COMSOL Compiler code [11] to obtain an executable code that runs in any Windows-based laptop without a COMSOL license.

In Section 3, we develop a FEA verification code written in DATAPLOT [12] to check whether the finite element solutions at increasing mesh densities converge to an asymptotic solution with an acceptable measure of uncertainty. In Section 4, we design a PYTHON code to manage the running of a coupled FEA code and a verification code such that a verified FEA solution is achieved to a prescribed level of uncertainty as required by the calibration mission.

2. Finite Element Analysis Code for a Simple NSMM Flaw Depth/Size Estimation Problem

In Figs. 2 and 3, we show the governing equations and a list of 19 adjustable parameters for the COMSOL FEA code of the simple NSMM problem, respectively. In Figs. 4, 5, and 6, we show



$$\nabla \cdot \mathbf{J} = Q_j$$
$$\mathbf{J} = \sigma\mathbf{E} + j\omega\mathbf{D} + \mathbf{J}_e$$
$$\mathbf{E} = -\nabla V$$

Note: **J** is the current density, Q_j, the current source, σ, the conductivity, **E**, the electric field, ω, the frequency, **D**, the electric flux density, $\mathbf{J_e}$, the external current density, *V*, the electric potential, and $j = \sqrt{-1}$.

[6] COMSOL's license terms state that a code generated by the COMSOL Compiler may be executed by anyone without the need to access a license file. Thus, the generated program can be run by anyone, including those who do not have a paid COMSOL subscription. In this paper we use the term "license-free" when describing these particular terms-of-use for a COMSOL Compiler-generated code**.** It does not apply to DATAPLOT, a non-commercial code.

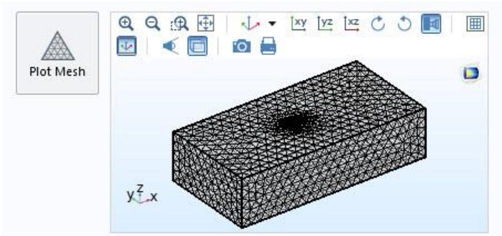

Figure 5. A typical finite element mesh design for the semiconductor block with a buried spherical inclusion where all the elements are tetrahedrons. It is worth noting that meshing in finite element analysis of electromagnetism problems differs from that of structural problems in one important feature, namely, the degrees of freedom of electromagnetic elements are associated with edges, faces, cells, not nodes. For brevity, we shall make no attempt in this paper to explain in details how the meshing was done in a COMSOL code except by referring to its manual [8].

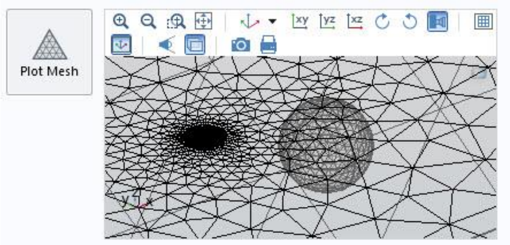

Figure 6. An enlarged view of the finite element mesh design for the buried spherical inclusion with a simultaneous display of the surrounding mesh without the presence of the inclusion. For details, see manual [8].

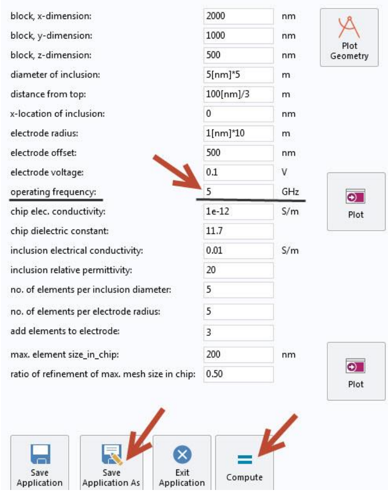

block, x-dimension:	2000	nm

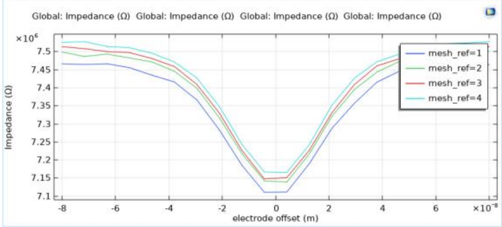

Figure 8. Impedance results of the first four runs at four different finite element mesh densities to check convergence of solutions.

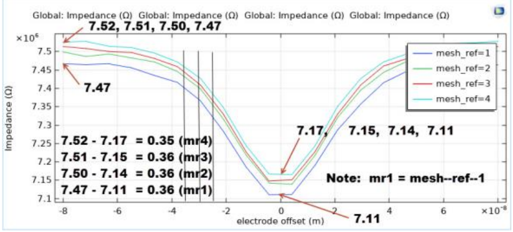

Figure 9. Readings for a key result of the FEA runs for four different mesh densities. When the probe is located directly over the center of the spherical inclusion, the values of the impedance correspond to four mesh densities are:

Mesh Ref. No.	d.o.f.	Impedance (million ohms)
1 (coarser)	51,020	7.11
2	52,058	7.14
3	53,537	7.15
4 (finer)	55,313	7.17

3. A Finite Element Solution Verification Code

To obtain an asymptotic solution of a sequence of FEA candidate solutions at increasing mesh densities (or degrees of freedom, d.o.f.), we apply a 4-parameter nonlinear least-squares (NLLSQ) logistic function fit method (see, e.g., Fong, et al. [6, 7]). A minimum of five candidate solutions is required to run the fit method. For the results given in Fig. 9, we had only four candidate solutions, so we need to run the executable FEA code one more time to generate a fifth candidate solution as follows:

Mesh Ref. No.	d.o.f.	Impedance (million ohms)
1 (coarser)	51,020	7.11
2	52,058	7.14
3	53,537	7.15
4 (finer)	55,313	7.17
5 (new)	**57,089**	**7.18**

In Fig. 10, we show a plot of the NLLSQ fit of 5 points with an asymptotic solution = 7.186 M-ohms. In Fig. 11, we re-plot the result of the 5-point fit with an estimate of uncertainty defined at one million d.o.f. For the calibration purpose in mind, that uncertainty (= 14 %) is too large, so we need to add more points until the uncertainty is less than 2 %. In Figs. 12-14, we show that the goal is reached where the number of candidate solutions reaches nine.

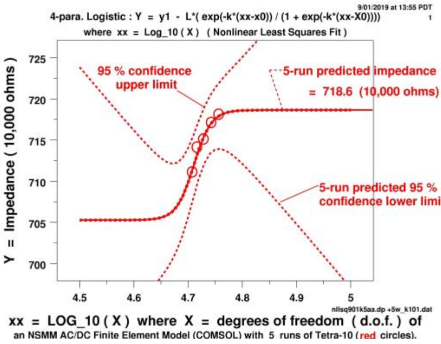

Figure 10. A NLLSQ logistic function fit of 5 candidate solutions yields an asymptotic solution = 7.186 M-ohms**.**

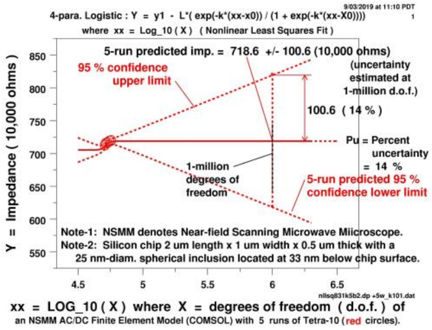

Figure 11. A re-plot of the NLLSQ fit of the 5 candidate solutions with 95 % confidence limits and an estimate of the uncertainty as defined for a million d.o.f. The asymptotic solution now equals 7.186 +/- 1.006 M-ohms.

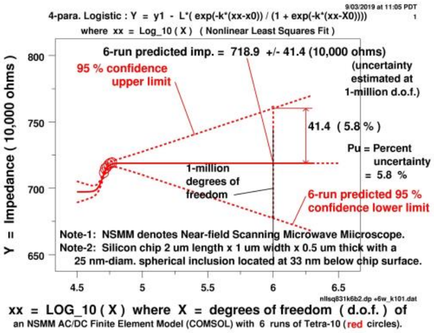

Figure 12. A NLLSQ fit of 6 candidate solutions yields an asymptotic solution equal to 7.189 +/- 0.414 M-ohms.

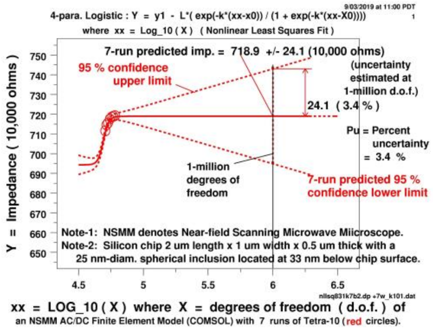

Figure 13. A NLLSQ fit of 7 candidate solutions yields an asymptotic solution equal to 7.189 +/- 0.241 M-ohms.

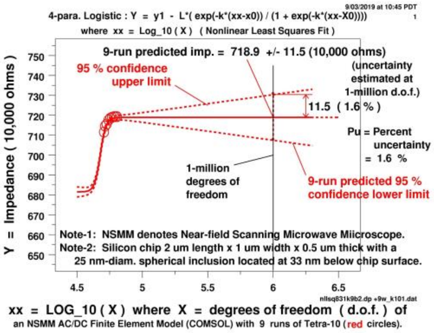

Figure 14. A NLLSQ fit of 9 candidate solutions yields an asymptotic solution equal to 7.189 +/- 0.115 M-ohms.

4. Design of a PYTHON Calibration Code

As shown by Chollet [9], PYTHON is highly suited as a language for writing AI codes in general, because PYTHON code acts as a manager to call on all types of application codes to run on different platforms either sequentially, iteratively, or both.

For example, the following chunk of codes, written in PYTHON, is part of a larger code that will allow a user to run a COMSOL application code named "Fong_Kabos_app_Altasim_paid_license.exe":

```
Def InverseProgram() :
  self_m_fileInput=True
  print '***  Run ComsolManager.py '
  total_volume=0.0
  if self_m_fileInput :
    returncode=None
    try :
      z=y[0]+'.dat'
      comsol_data=os.path.join(dir_name,z)
      #returncode= call(['C:/
Fong_Kabos_app_Altasim_paid_license.exe' ,
comsol_data])
      returncode= subprocess.Popen(['C:/
Fong_Kabos_app_Altasim_paid_license.exe' ,
comsol_data])
      #subprocess.Popen.terminate()
      pass
      if returncode :
        print 'Failure with return code' ,returncode
    except :
      pass
InverseProgram()
```

In short, a PYTHON code can be written to run two application codes, namely, a parametric FEA code to solve an NSMM problem and a FEA verification code to obtain an asymptotic solution within a prescribed level of uncertainty. Since it is desirable for all NSMM calibration codes to run on Windows-based computers without FEA software licenses, we show in this paper that with a compiled COMSOL finite element code and an open-source DATAPLOT statistical analysis code, it is feasible to design an intelligent PYTHON code to calibrate instruments such as the near-field scanning microwave microscope.

5. A License-free Calibration Code

The availability of a compiler for COMSOL FEA codes makes it possible for engineers to design all kinds of parametric FEA codes that will run in any Windows laptop without a FEA software license. In Fig. 15, we show how to change the operating frequency from 5 GHz to 2 GHz and re-compute to get new results in a laptop without a software license. The new results are given in Fig. 16. Using the PYTHON code, we can obtain a FEA asymptotic solution to any prescribed degree of uncertainty.

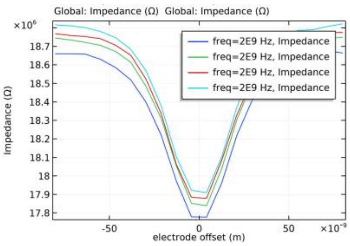

Figure 16. Impedance results for the simple NSMM spherical inclusion problem where the operating frequency has just been altered from 5 GHz to 2 GHz. Since the run only produced 4 candidate solutions, and the NLLSQ fit method requires a minimum of 5 candidates, the intelligent PYTHON code will automatically activate the executable COMSOL code to produce a 5th point.

6. Significance and Limitations of the Conceptual Design of an Intelligent Calibration Code

The conceptual design of an intelligent PYTHON code to run license-free coupled FEA and verification codes is significant in at least two innovative aspects of engineering, namely, (a) it removes a dependency on FEA license for heavy use of candidate runs to achieve solution accuracy, and (b) it provides the engineer access to a sophisticated FEA solution verification tool that would otherwise be unused for lack of lengthy training. It is obvious that the idea of designing an intelligent calibration code for NSMM is not limited only to a specimen with a spherical inclusion, because the finite element method is quite general. However, the proposed design is not without limitations, chiefly among which is the limited emphasis on seeking an asymptotic solution based on mesh density variations. It ignores uncertainty due to other factors such as material properties, voltage and frequency accuracy.

7. Concluding Remarks

Finite element analysis (FEA) methodology is a powerful tool to assist engineers and scientists in calibrating precision instruments such as near-field scanning microwave microscopes (NSMM). The availability of a compiler for any FEA software to convert the source code into an executable code that runs in a laptop without a software license is a major step forward to broaden the usage of FEA methodology. The introduction of an intelligent PYTHON code to run seamlessly both the FEA executable code and a FEA verification code in order to achieve a verified FEA asymptotic solution to a prescribed degree of uncertainty is a much-needed addition to the calibration group of the scientific measurement community.

***Abstract*—We present an end-to-end workflow to generate annotated image datasets for object detection semi-automatically, thereby reducing manual annotation need. With this workflow, which we call assistive learning, we are able to reduce manual annotation time on two experimental datasets by approximately 80%. The experimental results of this work show three contributions of the assistive learning workflow: (1) Savings on human annotation time; (2) generalizability to variable dataset sizes, domains and convolutional neural network (CNN) models; and (3) faster CNN training with limited amount of labeled data using a novel contextual sampling method, thereby a reduction in human workload early on in the assistive learning process. In addition, we wrap the workflow in an interactive annotation interface, allowing annotators without any machine learning experience to speed up the annotation process for training the CNN models.**

Keywords—data annotation workflow, computer vision, object detection, smart manufacturing, vehicle detection

I. Introduction

Object detection is one of the fundamental tasks in computer vision. This task is often useful for industrial applications in a variety of domains, such as medical imaging [1], agriculture [2] and robotics [3]. State-of-the-art object detectors are built with convolutional neural networks (CNNs). With well-built CNN architectures, object detectors can achieve excellent accuracies [4]. However, to obtain a high performance, object detectors must be trained with a vast number of training images. The images are typically labelled with bounding boxes; the process is laborious and time consuming to draw [5]. Given a diverse set of tasks that we would like to use CNNs for, being able to quickly build domain-specific datasets and models is important. There is therefore a need for a faster and more automatic annotation process.

Many existing works have been reported on methods that can reduce data-labeling efforts, including transfer learning [6], semi-supervised learning [7], and weakly supervised learning [8]. However, most of these methods still require a certain amount of training data specific to the problem being solved. Data scientists usually still have to build their own dataset to fine-tune their models. Obtaining ground truth labels for these custom datasets remain crucial and time-consuming.

Another notable technique to reduce training time for building a CNN model is active learning, where the model selects the most informative data points based on certain criteria, then inquires a human annotator to obtain labels of those points [9]. However, existing active learning algorithms face limitations. For instance, most criteria that determine informativeness can only be computed with classification problems and require extra CNN training and inference time to obtain. These limitations are further discussed in Section II.A. With the biggest drawback of active learning being the cost of computation, there is currently no practical, end-to-end workflow that uses active learning algorithms to sample image datasets for object detection.

On the other hand, works have been done to accelerate the obtainment of annotated data. Crowd-sourcing has been proposed to combine the efforts of many annotators [5]. This is, however, still costly when building large, problem-specific datasets that require expert labelers. Self-training, a technique for semi-supervised learning, has been suggested, where a model trained with a small amount of labeled data is employed to generate annotations for the remaining unlabeled data [10]. Most existing self-training works, as discussed later in Section II.B, suffer from the tradeoff between the workload of manual labeling and the accuracy of the predicted labels. The tradeoff is that it would cost more labor in the first place to get a more accurate model, but if we reduce the number of expensive manual annotations, the model trained can be inaccurate, and the generated annotations are of low quality.

In this work, we have developed an assistive learning workflow, which builds upon techniques of active learning and self-training. In active learning, the model samples the most informative data points and sends them to the annotator. In self-training, the model is first trained with partially labeled data, then used to annotate the remaining data. In the proposed assistive learning workflow, the model not only combines the behavior of learners in both techniques, but can also learn from the labeled instances and therefore gradually improve the

Paper presented at 2019 IEEE International Conference on Big Data, Los Angeles, CA, US. December 09, 2019 - December 12, 2019.

accuracy of predicted labels. This process is iterated through a feedback loop involving the annotator and the model.

This paper describes an end-to-end workflow called assistive learning that consists of a human annotator and a machine annotator cooperating in a feedback loop to annotate images in an object detection dataset. Our work shows that the assistive learning workflow is able to generalize well across object detection models and domains, and to overcome the limitation of labor-accuracy tradeoff. In addition, users can access the workflow using an intuitive user interface (UI), which allows visualization and generation of annotations. To demonstrate the robustness of assistive learning, we conduct experiments on two datasets with two CNN architectures, namely YOLOv3 [11] and Mask R-CNN [12]. The end-to-end workflow reduces the time of annotation by 79.4% and 83.1% in the two experimental datasets. Furthermore, the system is designed such that assistive learning can be utilized without the annotators having to concern themselves with the technical aspects of machine learning.

The rest of the paper is organized as follows. Section II provides an overview of related works. Section III presents a brief introduction to object detection and the CNN architectures deployed in our experiments. Section IV gives the details of the assistive learning workflow. Section V presents the experimental results. Section VI discusses the implications of the results, and, finally, Section VII briefly concludes our work.

II. Related Works

This study relates closely to the existing works on active learning and self-training for object detection. This section discusses how assistive learning leverages these works and the points of departure.

A. Active Learning

The key idea of active learning is the sampling of the most informative data point and querying it to an annotator. Active learning has been shown to reduce labeling costs on image classification tasks [13,14]. Several strategies have been formulated to evaluate the informativeness of a data point.

The most popular active learning sampling strategy for object detection is to use uncertainty indicators as measures of informativeness. The key to uncertainty-based sampling is to first calculate a degree of uncertainty of classification labels using, for example, entropy measure, and then sample the instance with the highest uncertainty. For example, uncertainty-based sampling strategies have been used for object detection tasks with shallow machine learning models [15,16,17]. Other works have applied uncertainty-based sampling to deep neural network architectures [18,19]. The works mentioned above, though achieve good results in many scenarios, sample instances solely based on the classification labels of one or two of the most uncertain detections. More information can be captured by aggregating the scores from each detection to calculate the total uncertainty of one image [20]. However, the method on deep CNN architectures still suffers from two drawbacks: First, the method does not account for the representation of the entire dataset [21]. Second, it has been shown that deep CNN models can fit even random noise labeling with high confidence, thereby reducing the effectiveness of uncertainty calculations [22]. In addition to uncertainty-based sampling, details of other sampling strategies in active learning, such as Query-By-Committee, can be found in [9].

The methods mentioned above mostly evaluate their trained model on every unlabeled instance, then calculate their measure of informativeness based on the outputted classification scores. This is impractical in the annotation scenario, because having a deep CNN model to evaluate every unlabeled image would be costly in both time and computational resources with many unlabeled images. Furthermore, with the most labor-intensive part of annotation being the accurate placement of bounding boxes, a sampling criterion computed with classification scores would not seem to be a natural and practical approach, and do not generalize to single-class object detection datasets.

Besides the above-mentioned active learning methods that solely use classification scores to determine informativeness, it has been proposed to use an intermediate CNN layer as a descriptor function to represent all images in the dataset [23]. The unlabeled image whose representation has the highest average Euclidean distance to all labeled image representations is sampled. This method, although theoretically feasible for CNN architectures and single-class datasets, is computationally inefficient, since every sampling instance requires a new round of training and evaluation with the CNN model. Our sampling method considers not only the average Euclidean distances of unlabeled images, but also some contextual criteria. The contextual sampling strategy is more computationally efficient as it does not require running machine learning models against every image. Furthermore, our method does not rely on the prediction of classification scores to sample the unlabeled images.

B. Self-Training

Many works have used a trained model to complete parts of the annotation process. A model trained with a limited number of labeled images is used to predict labels for a set of either unlabeled or weakly labeled images [24,25].

Some works, in addition to self-training, have involved humans in the process of correcting predicted labels. A Polygon-RNN tool has been introduced to allow the users to correct the polygon segmentation masks being generated by a deep CNN model [26,27]. Hand correction of masks can also be incorporated, and the model is iteratively retrained with corrected labels for medical image analysis [28].

The drawbacks of self-training works mentioned above are that they either do not cover the full end-to-end workflow or focus only on specific datasets. Our work leverages the level of human-machine interaction in existing self-training works by feeding the corrected data back to the model to continuously improve its accuracy throughout the annotation process.

III. Object Detection

Object detection is the task of generating a bounding box around the object of interest [29]. Different object detectors have been reported using machine learning methods [30,31,32]. Nowadays, CNNs (e.g. AlexNet [33], SqueezeNet [34]) trained using deep learning technologies are the predominant approach. There are two main types of CNN architectures for object detectors: one-stage and two-stage.

In this work, we have experimented both a one-stage and a two-stage detector, each with a different dataset, in order to demonstrate that the annotation tool is able to generalize across domains. We implement the one-stage YOLOv3 [11] architecture on a vehicle detection dataset [35], and the two-stage Mask R-CNN architecture on a manufacturing casting defect dataset named GDXray [36]. These two cases were chosen due to the high model scoring accuracies achieved in [35] and [37], as well as the fact that the two datasets have very different types of images. Vehicles on an image are much larger in size than defects on metal castings. Therefore a one-stage detector's grid-based prediction approach can achieve a high accuracy for the vehicle detection problem while dispensing less computational times compared to two-stage detectors. Manufacturing defects, however, are much smaller and can be easily mistaken as noise. Therefore a region proposal stage will increase the detection accuracy. Figs. 1 and 2 illustrate the images of each dataset.

A. *One-stage Object Detectors*

CNN architectures, such as RetinaNet [38], SSD [39] and YOLO [40], are one-stage object detectors whose single task is to directly predict confidence scores for classifying and constructing bounding boxes that surround the objects of interest. One-stage detectors have been shown to train faster than two-stage detectors [11,39].

A popular one-stage object detector is YOLOv3, which is one of the two refined models of YOLO, the first one-stage deep learning object detector published in 2015 [11,40,41]. YOLOv3 has been demonstrated to give a good balance of speed and accuracy in [35] and is adopted as an illustrative implementation of the assistive learning workflow for the vehicle detection dataset.

B. *Two-stage Object Detectors*

Other CNN architectures such as R-CNN [42], Fast R-CNN [43] and Mask R-CNN [12] are two-stage detectors, which consist of an intermediate stage that generates region proposals. Two-stage detectors are able to perform with very high accuracies even for images with fine details but require more computing resources to train [11].

Although training speed differs for different CNN architectures, in general, training good object detectors require a massive amount of training images with ground truth labels.

IV. Assistive Learning

We propose an end-to-end assistive learning workflow. This section is organized into two subsections. In the first subsection, we introduce the underlying framework of assistive learning, and we describe the role of the human annotator and the machine annotator in detail. In the second subsection, we describe the functionalities of an interactive UI, which allow any annotator to engage in the workflow.

A. *End-to-end Workflow*

We introduce a framework that involves the collaboration between a human annotator and a machine annotator, which *assists* and *learns* from the human. Given an unlabeled dataset, the framework consists of the feedback loop shown in Fig. 3.

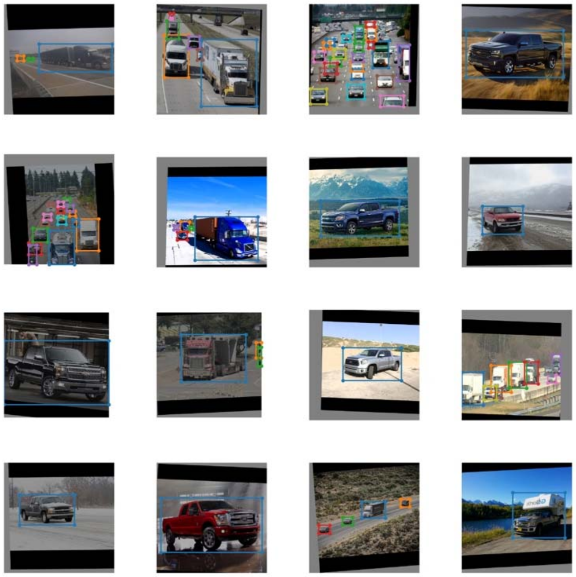

Fig. 1. Examples of labeled vehicle detection images. Vehicles are generally large and easily distinguishable visually.

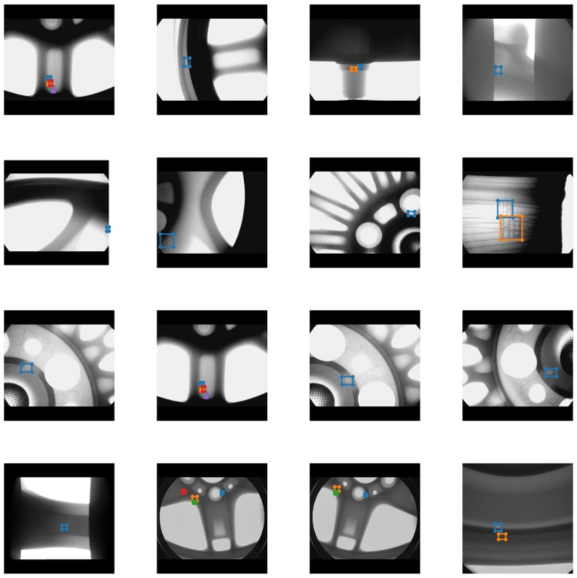

Fig. 2. Examples of labeled GDXray Casting images. Defects are small and very similar to surrounding design features.

The *human annotator* observes and annotates images suggested by the machine annotator. If the machine annotator has already annotated the image, the human annotator reviews the machine-generated labels and correct them if necessary. We consider human-generated labels as ground truth labels. The *machine annotator* consists of two modules: the object detection module and the contextual sampling module. The two modules work together to suggest and label a subsequent image, which is then sent to the human annotator for review.

1. The object detection module is a CNN model that is able to train on the ground truth labels that the human annotator has provided. It can therefore learn from more and more training

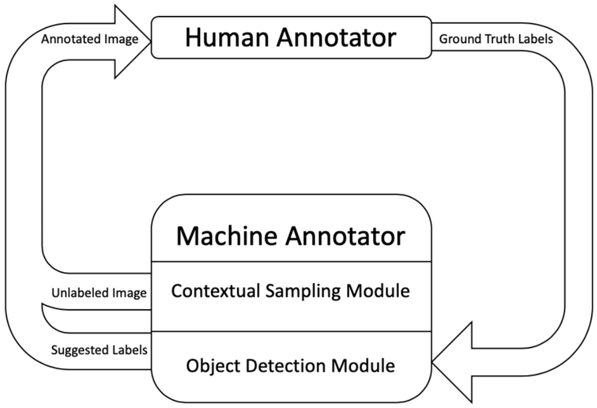

Fig. 3. Assistive learning feedback loop.

samples as we iterate through the loop as shown in Fig. 3. The object detection module annotates the sampled image outputted from the contextual sampling module and suggests the annotation to the human annotator.

2. The contextual sampling module ensures that the next unlabeled image sent to the human annotator satisfies the contextual criteria. The contextual criteria consist of two parts: uniqueness and average Euclidean distance. The criteria are applied on the raw images.

In industry applications, datasets often contain images captured from the same source or specimen. These images are therefore very similar. An example is the GDXray dataset [36], where several images are captured using the same metal casting. In contextual sampling, we avoid repeatedly sampling from the same specimen by examining an image's uniqueness. Uniqueness is defined as follows: Let's define a set of all images in a dataset, $\mathcal{X}$, consisting of labeled images $\mathcal{M}$ and unlabeled images $\mathcal{N}$, i.e. $\mathcal{X} = \mathcal{M} \cup \mathcal{N}$. Suppose there are $K\ (K \geq 1)$ pre-defined specimens in the dataset $\mathcal{X}$, the dataset $\mathcal{X}$ can also be expressed as $\mathcal{X} = \bigcup_{\mathrm{i}=1}^{K} X_i$, where X_i is the set of all images in specimen *i*. An unlabeled image x in specimen *k* (i.e. $x \in \mathcal{N} \cap X_k$, where $1 \leq k \leq K$) is considered unique if specimen *k* has the fewest number of images in the set of labeled images $\mathcal{M}$. In other words, if an unlabeled image x in specimen k ($x \in N \cap X_k$) is considered unique, then the number of images in $X_k \cap \mathcal{M}$ is fewer than or equal to that in all other $X_1, \dots, X_i, \dots, X_K \cap \mathcal{M}$, for $i \neq k$.

The other contextual sampling criterion considers the average Euclidean distance of an image. An image $x \in \mathcal{N}$ is sampled if of all the images that satisfy the uniqueness criterion, *x* has the highest average Euclidean distance to all images in the labeled set $\mathcal{M}$. We denote the average Euclidean distance between an image *x* and all images in $\mathcal{M}$ as $d_x = d(x, \mathcal{M})$.

Following the definition of the two contextual criteria, we now present the procedure of contextual sampling. We calculate the number of images in $X_i \cap \mathcal{M}$ for all $X_i \in \{X_1, \dots, X_K\}$ and select specimen *k* that has the fewest number of images among $X_i \cap \mathcal{M}$. For each unlabeled image $x \in \mathcal{N} \cap X_k$, we compute $d_x = d(x, \mathcal{M})$, the average Euclidean distance between *x* and all images in $\mathcal{M}$ and select the sampled image (denoted by $\hat{x}$) with maximum d_x among all unlabeled images *x* in specimen *k*. The pseudocode of this procedure is presented as shown in Algorithm 1. Note that for images that do not have pre-defined specimens (for example, the vehicle detection dataset), we set the number of specimens $K = 1$. Since there is only one specimen, the average Euclidean distance is the only contextual criterion.

B. *Functionality of User Interface*

A user interface (UI) is necessary for the level of human-machine interaction needed in our workflow. To that end, we develop an interface for the workflow and implement features to visualize, create, edit and remove annotations, to sample images, and to train the object detector.

1) Visualization and Annotation

Fig. 4 illustrates an example of using the interface to visualize bounding boxes generated by the machine annotator. Since the workflow is flexible to the object detector deployed, it can output any box predicted by the object detectors.

Using the library Fabric.js [44], the UI is able to render images and boxes. Furthermore, it is intuitive for a user to rescale bounding boxes with anchor points on the four edges and corners. Deletion of a box is done simply with the click of a key. An additional box can be drawn by pressing down the mouse on the location of one corner and releasing the mouse at the box's diagonal corner. An example of a human-reviewed annotation is illustrated in Fig. 5.

In addition to the intuitive annotating features, a visualization feature of the UI is to allow the annotator to detect with different models. In Fig. 4, we demonstrate that prediction can be done with YOLOv3 and Mask R-CNN on the same image. This is a convenient feature for debugging when switching models, or for the annotator to compare their accuracies.

2) Training

After the human annotator has reviewed and labeled a batch of images, the training function can take the batch of ground truth data and use it to train the object detector. Training will occur whenever the human annotator decides to do so. Since the

Paper presented at 2019 IEEE International Conference on Big Data, Los Angeles, CA, US. December 09, 2019 - December 12, 2019.

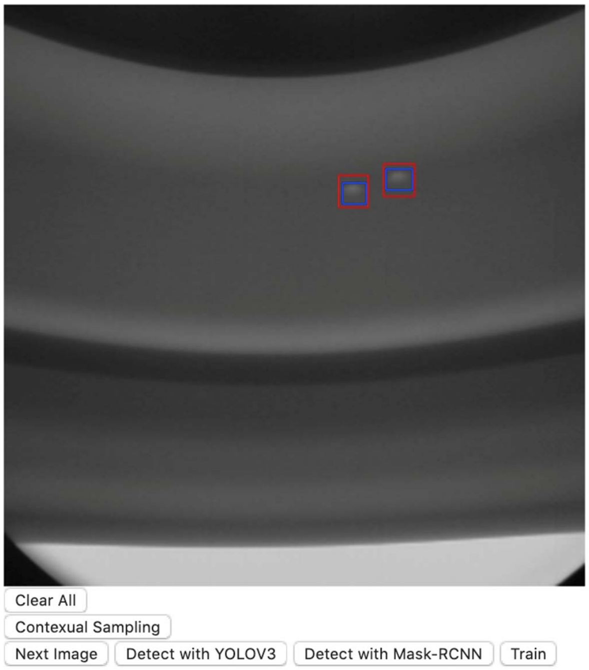

Fig. 4. A screenshot of the annotating UI. Image labeled is from the GDXray Castings dataset. Red bounding boxes are from YOLOv3 object detector. Blue bounding boxes are from Mask R-CNN object detector.

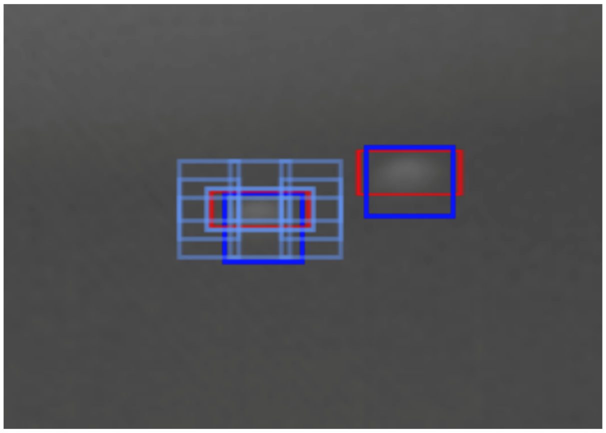

Fig. 5. An example of editing bounding boxes using anchors. With the same image in Fig. 4, the human annotator can manually edit the red bounding boxes to fit them tighter to the defects. The blue bounding boxes recommended by the object detector are kept in place as reference.

model can be trained in the background, the human annotator has the option to do manual annotations while the model trains itself. We specifically allow this parallel process because annotators are usually paid, for example, on an hourly basis, so any unnecessary waiting would be uneconomical.

The training function must be called by the human annotator by pressing the "Train" button. It will not automatically commence whenever an image has been annotated. This is a designed feature, since usually, training after every image is undesirable. Although training time differs for each model, the improved accuracy of adding only one image to the training set does not usually compensate for the cost in training time.

C. *Implementation Details*

The annotation interface developed is an application on the web browser built using the model-view-controller architecture [45]. As shown in Fig. 6, the frontend development of the tool is implemented with Javascript and HTML. The Javascript HTML5 canvas library Fabric.js [44] is used to render the images and bounding boxes on an HTML canvas, as well as to draw, edit or remove bounding boxes. In backend development, the tool uses Python 3.7 for contextual sampling, model training and detection. The CNN implementation is based on the PyTorch framework [46]. A controller module is written to connect the frontend to the backend features.

V. Experimental Results

This section discusses the two case studies to estimate the amount of manual annotation time reduced by assistive learning, and to show that our sampling method is able to reduce the amount of data required for a CNN model to achieve a certain level of accuracy.

A. *Vehicle Detection with YOLOv3*

The YOLOv3 model is trained and evaluated using a total of 3500 vehicle images from [35]. The training set consists of 2600 images, including a combination of daytime camera photos on a highway and online vehicle images. The training set has 4391 vehicle instances (2947 trucks, 344 pick-up trucks, and 1100 cars). The testing set has 900 daytime camera images captured on the highway, and consists of 1226 vehicles (566 trucks, 178 pick-up trucks, and 482 cars). Camera images under various weather and lighting conditions as well as online images are included to ensure that the machine annotator (when both detecting and sampling) can generalize, and that future camera images captured under various conditions can receive an accurate predicted label. We also augment the images by flipping them vertically and horizontally. A weight pre-trained on ImageNet data is used to initialize parameters of the model [29].

1) Annotation Time

To estimate the time taken to annotate, we use the results presented in [5], which states that the average time it takes a person to draw a bounding box is 88.0 seconds [5]. We make the assumption that editing or removing an incorrect bounding box takes half the time, or 44.0 seconds. This is in fact, quite a conservative estimation, since deleting a bounding box takes only a couple of seconds, and the adjustment of an existing box is easy when there is already a suggestion. Using the common standards in the object detection field, an intersection-over-

union (IOU) of 0.5 or above is considered a correct prediction [47]. We therefore assume that a bounding box will need to be either edited or removed when IOU is under 0.5. Note that we do not count the training time into the calculation of manual annotation time. This is because during training, the human annotator is not required to do any work. Using our system, the human annotator is free to either take a break or annotate while the model trains in the background.

To simulate annotating the vehicle detection dataset with YOLOv3, we split the 2600 images in the training set into 10 smaller datasets as shown in Table I, with dataset sizes ranging from the smallest to the largest. The order of images is obtained using the contextual sampling method described earlier in Section IV. Since the vehicle detection dataset does not contain specimens, we use average Euclidean distance as the only contextual criterion. The first dataset is considered fully annotated by a human annotator. For the first dataset, we train it for 5 epochs with weights frozen for intermediate layers of the CNN, and another 35 epochs without holding weights fixed. We test the newly trained model on the second dataset, and compare the evaluation result to ground truth labels to compute the amount of human annotation time needed to correct inaccurate labels. The second dataset, after the simulated correction process, is now considered fully annotated. The model then trains on all fully annotated images, which now consist of the first and the second dataset, for 35 epochs. The process is repeated for all remaining datasets: For each dataset after the first, we evaluate it with the model trained with previously added fully annotated images. We then add the evaluated images to the fully annotated images, simulating the hand-correction of a human annotator, then train for 35 epochs.

Since the goal of this study is to demonstrate the effectiveness of the techniques proposed, no hyperparameter optimization is conducted. The training schedule is also not aiming to fully minimize training loss. As shown in Table I, when trained on the same training set and tested on the testing set as [35], the model achieves an mean average precision (mAP) of 0.831, which is 88.7% of the mAP of 0.937 in [35]. Our accuracy is sufficiently high for the purpose of this study, but to achieve accuracies as high as [35], one will need to tune all hyperparameters and train for more epochs.

TABLE I. TOTAL ANNOTATION TIME TO LABEL ALL IMAGES USING YOLOV3 WITH VEHICLE DETECTION DATASET. RESULTS COMPARED WITH AND WITHOUT THE USE OF MACHINE ANNOTATOR.

# of images trained	**# of images annotated with machine annotator**	**Time with human annotator alone (hours)**	**Time with assistive learning (hours)**	**% Time reduced**	**mAP**
30	5	0.54	0.48	11.4%	0.042
35	10	0.37	0.32	13.3%	0.197
45	25	1.10	0.88	20.0%	0.097
70	30	1.54	0.83	46.0%	0.343
100	100	6.43	2.86	55.5%	0.227
200	200	9.34	2.59	72.3%	0.535
400	400	15.11	3.37	77.7%	0.674
800	800	29.02	5.15	82.3%	0.691
1600	1000	37.74	6.28	83.4%	0.767
2600	900	32.24	4.68	85.5%	0.831
Total hours	-	133.42	27.44	**79.4%**	

Table I shows that when annotating the entire vehicle detection dataset, assistive learning significantly reduces manual annotation time compared to a human annotator working alone. As more labeled images are added to the training set, the machine annotator saves a higher percentage of time for the human annotator, due to improved performance of the machine annotator with more training.

2) Sampling Methods

By experimenting with YOLOv3 on the vehicle detection dataset, we compare the contextual sampling method (average Euclidean distance as the only contextual criterion) proposed in Section IV with random sampling. To conduct the experiment, we train a YOLOv3 model on various numbers of images, then compare the results with those obtained from random sampling. Pre-trained ImageNet weights are used for training. Each time the model is trained on 5 epochs with weights of intermediate layers fixed, then 35 epochs not fixed. Five identical, independent experiments are run.

Fig. 7 shows that the contextual sampling method improves the performance of the object detector when there are little labeled data. With 50 labeled images, the mean mAP from 5 independent runs is 0.32 for random sampling and 0.40 for contextual sampling. Contextual sampling improves the mean mAP by 25.0%. With 100 labeled images, contextual sampling improves the mean mAP by 23.3%, from 0.43 with random sampling to 0.53 with contextual sampling. This is because with contextual sampling, the labeled data show less similarity. The object detector can therefore generalize and fit faster. As the number of labeled images grows larger, however, the performance of the model given the two sampling methods converge.

B. *Castings Defect Detection with Mask R-CNN*

The Mask R-CNN model is trained and evaluated using images from the GDXray Castings dataset [36]. The Casting Series dataset contains 2727 images. Many of the images in the

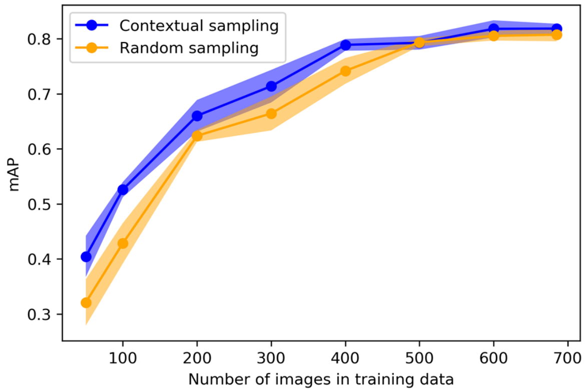

Fig. 7. Relationship between mean average precision (mAP) and number of training images, sampled randomly and contextually on the vehicle detection dataset. mAP are obtained by testing on the same test dataset. The shaded areas show the standard deviations from 5 independent runs.

# of images trained	**# of images annotate d with machine annotator**	**Time with human annotator alone (hours)**	**Time with assistive learning (hours)**	**% Time reduced**	**mAP**
30	5	0.22	0.09	61.1%	0.483
35	10	0.46	0.28	39.5%	0.150
45	25	2.47	0.31	87.6%	0.616
70	30	2.98	0.55	81.6%	0.750
100	100	8.75	1.14	87.0%	0.656
200	200	16.57	3.24	80.5%	0.793
400	285	23.44	4.11	82.5%	0.768
685	171	12.27	1.64	86.7%	0.872
Total hours	-	67.17	11.34	**83.1%**	

dataset were unlabeled or had ambiguous labels, so we chose to train on the 685 training images specified in [37,48]. Testing was conducted on the 171 images specified in [37,48]. This dataset contains a single casting defects class, but the labeled X-ray images come from 33 specimens. Images coming from the same specimen are very similar. The model parameters are initialized with weights pre-trained on COCO data [49].

1) Annotation Time

Similar to the vehicle detection problem, to simulate annotating the GDXray Castings dataset with Mask R-CNN, we split the 685 images in the training set into 8 smaller datasets, with dataset sizes ranging from the smallest to the largest. Contextual sampling is applied (with average Euclidean distance and specimen uniqueness as the contextual criteria). Due to high computing time of Mask R-CNN, we only train 5 epochs for each dataset. The first dataset includes an additional epoch for fixing the weights on all except the output layer. We evaluate every dataset after the first dataset with the model trained with previously evaluated datasets.

Table II shows the reduction of manual annotation time using a Mask R-CNN object detector to assist the annotation of GDXray Castings images. In this experiment, the models are trained on 1 epoch with fixed weights on intermediate layers followed by 5 epochs without holding weights fixed, the mAP of 0.872 for constructing the bounding boxes surrounding the defects is obtained using the same 685 training images and 171 testing images as discussed in [37,48]. The result is also compatible with the CNN model training under similar setting [37]. Although it is not conducted in this study because of extensive computational time and hyperparameter tuning required, as reported in [37], an mAP of 0.957 could be obtained when trained with 80 epochs of fixed weights on intermediate layers and another 80 epochs without holding weights fixed. That is, the trained model in this experiment achieves 91.1% of the best mAP as reported in [37]. This result is reasonable, considering that the model parameters are not optimally updated at each incremental training step. In short, the results show the workflow has the capability to greatly reduce manual annotation time.

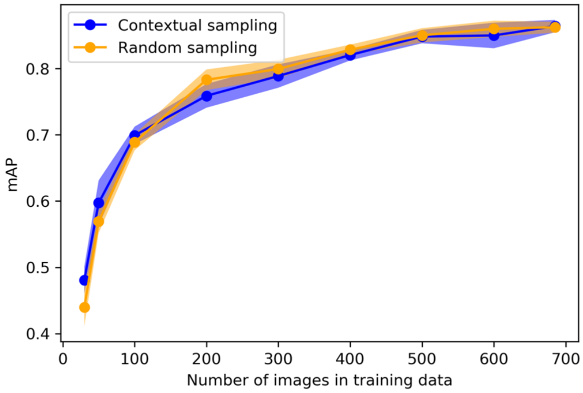

Fig 8. Relationship between mean average precision (mAP) and number of training images, sampled randomly and contextually on the GDXrays castings dataset. mAP are obtained by testing on the same test dataset. The shaded areas show the standard deviations from 5 independent runs.

2) Sampling Methods

Since the GDXray Castings dataset consists of specimens that consist of similar images, the contextual sampling method considers uniqueness and average Euclidean distance when sampling. Similar to the sampling experiments conducted in Section A, with GDXray dataset and Mask R-CNN object detector, similar results are obtained as shown in Fig. 8. When the dataset size is small, contextual sampling slightly outperforms random sampling by 9.4% mAP when trained on 30 images and 5.0% mAP when trained on 50 images.

Even though the contextual sampling method improves performance with limited labeled images, the human annotator should still take into consideration the labor-accuracy tradeoff. More upfront labor investment leads to better predicted labels. However, with the assistive learning workflow, the tradeoff can be converted to a training time-labor tradeoff. The human annotator can choose to train more frequently to increase accuracy of predicted labels, thereby reducing data-labeling efforts.

VI. DISCUSSION

In this section, we evaluate our workflow based on the experimental results presented in the previous section. Besides having shown that the workflow efficiently reduces the workload of human annotators, this section discusses additional benefits and the costs to consider when using assistive learning.

A. Generalization on Datasets

By experimenting our tool with two datasets, we were able to show that the workflow can be applied to problems from different domains due to the flexibility of the object detector and sampling strategy. In this subsection, we outline why the two datasets differ a lot in object detection, in order to illustrate the importance of cross-domain capability.

The two datasets studied are both commonly observed industrial problems in engineering yet differ mainly in the following ways:

- **Size of objects** Vehicles usually take up a larger portion of an image compared to casting defects. YOLO is not ideal for small objects since it limits the number of nearby detections [50]. Two-stage architectures that use regional proposal are shown to be better at locating small objects [40]. Alternatively, one-stage architectures can be finetuned to target small objects [51].

- **Noisiness of background** Vehicles, which have distinct colors and shape, are normally quite distinguishable from their backgrounds. On the other hand, casting defects often look very similar to design features like holes and edges [37]. CNN architectures with high quality feature maps would be better at distinguishing such defects.
- **Classes and specimens** The vehicle detection dataset has three classes of vehicles, whereas the GDXray Castings dataset has a single class but contains similar images from the same specimens. It is therefore important to have a contextual sampling method that is applicable to either scenarios.

In summary, it is important for the human annotator to take caution when choosing a suitable object detector (i.e. the CNN architecture) for annotation, as it greatly depends on the type of objects in the custom image dataset being built. Our workflow offers flexibility to customize CNN models and datasets, and introduces a computationally efficient contextual sampling method that is applicable to a variety of datasets.

B. Costs for Consideration

Although the tool is able to reduce the need of manual labor, there are additional costs to be considered. Firstly, the cost of training time can be quite significant with more complex CNN models. With these complex models, it might cost less time overall to annotate with human annotators. For example, with a one-stage object detector like YOLOv3, training time increases linearly with the number of training images. Although training the object detector more often will allow it to learn faster and reduce labeling efforts, one must evaluate whether the overall cost in time is more expensive than hand-annotation.

The second factor is the monetary cost of computational resources. CNN model training nowadays is mostly done on GPUs, which are powerful in computation. For the tool to train effectively, it therefore must connect to either a cloud GPU or a physical GPU, which can be costly. To find the most economical way to annotate a dataset, it may worth to compare the cost of hiring human annotators versus the available (and, possibly, purchasing) computing resources.

C. Future Work

The assistive learning workflow presented in this work is able to reduce manual annotation time and can be applied to annotate and build datasets. However, the training process of the machine annotator can be computationally expensive. Future work could explore training time and its tradeoff between prediction accuracy. It would also be interesting to further evaluate the workflow on object detection with other datasets and to apply the approach to other applications, such as image segmentation, natural language processing and multimodal deep learning.

VII. Conclusion

This paper has presented an assistive learning workflow to annotate bounding boxes on images for the task of object detection. By conducting two experiments, we are able to show that by connecting a human annotator and a machine annotator with a feedback loop, we can significantly reduce the amount of manual annotation time. We also propose a novel contextual sampling method, which improves the performance of YOLOv3 and Mask R-CNN object detector when trained on a very limited number of labeled images. Together, we deploy the workflow in the backend of an intuitive user interface. The experimental results show that our workflow is able to generalize to datasets in different domains and is flexible to various object detection architectures. We also note that there exists a tradeoff between training time and hand-annotation workload.

In summary, this work proposes an end-to-end workflow that uses assistive learning to annotate images for object detection. Our estimation of savings in hand-annotation efforts is conservative yet still exceptional. We hope that this workflow can be adopted to produce valuable labeled datasets across all domains, while minimizing manual labor.

Highlights:

- Gas species and soot measurements of steadily burning methanol, ethanol, and acetone 30 cm pool fires are reported.
- Measurements were verified using theoretical gas species ratios.
- Flame structure was found to be in agreement with previous work.
- Gas species concentrations were shown to vary between different fuels.

Abstract: This work documents a series of time-averaged local gas species measurements made throughout the centerline profile of 30 cm methanol, ethanol, and acetone pool fires steadily burning in a quiescent environment. All gas species measurements were obtained using extractive sampling, then analyzed using a gas chromatograph equipped with a mass spectrometer detector (GC/MS). The volume fraction of each species was calculated via the number of moles identified by the GC/MS at each location along the fire's centerline. Soot mass fractions were also measured during the gas-sampling process. The gas species and soot mass fractions were compared at different locations for fires burning three fuels.

Keywords:

Moderately-sized pool fires, acetone fuel, ethanol fuel, methanol fuel, gas species measurements

1. Introduction

Computational fire models, such as the Fire Dynamic Simulator (FDS) [1], have increased in usage within the fire protection engineering community due to their effectiveness, ease of use, and the decreased cost of computational power. To be reliable, fire models require validation to aid in their development and confirm their accuracy and limitations. The objective of this research is to provide experimental data for use in fire model development and evaluation.

Pool fires are a fundamental combustion configuration of interest. In a pool fire, the fuel surface is flat and horizontal, which provides a simple and well-defined configuration for testing models and furthering the understanding of fire phenomena. In moderate and large-scale pool fires, radiative heat transfer is the dominant mechanism of heat feedback to the fuel surface. Species concentrations and temperatures control the radiative heat transfer. An area of particular interest is the fuel rich core just above the pool surface, where vaporizing fuel molecules and other gas

Falkenstein-Smith, Ryan; Sung, Kunhyuk; Chen, Jian; Hamins, Anthony. "Chemical Structure of Medium-Scale Liquid Pool Fires." Paper presented at 13th International Symposium on Fire Safety Science, Waterloo, CA. April 27, 2020 - May 01, 2020.

species can absorb energy that otherwise would have been transferred to the fuel surface. An essential component in this zone is the spatial distribution of gas-phase chemical species. It is well known that the local gas species within a fire is a critical component of its structure. However, there are few studies in the pool fire literature that have reported local chemical species measurements, which elucidate the chemical structure of the fire and provide insight on its kinetic, heat, and mass transfer processes.

The purpose of this study is to characterize the spatial distribution of stable gas-phase chemical species in moderate-scale liquid pool fires steadily burning in a well-ventilated, quiescent, environment. Here, methanol, ethanol, and acetone are the fuels of interest. Contrary to ethanol and acetone, fires established using methanol are unusual as no carbonaceous soot is present or emitted.

In this study, all gas species measurements are made in a 30 cm diameter pool fire using liquid fuels. These fuels are selected since the measurements complement results from previous studies, including analyses of the mass burning rate, the temperature and velocity fields, radiative emission, flame height, and pulsation frequency [2, 3, 4, 5]. Additional characterization of these fires enables a more comprehensive understanding of its detailed structure, enhancing the understanding of fire physics.

2. Experimental Methods

2.1 Pool Burner Setup

A circular, stainless-steel pan with an outer diameter of 30 cm, 15 cm deep, and a 0.16 cm wall thickness was used as the pool burner. As shown in Fig. 1, the burner has an overflow basin, which extended 3.0 cm beyond the burner wall. The burner is fitted with legs such that the burner rim was 30 cm above the ground. The bottom of the burner was maintained at a constant temperature by flowing water (20 °C ± 3 °C) through the 3 cm section on the bottom of the fuel pan. Additionally, a fuel level indicator was positioned near the center of the burner to monitor the fuel level during burning.

The pool burner was located under a canopy hood surrounded by a 2.5 m x 2.5 m x 2.5 m enclosure made of a double-mesh screen wall. The walls of the enclosure were formed by a double layer wire-mesh screen (5 mesh/cm) to reduce the influence of ambient air flows that could disrupt the flow field. All measurements were made once the mass burning rate reached steady-state, achieved approximately 10 min after ignition.

The time-averaged mass burning rate, $\dot{m}$, was determined from the rate at which fuel was delivered to the pool from a reservoir positioned on a mass load cell located outside the enclosure and monitored by a data acquisition system (DAQ). The operator was able to observe a close up of a slightly discernible dimple on the fuel surface using a live video feed. The fuel level was maintained at 10 mm below the burner rim by manually adjusting the fuel flow with a needle valve.

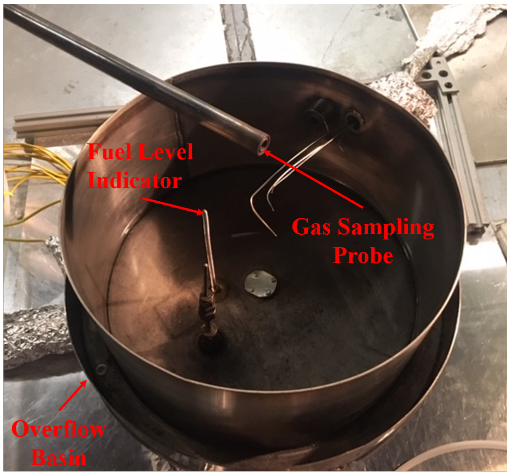

Fig. 1. 30 cm pool burner with fuel level indicator, overflow section, and water-cooled gas sampling probe.

The idealized heat release rate of each fuel, $\dot{Q}$, was calculated from Eq. 1 using the time-averaged mass loss measurements:

$$\dot{Q} = \dot{m}\,\Delta H_c \tag{1}$$

where ΔH_c is the heat of the combustion of the burned fuel provided by DIPPR® [7] and listed in Table 1.

The mean flame height was estimated from 3600 frames obtained from high-quality video recordings of the pool fire experiments, using a technique reported in Ref. [8]. Frames were processed using MATLAB's Image Processing Toolbox[1]. Imported RGB images were decomposed into binary (black and white) images using a pre-set threshold level. The flame height for a single frame was defined as the distance between the pool surface and flame tip established using MATLAB software. All measurements were repeated, then averaged to provide mean values.

2.2 Temperature Measurements

Time-averaged temperature measurements were made along the pool fire centerline. The height locations ranged from 2 to 60 cm relative to the burner rim for all fires. Additional measurements were made higher, up to 100 cm, in the acetone fire to sample its taller flame. A fine S-type thermocouple with a diameter of 50 µm (P10R-001, OMEGA) was positioned onto a traverse

[1] Certain commercial products are identified in this report to specify adequately the equipment used. Such identification does not imply a recommendation by the National Institute of Standards and Technology, nor does it imply that this equipment is the best available for the purpose.

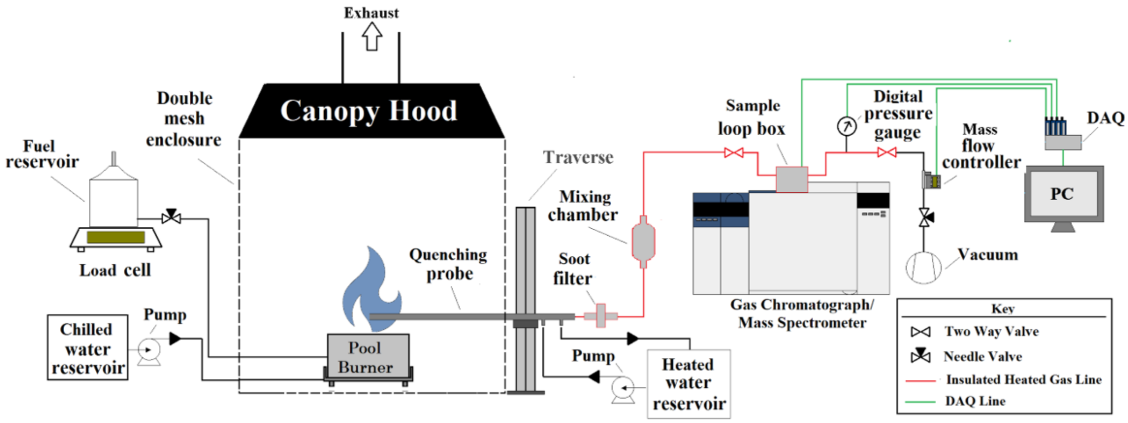

Fig. 2. A schematic of the extractive sampling setup used to extract and transport fire samples from the pool fire to the GC/MS.

such that the bare thermocouple bead was centered above the middle of the burner. The traverse controlled the position of the thermocouple relative to the burner rim as prompted via computer. Temperature measurements were sampled at 250 Hz for 2 min which represented more than 300 fire pulsing cycles [9]. The thermal inertia and radiative heat loss associated with the thermocouple were corrected following Shaddix [10]. The temperature dependent emissivity of platinum was taken from Ref. [11]. The thermal inertia correction had little influence ($<$ 5 K) on the mean temperature but significantly altered the RMS.

2.3 Measuring the Volume Fraction of Gas Species

Figure 2 displays the flow diagram for gas sampling into an Agilent 5977E Series Gas Chromatograph equipped with a mass spectrometer detector (GC/MS) fitted with a thermal conductivity detector (TCD). After achieving steady-state burning conditions, approximately 10 min after ignition, flow was initiated by a vacuum pump located downstream from the GC/MS was initiated. Gas samples were collected using a water-cooled probe. The probe was composed of two concentric, stainless-steel tubes with outer annular coolant flow and inner, extracted, gas-sample flow. The inner and outer tube diameters were 8 mm and 16 mm, respectively. Water at 90 °C flowed through the sampling probe during the experiment. The remainder of the sampling line leading into the GC/MS was heated with electrical heating tape to 140 °C to prevent condensation of water and fuels in the line.

The gas sampling period varied from 12 to 25 min, depending on the sampling location within the fire. Ensuring that the gas sample had completely swept through the GC/MS sample loop, the sampling flow was controlled using a mass-flow controller (Alicat Scientific MC-Series) located in front of the vacuum pump within the sampling line. During the gas sampling procedure, the volumetric flow was approximately 0.2 SLPM, recorded using a DAQ at 2.0 Hz. The mass-flow controller also provided temperature readings of the gas flow.

After the gas sampling period, two quarter-turn valves located on opposite ends of the GC/MS sample loop within the sampling line were closed. Once the sampled gas reached equilibrium, pressure measurements, obtained from a digital pressure gauge (OMEGA DPG409-030DWU), and temperature measurements, acquired by a K Type Thermocouple located at the GC/MS sample loop injection port, were collected at 2.0 Hz for 50.0 s. After collecting pressure and temperature measurements, the sampled gas was injected into the GC/MS.

The volume fraction, $\bar{X}_i$, was calculated from the ratio between the number of moles of a given gas species, n_i, and the total number of moles, n_{tot}. The moles of a given species were identified using the mass spectrometer and quantified from the TCD within the GC/MS. The total number of moles was determined from the summation of moles for each species detected by the TCD.

$$\bar{X}_i = \frac{n_i}{n_{\text{tot}}} \tag{2}$$

The mass fraction, $\bar{Y}_i$, of each species i was calculated from the measured volume fraction, $\bar{X}_i$, using the following expression:

$$\bar{Y}_i = \frac{\bar{X}_i \, W_i}{W_{\text{tot}}} \tag{3}$$

where W_i is the molecular weight of a given species and W_{tot} is the average molecular weight of the sample represented by

$$W_{\text{tot}} = \sum \bar{X}_i \, W_i \tag{4}$$

All measurements using the GC/MS were repeated at least twice along the centerline of the pool fire, at the same positions as the temperature measurements. Gas species concentration measurements made at the same location were averaged. The variance in the gas species volume fraction was a function of position and species.

2.4 Soot Mass Fraction Measurements

Soot was collected simultaneously with gas samples using the sampling procedure described in Section 2.3. Before a test, a desiccated 47.0 mm diameter polytetrafluoroethylene (PTFE) filter was weighed and placed into an in-line stainless steel particulate filter holder. During an experiment, the filter holder was positioned within the gas sampling line behind the sampling probe and heated to 140 °C, using heating tape to prevent condensation of water and liquid fuels on the filter. After testing, the PTFE filter was removed from the filter holder and dried in a desiccator. After desiccating for 48 h, the PTFE filter's final weight was measured. Typically, 2 mg of soot was collected during the sampling period. To obtain a meaningful sample, the sampling period varied from 12 min to 25 min depending on the sampling location within the fire.

After some tests, soot deposits were observed on the inner walls of the quenching probe. Desiccated gun cleaning patches were used to collect soot on the inside of the sampling probe. At least two patches were used to collect soot on the inside of the probe. Soot collection on the inside of the probe concluded once a used patch was observed to have no soot. Patches were weighed immediately before and 48 hrs after cleaning the inside of the probe. The soot collected from the dry patches was accounted for when calculating the soot mass fraction. The portion of the soot collected on the inner walls of the quenching probe relative to the PTFE filter varied based on the sampling location. The mass of the PTFE filter and cleaning patches were measured three times before and after each test.

The soot mass fraction, Y_s, was computed from the mass of the soot collected from the PTFE filter and gun cleaning patches, m_s, the ratio of the mass-flow controller's temperature reading, T_∞, to the temperature at the probe entrance, T_g, the total mass of gas sampled, m_t, based on the mass-flow controller readings:

$$Y_\mathrm{s} = \frac{m_\mathrm{s}}{m_\mathrm{t}}\frac{T_\infty}{T_\mathrm{g}} \tag{5}$$

The total mass of gas sampled was estimated from the product of the average volumetric flow rate measured by the mass-flow controller, $\dot{V}$, the density of the sample gas injected into the GC/MS, ρ_g, and the gas sampling time, δt.

$$m_t = \dot{V}\rho_\mathrm{g}\delta t \tag{6}$$

In Eq.6, the density of the sample gas was determined from the total mass detected in the TCD chromatogram, m_{tot}, for the injected sample volume, V_s.

$$\rho_\mathrm{g} = \frac{m_\mathrm{tot}}{V_\mathrm{s}} \tag{7}$$

2.5 Uncertainty Analysis

The expanded uncertainties of the mass burning rate, mean flame height, volume fraction of gas species, and soot mass fractions were estimated through a combination of Type A and B evaluation of standard uncertainty using a 95 % confidence interval and a coverage factor of 2. The Type A evaluation of standard uncertainty was determined from the variance of repeated measurements. The Type B evaluation of standard uncertainty was defined as the bias errors in the instrumentation. The combined uncertainty of calculated parameters were estimated using the law of propagation of uncertainty. The uncertainty of all measurements is discussed further in Ref. [6].

3. Results

3.1 Flame Observations

Figure 3 displays a series of snapshots depicting the puffing cycle for methanol, ethanol, and acetone pool fires. A repeated cycle was observed in each of the pool fires; uniformly curved flame sheets present at the burner rim repeatedly rolled towards the fire centerline to form a long and narrow plume.

The shape and visible color of the fires differed between fuel types. The methanol fire appeared to be completely blue, whereas the ethanol, and acetone fires were luminous and yellow. The methanol pool fire was observed to exhibit a quasi laminar flame structure compared to the more turbulant nature of fires seen for the other two fuels. The observed dynamic shapes were consistent with previous experiments [3, 4, 5, 12, 13, 14].

Falkenstein-Smith, Ryan; Sung, Kunhyuk; Chen, Jian; Hamins, Anthony. "Chemical Structure of Medium-Scale Liquid Pool Fires." Paper presented at 13th International Symposium on Fire Safety Science, Waterloo, CA. April 27, 2020 - May 01, 2020.

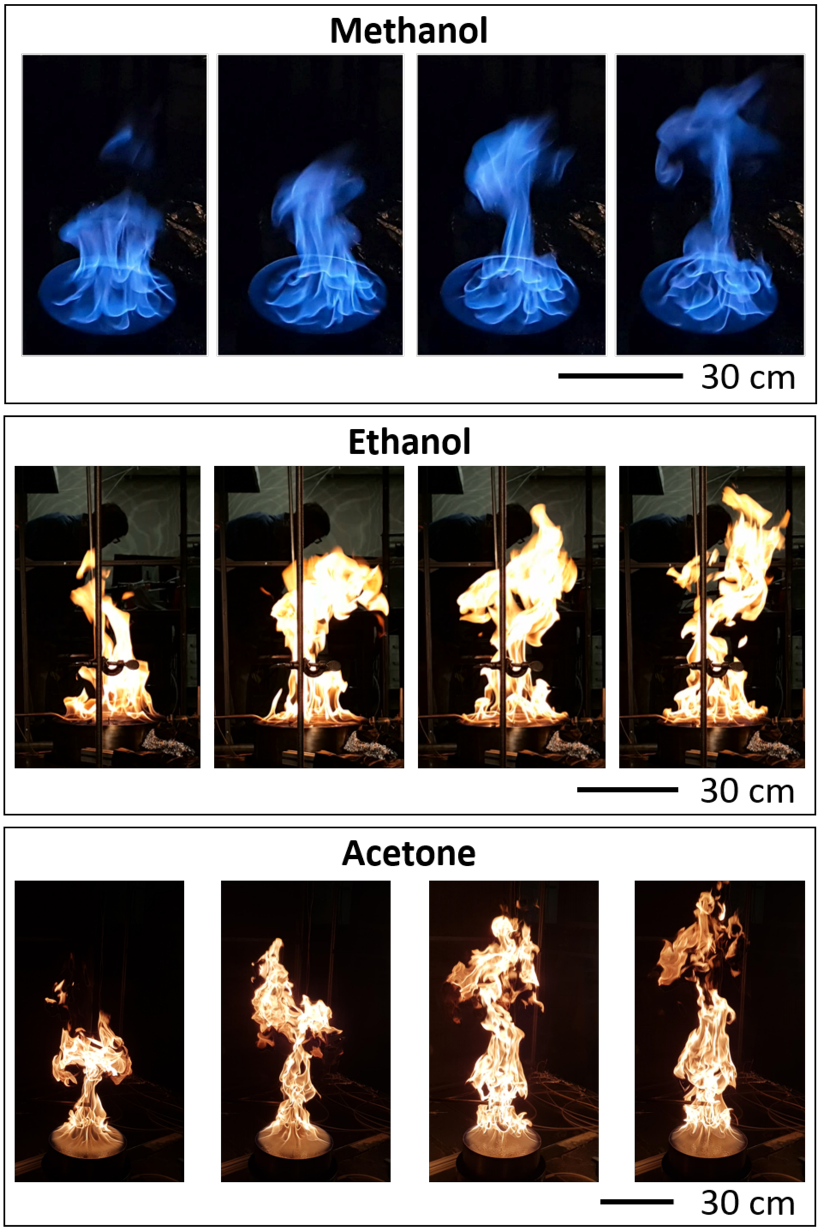

Fig. 3. Snapshots of the methanol (top), ethanol (middle), and acetone (bottom) pool fires during their pulsing cycles of frequency 2.6 Hz [9].

Table 1: List of measurements and thermochemical properties of fuels burning in a well-ventilated round 30 cm diameter pool fire burning in a quiescent environment. Measurement uncertainties are discussed in detail in Ref. [6].

Parameter (units)	**Methanol**	**Ethanol**	**Acetone**
Mass Burning Flux (g/m^2s)	12.4 ± 1.1	13.9 ± 0.8	17.6 ± 2.7
Heat Release Rate (kW)	17.4 ± 1.4	26.3 ± 1.5	35.5 ± 5.4
Mean Flame Height (cm)	36.4 ± 16.0	61.1 ± 28.2	91.5 ± 34.6
Heat of Combustion (kJ/g) [7]	19.9	26.8	28.6
C/H	3.0	4.0	6.0

The measured time-averaged burning flux and calculated ideal heat release rate are provided in Table 1. The heat release rate was calculated from Eq. 1. The time-averaged flame height reported in Table 1, of the methanol pool fire, was the shortest, followed by the ethanol, and then the acetone pool fires. In comparison to the measured mean flame height of each fuel, Heskestad's theoretical flame height, reported in Ref. [16], falls within the experimental uncertainty. The measurements in Table 1 are in agreement with measurements from Ref. [4] within experimental uncertainty.

3.2 Temperature and Gas Species Measurements of Methanol, Ethanol, and Acetone Pool Fires

To account for the difference in height between the methanol, ethanol, and acetone pool fires, the mean flame height, H, of each fuel was converted to dimensionless distance, Z^*, which was calculated as follows:

$$z^* = H\left(\frac{\dot{Q}}{c_p\sqrt{g}\rho_o T_o}\right)^{\frac{2}{5}} \tag{8}$$

Here $\dot{Q}$ is the heat release rate, g is the gravitational constant, and c_p and ρ_o are the specific heat and the density of air at room temperature, T_o.

Figure 4 shows the time-averaged corrected gas temperatures from the centerline of the methanol, ethanol, and acetone pool fires. The maximum mean temperature from each pool fire was found to peak at an approximate z^* of 0.6. Methanol was determined to have the highest mean temperature of 1316 K with ethanol and acetone exhibiting maximum mean temperatures of 1281 K and 1190 K, respectively. The maximum mean temperature of fuels with higher heat release rates is shown to be lower compared to other fuels.

Figure 5 displays the volume fraction, $\bar{X}_i$, of major species centerline measurements as a function

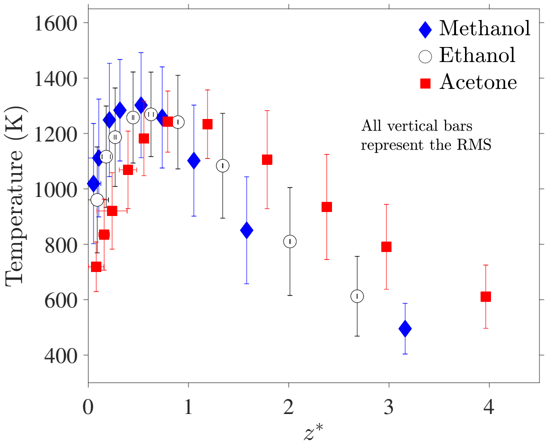

Fig. 4. Mean and RMS centerline temperature profiles of methanol, ethanol, and acetone pool fires during their pulsing cycles with z^* expanded uncertainty.

of Z^* along the centerline for the methanol, ethanol, and acetone fires. Major species detected in the TCD chromatogram include combustion reactants (fuels and oxygen, O_2), combustion products such as water, H_2O, and carbon dioxide, CO_2, combustion intermediates such as carbon monoxide, CO, hydrogen, H_2, and inert gases such as Nitrogen, N_2, and Argon, Ar. Methane was detected and quantified in all fires. In the case of the ethanol and acetone fires, soot, benzene, acetylene, ethylene, and ethane were also detected and quantified. Trace amounts of other species were also detected including propene, acetaldehyde, and ethyl acetate, which is consistent with the literature [17, 18].

For all fuels, the fuel and oxygen volume fractions were largest and smallest, respectively, close to the fuel surface. The volume fraction of fuel did not reach 1.0, since the lowest position of gas species measurement for all fuels was 2 cm above the burner rim. The volume fractions of inert gases were found to have increased relative to the distance from the fuel surface. Additionally, the maximum concentration of each species was observed at a lower z^* compared to where the maximum temperature was achieved.

Methanol and ethanol volume fraction profiles of H_2O and CO_2 with respect to Z^* were similar. The largest volume fractions for all product species, such as CO_2, CO, and H_2O, were achieved when burning acetone, except for H_2, whose peak was the lowest compared to the other fuels. Acetone was also found to produce a larger mass fraction of soot at every location along the centerline profile compared to the ethanol fire. No soot was observed in the methanol fire.

3.3 Comparison of Gas Species Measurements to Theoretical Values

Verification schemes were developed in order to assess the accuracy of the gas species measurements, carbon to hydrogen, product species, and inert species ratios were calculated and compared to theoretical values for the methanol, ethanol, and acetone pool fires. Each calculation

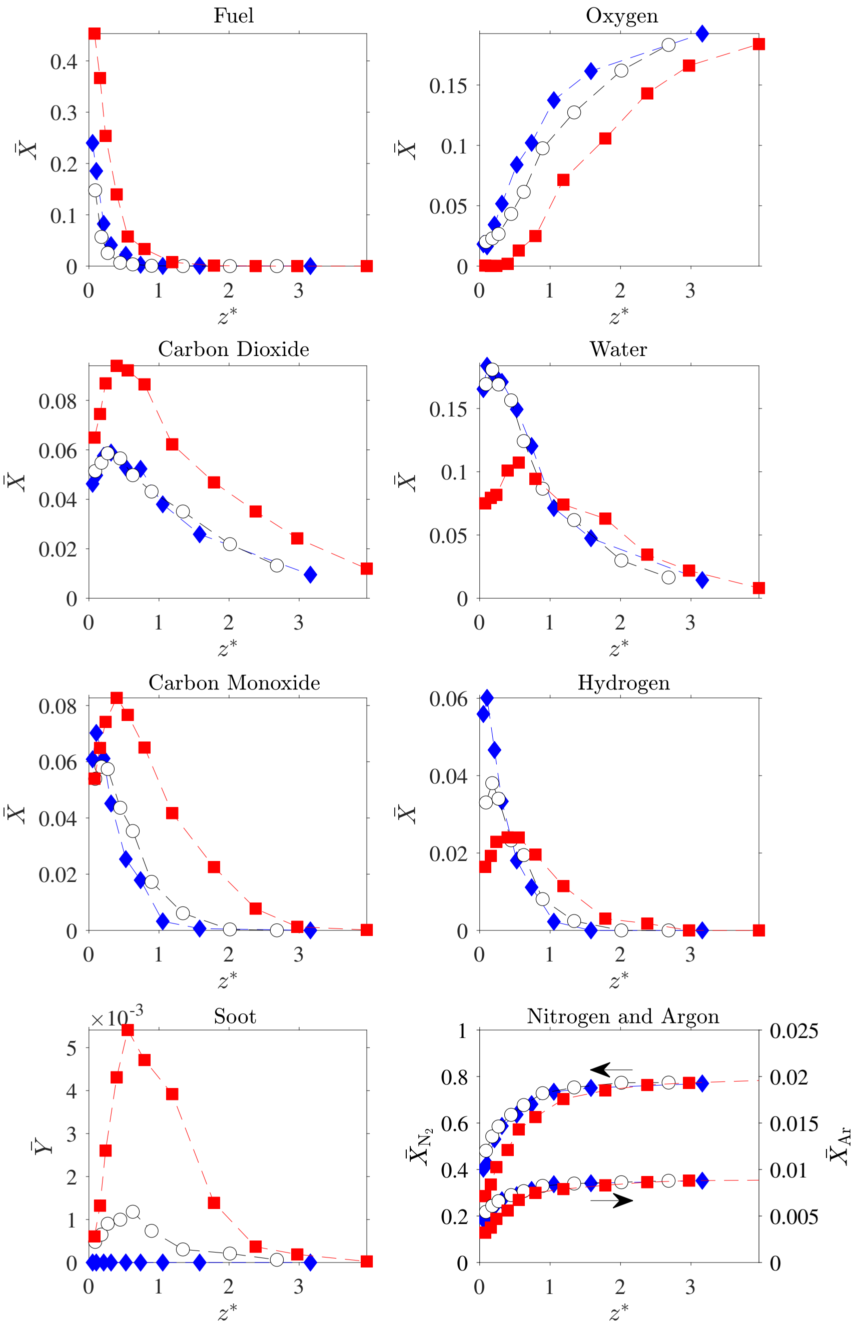

Fig. 5. Centerline volume fraction and soot mass fraction profiles of methanol (♦), ethanol (○), and acetone (■) pool fires.

only incorporates quantified species and assumes other identified species are trace amounts. The expanded uncertainty of the carbon to hydrogen, product, and inert ratios was determined using the law of propagation of uncertainty that accounted for the error of each volume fraction measurement.

The theoretical value of the carbon to hydrogen ratio was determined from the mass fraction of carbon and hydrogen residing within the parent fuel and are reported in Table 1. As shown in Eq. 9, the carbon to hydrogen ratio was calculated from the mass fraction of any quantified gas species that contained either carbon, $\bar{Y}_{i,\mathrm{C}}$, or hydrogen, $\bar{Y}_{i,\mathrm{H}}$. Here W_C and W_H are the molecular weights of carbon and hydrogen.

$$\frac{\mathrm{C}}{\mathrm{H}} = \frac{\sum \bar{Y}_{i,\mathrm{C}} \frac{W_\mathrm{C}}{W_i}}{\sum \bar{Y}_{i,\mathrm{H_2}} \frac{W_{\mathrm{H_2}}}{W_i}} \tag{9}$$

The carbon to hydrogen ratio for each experiment is shown in Fig. 6. The dotted line represents the theoretical value stated in Table 1. For each fuel, the data are shown to be in agreement with the theoretical value, indicating that the analysis is successful in quantifying most of the carbon and hydrogen containing species.

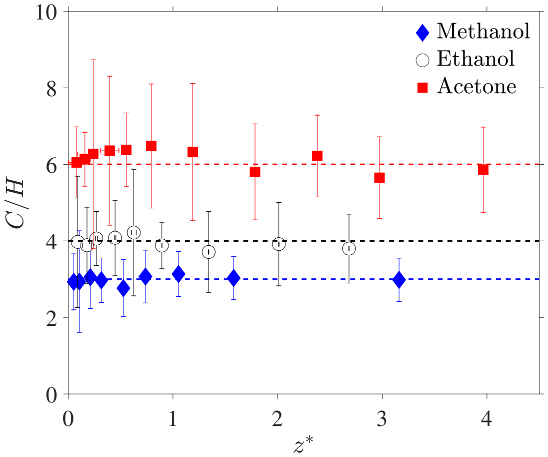

Fig. 6. Carbon to hydrogen ratio calculated from experimental values, with uncertainty bars, compared to theoretical values. Dotted lines represent the theoretical carbon to hydrogen ratio calculated from the mass fraction of carbon and hydrogen residing within the parent fuel.

Another verification test compared volume fraction measurements to stoichiometric combustion ratios, SCR, determined from the reaction below.

$$\begin{aligned} &\mathrm{C_xH_yO_z + a\ (O_2 + 3.76\ N_2 + 0.0445\ Ar)} \\ &\quad \mathrm{\rightarrow b\ C_xH_yO_z + c\ O_2 + d\ CO_2 + e\ H_2O + f\ H_2 + g\ CO} \\ &\quad\quad \mathrm{+ h\ CH_4 + i\ C_2H_2 + j\ C_2H_4 + k\ C_2H_6 + l\ C_6H_6} \\ &\quad\quad \mathrm{+ f\ (3.76\ N_2 + 0.0445\ Ar)} \end{aligned} \tag{10}$$

When simplified, the SCR of each fuel was calculated as:

$$\mathrm{SCR}_{\mathrm{methanol}} = \frac{\bar{X}_{\mathrm{H_2O}} + \bar{X}_{\mathrm{H_2}}}{\bar{X}_{\mathrm{CO_2}} + \bar{X}_{\mathrm{CO}}} = 2 \tag{11}$$

$$\mathrm{SCR}_{\mathrm{ethanol}} = \frac{\bar{X}_{\mathrm{H_2O}} + \bar{X}_{\mathrm{H_2}} + \frac{1}{2}\bar{X}_{\mathrm{CH_4}}}{\bar{X}_{\mathrm{CO_2}} + \bar{X}_{\mathrm{CO}} + \frac{2}{3}\bar{X}_{\mathrm{C_2H_4}} + 4\bar{X}_{\mathrm{C_6H_6}}} = \frac{3}{2} \tag{12}$$

$$\mathrm{SCR}_{\mathrm{acetone}} = \frac{\bar{X}_{\mathrm{H_2O}} + \bar{X}_{\mathrm{H_2}} + \bar{X}_{\mathrm{CH_4}} + \bar{X}_{\mathrm{C_2H_6}}}{\bar{X}_{\mathrm{CO_2}} + \bar{X}_{\mathrm{CO}} + 3\bar{X}_{\mathrm{C_6H_6}}} = 1 \tag{13}$$

Figure 7 shows the difference between the SCR and experimental data. The dotted lines represents the SCR values calculated from Eq. 11, 12, and 13. Direct comparison of the measured values to the idealized values shows that there is general agreement and that the volume fraction measurements are not unreasonable. An exact match is not expected since the idealized values do not take into account molecular diffusion, nor the mass of soot.

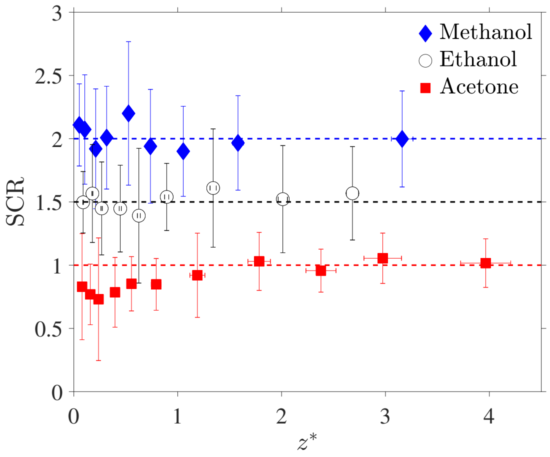

Fig. 7. Comparison of Stoichiometric Combustion Ratio, SCR, calculated from experimental and theoretical values. Dotted lines represent the theoretical SCR calculated using Eq. 12, 11, 13.

An inert ratio was also calculated from the volume fraction measurements of argon to nitrogen. Since both argon and nitrogen are inert, the ratio between them should be reasonably consistent across all fuels. The inert ratio was measured from ambient air samples using the setup described in Sec. 2.3. The inert ratio of ambient air was determined to be 0.012 ± 4 %. The range of the inert ratios calculated from the ambient air sample is depicted in Fig. 8 as the error band. The inert ratios determined from pool fire gas samples are shown to be within the error band region, which further supports the validity of the nitrogen and argon volume fraction measurements.

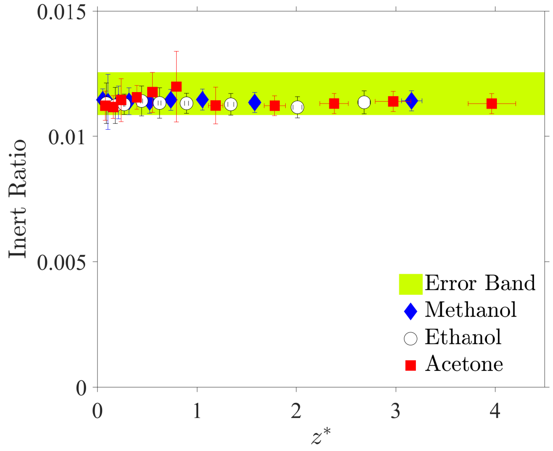

Fig. 8. Inert ratios calculated from the volume fractions for argon and nitrogen, compared to inert ratios determined from ambient air and represented as error band.

4. Conclusions

In summary, time-averaged local measurements of temperature and gas species concentrations were made to characterize the structure of methanol, ethanol, and acetone 30 cm diameter pool fire steadily burning in a quiescent environment. A verification scheme was developed to verify the gas species measurements that considered the overall stoichiometry of combustion for each fuel (see Eq. 12, 11, 13) Using this scheme, the gas species measurements were favorably compared to the idealized SCR values, which lends confidence to the veracity of the measurements. These local measurements complement previous measurements and provide insight into the complex chemical structure of medium-scale pool fires.

5. Acknowledgments

The authors would like to acknowledge Kimberly Harris of the Gas Sensing Metrology Group at NIST, who assisted in developing the species calibration method used in the study.

SUMMARY

The purpose of this summary is to review Air Infiltration and Ventilation Centre activities, as reflected in its publications, related to indoor carbon dioxide over the 40 years that have transpired since its creation. These activities, like most applications of indoor CO_2 to the fields of ventilation and indoor air quality, have focused on the following: control of outdoor ventilation rates, i.e., demand control ventilation; use as a tracer gas to measure outdoor air change rates; providing an indicator or metric of IAQ; and, directly impacting human health, comfort and performance. More recent work on CO_2 generation rates from building occupants and CO_2 concentrations in standards and building regulations is also covered. This summary was generated by searching on Air Infiltration and Ventilation Centre publications, though the findings also reflect the evolving application and understanding of indoor CO_2 in the broader literature.

KEYWORDS: carbon dioxide; indoor air quality; metrics; ventilation

GENERAL DISCUSSIONS OF INDOOR CO_2

One of the earliest Air Infiltration and Ventilation Centre (AIVC) publications on the application of indoor CO_2 is a short article covering a range of topics, including tracer gas applications, indoor air quality (IAQ) evaluation, and CO_2 as an indicator of occupancy (Liddament, 1996). Another short paper was published more recently, which focused on CO_2 as an IAQ indicator and for ventilation control (de Gids and Wouters, 2010). No other general reports or publications on CO_2 have been issued by the AIVC over its 40 years. The application of CO_2 has been covered mostly by individual conference papers on the topics covered below. For each of the topics, a table of references is provided at the end of this summary. These tables are not exhaustive but provide a sense of the issues covered for each topic.

DEMAND CONTROL VENTILATION

Indoor CO_2 has been discussed as a control parameter for outdoor air ventilation for decades, with the goal being to provide sufficient ventilation for the occupants in a space. Ventilating for the actual occupancy rather than a maximum design value provides an opportunity to reduce energy used for space heating and cooling, as well as assuring that the ventilation is sufficient to meet the needs of the occupants. In 2001 the AIVC generated a literature list (LL) that identified about 50 publications on the topic of CO_2 demand control ventilation, many of them not published by the AIVC itself. Additional work on the topic has continued in subsequent publications on sensor performance, energy and IAQ impacts, case studies in a variety of building types and other subtopics as noted in the table below.

CO_2 AS A TRACER GAS

Carbon dioxide has long been recognized as a useful tracer gas for studying building ventilation and airflow given its low reactivity and toxicity, relative ease of measurement and, in some

Persily, Andrew K.; Dols, William Stuart; Emmerich, Steven; Ng, Lisa. "The Role of Carbon Dioxide in Ventilation and IAQ Evaluation: 40 years of AIVC." Paper presented at 40th Air Infiltration and Ventilation Centre Conference, Ghent, BE. October 08, 2019 - October 09, 2019.

applications, building occupants serving as a convenient tracer gas source. CO_2 was identified as a potential tracer gas in an early AIC publication (Liddament and Thompson, 1983). Since that time, CO_2 has been used as a tracer gas in many studies, with several noted below.

IAQ ASSESSMENT

Indoor CO_2 concentrations have long been used as part of IAQ assessments with the oldest reference listed in the table below dating back to 1985. Some of these assessments measure CO_2 concentrations as one of many pollutants monitored, though many assessments do not explain the significance of the measured concentrations or compare them to a reference or guideline value. Such measurements are still common as part of IAQ investigations; the explicit consideration of CO_2 concentration metrics is a more recent development and is discussed next.

IAQ METRIC

The AIVC has focused on IAQ metrics in recent years, with the topic being a major theme of its 2016 conference held in conjunction with the ASHRAE IAQ conference series. Only two papers on the topic of CO_2 as an IAQ metric are listed in the table below, but the issue has been discussed in recent AIVC workshops and conference sessions without any papers being published and those discussions are likely to continue.

CO_2 GENERATION RATES

The use of CO_2 as a tracer gas for quantifying building and space ventilation rates requires a value of the rate of CO_2 generation by the building occupants. For many years, default values from ASHRAE and other sources have been used without evaluating their accuracy or the sources on which they were based. Recent publications have developed more well-documented and robust methods for estimating these generations rates, with three AIVC conference papers included in the table below.

STANDARDS AND REGULATIONS

While indoor CO_2 has been considered in ventilation and IAQ studies for decades, most standard or guideline values were only for industrial environments. More recently a number of standards and building regulations have been promulgated with specific indoor CO_2 concentration limits. Several of these are covered by the publications listed in the table below, though other countries and localities appear to also be setting such limits.

CO_2 IMPACTS ON BUILDING OCCUPANTS

Finally, a number of recent studies have taken a new look at how CO_2 impacts building occupants both physically and mentally. Many of these studies have been looking at concentrations that are typical of indoor spaces. However, the studies in the broader literature are not consistent as to the human effects observed. The three studies listed in the table below are just an example of such work that has been presented in recent AIVC conferences.

Highlights:

- Time series sensor data for cooking with electric-coil and gas cooktops are presented.
- Discussion of data preprocessing and feature selection for machine learning on real-time fire prevention application.
- Workflow for constructing and testing machine learning models is demonstrated.
- Support vector machine (SVM) detection algorithm correctly classifies 96.9 % of the data points as normal or hazardous conditions for oils on an electric-coil cooktop.
- Multi-step models can enhance data classification and improve overall detection accuracy.

Abstract:

This paper[1] presents a study to examine the potential use of machine learning models to build a real-time detection algorithm for prevention of kitchen cooktop fires. Sixteen sets of time-dependent sensor signals were obtained from 60 normal or ignition cooking experiments. More than 200 000 data instances are documented and analyzed. The raw data are preprocessed. Selected features are generated for time series data focusing on real-time detection applications. Utilizing the leave-one-out cross validation method, three machine learning models are built and tested. Parametric studies are carried out to understand the diversity, volume, and tendency of the data. Given the current dataset, the detection algorithm based on support vector machine (SVM) provides the most reliable prediction of pre-ignition conditions (with an overall classification accuracy of 96.9 % for oils on an electric-coil cooktop). Analyses indicate that using a multi-step approach could further improve overall prediction accuracy. The development of an accurate detection algorithm can provide reliable feedback to intercept ignition of unattended cooking and help reduce fire losses.

Keywords: machine learning, time series classification, cooking, fire prevention, fire detection

[1] Certain commercial products are identified in this paper in order to specify adequately the equipment used. Such identification does not imply recommendation by the National Institute of Standards and Technology, nor does it imply that this equipment is the best available for the purpose.

1. Introduction

A study conducted by the National Fire Protection Association (NFPA) based on fire loss data from the National Fire Incident Reporting System summarizes the US cooking fire problem [1]. During the period 2013 – 2017, household fires involving cooking were responsible for approximately 173 200 fires, 5 020 injuries, and 550 deaths annually. This represents 49 % of all reported home fires in the US. In 2017, U.S. Fire Departments responded to an average of 470 home cooking fires per day. Of these fires, cooktops (or ranges) were found to be involved in 62 % of reported home cooking fire incidents, 89 % of home cooking fire deaths, and 79 % of home cooking fire injuries. Unattended cooking was the leading cause of cooking fires.

Households that use electric ranges have a higher risk of developing a cooking fire than those using gas ranges. Although 60 % of households cook with electric cooktops, 79 % of reported cooktop fires were electric [1]. In terms of standards development, the abnormal ignition test in UL 858[2] represents significant progress in addressing unattended electric-coil heating element cooktop fires [2]. However, there are no current analogous standards applicable to other types of electric cooktops or to gas ranges in North America, and there are no standards for existing electric-coil element cooktops/ranges manufactured before 2019. Additionally, the cooking fire problem in the US may be worse than it was a few decades ago. Cooking caused more home fire deaths in 2013-2017 than in 1980-1984 [1]. In summary, the cooking fire problem has not been adequately addressed and the consequent fire casualties. New approaches are needed to reduce cooking fires.

Typical smoke detectors being installed in kitchens are well-known to be prone to nuisance alarms caused by normal cooking activities. Despite research efforts made to understand the cooking fire characteristics [3,4], the signal behavior of various sensors [5,6] and the development of advanced cooking ignition detection algorithms [7,8], only a few of these improvements can be used in practical environments. Indeed, studies [9,10] show that commercially available smoke detectors are primarily designed to provide alerts and/or warnings for flaming fires in which fuel packages such as upholstered furniture, appliances, and/or kitchenware are being ignited. For detection of cooktop pre-ignition conditions, alterative detection technologies and analysis are needed.

Johnsson [11] conducted a series of experiments to determine the feasibility of using research-grade sensors to distinguish the signal behaviors between normal cooking activities and ignition conditions on an electric range in a mock kitchen. Optimal location for sensor placement and the associated cut-off value for such a detection system were suggested. More recently, Mensch et al. [12] extended the work of Johnsson using a wide range of consumer-grade sensors to develop a pre-ignition detection system. Sensor signal differences were investigated, and a threshold based on the magnitude of a volatile organic compounds (VOC) sensor was determined to best differentiate the signal peak for normal cooking and the minimum signal 60 s before ignition. More recently, the pre-ignition detection system was extended to account for both normal and ignition cooking conditions using gas cooktops [13]. Mensch and co-workers conducted a statistical analysis and showed that the previously determined threshold for the VOC sensor had to be modified to accommodate the additional data and to assure detection sensitivity and

[2] An "abnormal" ignition test was extended to consider the average temperature of a dry (without cooking oil), round, 20 cm diameter, cast iron pan [2]. If the average pan temperature does not exceed 385 °C for 30 min with the element on its highest power setting, the test is considered a pass.

nuisance immunity. A machine learning algorithm was implemented to study the prediction performance of using signals from either individual sensor or all sensors. The preliminary results highlighted the potential benefits of implementation of machine learning algorithms. Indeed, as the volume of data becomes larger and data complexity increases, advanced data processing, such as considering the rate of change of a sensor signal or ratios of signals from different sensors, may be beneficial to discriminate different cooking conditions.

Machine learning algorithms have the capability to transform a large set of complex data with multiple variables in meaningful ways, such that a hyperplane or a dynamic threshold can be obtained for classification problems. In fact, data-driven analytics have been used to resolve complex problems for a variety of applications. In structural engineering [14], a logistic regression model was used to provide failure detection of a shackle with a dual sensing system. For outage prediction of power grids [15,16], three-dimensional support vector machine (SVM) [17] were developed using limited data. Hand-crafted features were extracted to improve the performance of prediction. In the combustion community [18], a convolutional neural network was used to predict the likelihood of ignition for a hydrogen jet in air crossflow. However, no previous studies have been carried out to study the use of machine learning models that can classify pre-ignition conditions for different cooking scenarios. Using the experimental data collected in [13], this paper contributes the use of machine learning for development of robust and reliable early warning algorithms for sensor data. The developed algorithm can help to automatically cut cooktop power or gas flow to prevent cooktop ignition.

The rest of this paper is divided into four sections. Section 2 presents the experimental apparatus and procedure. Section 3 presents detailed descriptions associated with the proposed machine learning models. Section 4 discusses the results and key findings. Conclusions are provided in Section 5.

2. Experimental Apparatus and Procedure

Here, the focus is on electric coil element cooktop fires although some experiments were conducted using a gas cooktop. The experimental apparatus and procedure have been previously described in [12,13,19]. Some details are included here to provide a general description of the work.

2.1 General Setup

A series of 60 experiments were conducted in a mock kitchen, previously reported in [12,13]. A schematic of the experimental setup is shown in Figure 1. As seen in the figure, a cooktop/range is located between two gypsum-board cabinets. The dimensions of the cooktop/range are 68 cm in depth and 76 cm in width. The top surface of the cooktop/range was level with the standing cabinets. Two cooktops were considered: a household electric-coil cooktop with two heating element sizes and a household gas cooktop with three heating element sizes. For the electric-coil stove, both the big (20 cm) and the small (15 cm) heating elements were used. The heating power was measured as approximately 1.1 kW and 1.8 kW for the 15 cm and 20 cm electric-coils, respectively. For the gas cooktop, the estimated heating power was 4.0 kW for the large burner and 3.4 kW for the medium burner. The small gas burner was not used in the experiments.

An aluminum shroud was used in some of the experiments to reduce the influence of air circulation in the room.

2.2 Range Hood and Duct

Figure 1 shows the mock kitchen with a nominal 76 cm wide exhaust hood. The separation distance between the bottom surface of the range hood and the upper surface of the cooktop was 84 cm. The range hood was a 200-CFM (approximately 0.1 m^3/s) rated venting system to remove smoke, grease, odors, and moisture from the cooking space. The fan had variable flow control. The outlet of the range hood was connected to a nominal 15 cm diameter aluminum duct and the exhaust air was vented to the outside environment. The exhaust flow was characterized using a velocity probe at the center of the duct after the sensor array. The average flow speed and its standard deviation was 3.4 m/s ± 0.1 m/s over all the experiments. Using the electric coil cooktop, the duct temperature increased by an average of 9 °C during cooking, causing an estimated reduction in duct mass flow of 3 %. For the gas cooktop, the duct temperature increased by an average of 23 °C, which is estimated to reduce the duct mass flow by 7 %. The duct length between the range hood opening and the sensors was approximately 3 m.

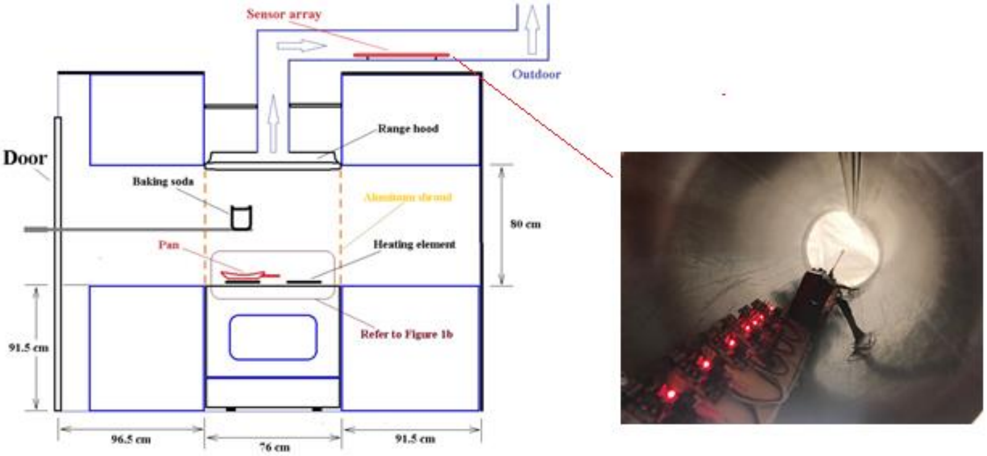

Figure 1. Schematic drawing of experimental setup (not to scale) and close-up view of the sensor array (in the duct).

2.3 Sensor Array

Figure 1 shows the sensor array secured inside the duct. There were 14 different sensors which are sensitive to smoke, alcohol, hydrocarbons, hydrogen, natural gas, carbon monoxide, volatile organic compounds (VOC), dust/aerosols, humidity, flow, indoor air quality (IAQ), temperature, and carbon dioxide. The dust sensor was modified from a commercial product to extend its range of sensitivity. Appendix A provides additional information for the sensor array.

2.4 Cooking Pans

A number of cooking pans were used in the experiments. The pans were either 20 cm or 25 cm diameter round pans. Four different types of pan materials were considered: cast iron, aluminum, stainless-steel, and a 5-layer aluminum/stainless-steel composite. Most of the experiments used the 20 cm cast iron pan, which is the cookware specified in the new UL 858 standard test [2]. It should also be noted that Type-K thermocouples were spot-welded or peened onto the top surface of each pan to monitor its temperature. In general, there were two thermocouples used to measure the pan temperature: one at the center of the pan, and one closer to the edge. Thermocouples were used to monitor the stage of cooking. For the 20 cm cast iron pan on the small electric burner, the temperature towards the edge of the pan was about 23 °C higher than the center temperature. For experiments that only measured the temperature in the center of the pan, the temperature closer to the edge was estimated using a linear regression of the relationship between the two temperatures from experiments that both temperatures were measured [13].

2.5 Food

A representative range of foods were considered, including cooking oil, butter, chicken legs, salmon, hamburger, bacon, and french fries. As mentioned in [12,13], the cooking oils tested included canola oil, corn oil, olive oil, sunflower oil, and soy oil. The most common experiment used 50 mL of oil, but larger volumes of oil were also considered. A list of important test conditions for all experiments is summarized in Appendix B.

2.6 Test Procedure and Data Acquisition

For most experiments, both oils and food samples were prepared and placed on the pan before turning on the burner. The pan was centered on the specified burner. The gas or electric burner was generally set to its maximum power setting, and the output from the sensors was monitored. Data acquisition started at least 180 s before the heating element was turned on. Experiments were conducted until the food samples ignited or charred, or until normal cooking was complete. If ignition occurred, the fire was extinguished immediately by remotely applying baking soda. The range hood was kept turned on for the entire test period. Background signal values for each sensor, obtained before the burners were turned on, were subtracted from the raw signals. LabVIEW was utilized and an in-house program was coded to facilitate data acquisition. The sampling rate was set to 0.25 Hz. In total, data was obtained across over 12 800 time points.

3. Procedure for Machine Learning

Depending on the nature of the data (i.e., time series, images, text), the optimal machine learning architecture may be different. However, the overall workflow is relatively the same. After data collection, there are five primary steps: data profiling, preprocessing, feature selection, training and evaluation.

3.1 Data profiling

Figure 2 shows the data for 11 selected sensors together with the pan temperature for Exp. 8, which tested 50 mL of canola oil in a round 20 cm cast iron pan on a small electric cooktop burner set to maximum power at time = 0. When the pan temperature is below 200 ºC, there is nearly no change to any of the sensor signals. At approximately 230 ºC, most of the signals begin to rise increase rather monotonically, which was generally true for all the oil experiments. The red dashed line indicates the cooking condition, either normal or pre-ignition. The curve changes from 0 to 1 when the pan temperature exceeds 300 ºC at about 320 s. At 704 s, the pan temperature reached 429 ºC, and auto-ignition occurred; the test was immediately terminated.

Tam, Wai Cheong; Fu, Eugene Yujun; Mensch, Amy; Hamins, Anthony; You, Christina; Ngai, Grace; Leong, Hong va. "Prevention of Cooktop Ignition Using Detection and Multi-Step Machine Learning Algorithms." Paper presented at International Association of Fire Safety Science 2020, Waterloo, CA. April 27, 2020 - May 01, 2020.

Figure 3 shows 3 sets of curves for Exp 8 (solid line)[3], Exp 46 (circle symbols)[4], and Exp 57 (triangle symbols)[5]. Each set of curves contain the sensor signals for IAQ (black) and VOC (green), as well as the red line denoting the end of normal cooking and the beginning of the pre-ignition condition. Sensor data were selected based on the clear independence of the sensor signals from each other. For the two oil experiments (Exp 8 and Exp 57), the IAQ signals monotonically increased with time. However, the profile of the IAQ signal associated with Exp 46 was observably different; it first increased to a value of 0.3 x 10^4, remained constant for more than 300 s, then increased to a peak value of 0.76 x 10^4, reached a minimum value of 0.4 x 10^4, before obtaining another peak value of 1.1 x 10^4. The VOC sensor for Exp 46 also shows the same complex behavior. The physical mechanism causing such behavior is not known. However, this test was repeated and the same behavior was observed. Sensor data associated with all experiments were examined; Exp 16 was eliminated because the pan was not cleaned before the experiment such that a layer of degraded oil was on the bottom of the pan before the fresh oil was added. In the future, this type of experiment could be considered.

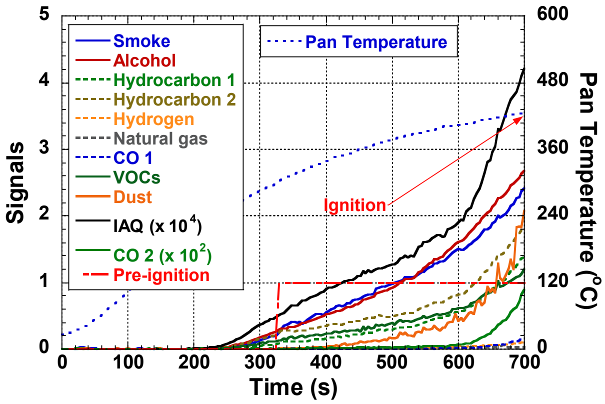

Figure 2. Signals for 11 selected sensors during Experiment 8.

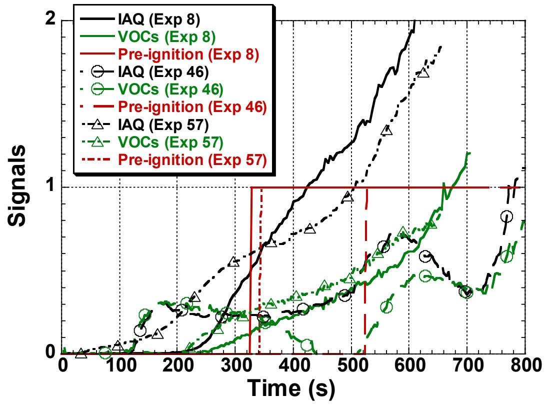

Figure 3. Comparison of IAQ (divided by 10^4) and VOC signals for 3 experiments (8, 46, 57).

[3] Exp 8 is for 50 mL canola oil on a 20 cm cast iron pan heated by the small electric-coil burner.

[4] Exp 46 is for 110 g bacon on a 20 cm cast iron pan heated by the small electric-coil burner.

[5] Exp 57 is for 50 mL canola oil on a 20 cm cast iron pan heated by the big gas burner.

3.2 Preprocessing

As illustrated in Fig 2, the data range significantly differed between some of the sensor signals. For instance, in Exp 8 the data range of the smoke signal was from 0 to 2.5 V, while the IAQ signal range was more than 48 000. The difference in magnitude associated with the data is known to affect training efficiency, so a min-max normalization was applied to all signals to impose a range from 0 to 1.

In machine learning, a classifier is applied to a set of data instances that are well-annotated. The classifier learns the data distribution, or fits a hyperplane in multi-dimensional space, to separate data instances based on feature vectors and corresponding labels. Here, data instances are generated using a moving window. The advantage of this approach is to provide more information for each data instance, such as temporal information for the historical data.

The analysis applies a moving time window of size, W, as demonstrated in Figure 4. Each moving window represents one data instance. The measurement frequency of each signal was f = 0.25 Hz (1 sample every 4 s) and there were W x f sample points for each signal in a moving window. Six signals are considered here, measuring alcohol, CO, dust, indoor air quality (IAQ), smoke, and VOC, leading to 6 time series with W x f sample points for each instance of processed data.

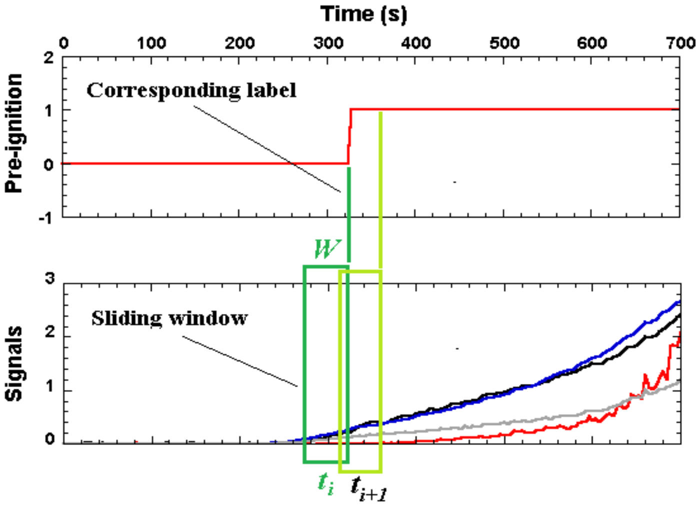

Figure 4. Schematic of moving windows with window size, W, and its corresponding label (the two sliding windows are not to scale; t_i and t_{i+1} are 4 s apart).

Table 1. Number of normal cooking and pre-ignition data instances for different groups of experiments when W = 60 s.

Group Label	Food type	Cooktop type	Normal cooking	Pre-ignition
OE (Oil, Electric)	Oil	Electric	2486	2249
OFE (Other Foods, Electric)	Other foods	Electric	2702	606
OG (Oil, Gas)	Oil	Gas	675	1022
All (OE+OFE+OG)	All	All	5863	3877

In addition to feature representation, each instance also needs to be well annotated. As shown in Fig 4, each data instance was labeled "*Normal cooking*" or "*Pre-Ignition*". For oils, the data is defined as "*Normal Cooking*" if the pan temperature is less than 300 ºC. Reference [13] provides detailed descriptions for the determination of normal condition for other foods, such as salmon, bacon, chicken, hamburgers, and french fries. Table 1 illustrates data distributions for different groups of experiments with W = 60 s. Depending on the size of time window (W), it should be noted that several instances (i.e. W x f – 1) will be lost.

3.3 Feature selections

After obtaining the processed data instances, features are extracted to build classifiers. Statistics, such as the mean, maximum, and standard deviation, are used to characterize a series of data or approximate the data distribution. These statistic-based representations may be useful to detect pre-ignition. For instance, pre-ignition is usually associated with high values of IAQ signal, so the maximum of the IAQ signal would be useful. We therefore propose a set of statistic-based features for unattended cooking detection.

Statistic-based features can represent the character of the data. However, they cannot capture the temporal or trend information. In order to extract this information, we also propose a set of trend-based features. Given the values of the signal within the data window, $S = [s_1, \dots, s_{n/2}, \dots, s_n]$, we extract trend-based features by computing: $s_n - s_1$, $s_{n/2} - s_1$, $s_n - s_{n/2}$, and max(S) – min(S). In addition to the raw signal, the first derivative is also calculated. We further extract the same set of features from the first derivative signal $S' = [s'_1, \dots, s'_{n/2}, \dots, s'_{n-1}]$, where $s'_i = s_{i+1} - s_i$. In total, 18 features for one signal can be extracted. As shown in Table 2, signals from 6 sensors, including alcohol, CO, dust, IAQ, smoke, and VOC are used. With these signals, a feature vector of 108 dimensions for each data instance is obtained. The feature vector is fed into a classifier to build the pre-ignition detection model.

Table 2. Signals and their features.

Sensors	Alcohol	CO	Dust	IAQ	Smoke	VOC
Signals	Raw signal (S) and the first derivative (S')					
Trend-based features	$s_n - s_1$, $s_{n/2} - s_1$, $s_n - s_{n/2}$, max(S) – min(S) $s'_{n-1} - s'_1$, $s'_{(n-1)/2} - s'_1$, $s'_{n-1} - s'_{(n-1)/2}$, max(S') – min(S')					
Statistical features	Mean, maximum, minimum, median, standard deviation					

3.4 Training and evaluation

The features introduced above are extracted for each instance, and then fed into a conventional machine learning algorithm to build the pre-ignition detection model. In this analysis, multiple machine learning algorithms are adopted for the detection model, including support vector machine (SVM), random forest (RF) [20], and decision tree (DT) [21]. These commonly used machine learning algorithms are reliable for many classification applications. Appendix C provides the basic concept and the model configuration for the three machine learning algorithms. Investigating and comparing the performance of these machine learning algorithms can help determine the most suitable machine learning model for ignition detection. In general, there is a tradeoff in real-time detection associated with the size of the moving window. Using a smaller moving window can increase the response time of the model, which is an important factor in real-time detection. On the other hand, using a larger moving window is likely to achieve higher accuracy, as the model has more information. Therefore, the impacts of algorithm type as well as window size are investigated here. Three window sizes are considered: 60 s, 32 s, and 16 s based on the frequency of the input signal (0.25 Hz).

For evaluation purposes, a leave-one-experiment-out cross-validation approach is used. The dataset is divided into N subsets, where N is the total number of experiments. Each subset contains all the data instances from one particular experiment, then the classifier is trained with N - 1 subsets and the classifier predictions are evaluated for the data instances in the remaining subset. This is repeated N times until all the subsets are evaluated once. Final performance is taken as the overall average accuracy across all data instances in the N evaluations.

4. Results and Discussion

4.1 Classification of unattended cooking for OE and OFE data

Data associated with all experiments[6] with oil on the electric cooktop (denoted as OE in Table 1) and other foods (OFE) on the electric cooktop were considered. Figure 5 shows an example of the prediction results of SVM with a moving window of 16 s for Exp 8 and Exp 46. The black curves are the classifier predictions. Blue curves are the converted values based on a discrimination threshold of 0.5. If the prediction value is less than 0.5, the prediction is classified as normal cooking. If the prediction is larger than 0.5, the prediction is classified as pre-ignition. As compared to the data label (red curves), the SVM tends to predict pre-ignition well before the ignition. In order to evaluate the performance over all experiments, the precision, recall, and F1-score measures are reported. Table 3 shows the prediction performance for the three moving window sizes. Here, precision is defined as the ratio of the number of true positives over the sum of true and false positives; recall is defined as the ratio of true positives over sum of true positives and false negatives. The F1 score is the weighted average of precision and recall.

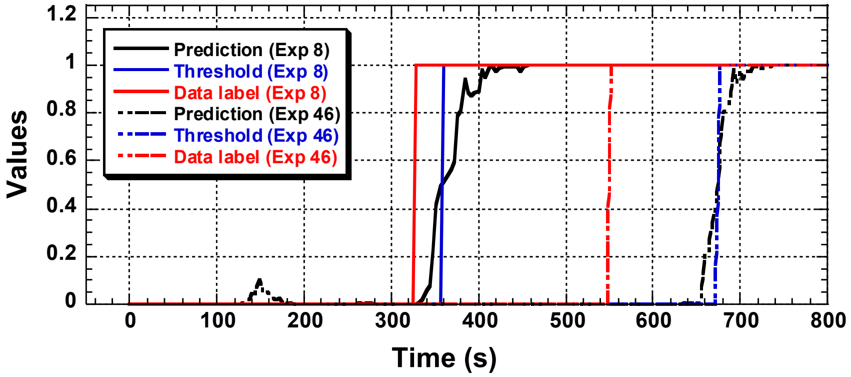

Figure 5. Performance comparison of SVM with W of 16 s for Exp 8 and Exp 46 considering both OE and OFE data.

[6] Exp 16, 39, 48, 49, 50, and 60 are excluded. Exp 39, 48, 50 and 60 are dual-pan experiments. Since single pan experiments are of interest, the dual-pan experiments will be considered in future study.

The Correct Classified Rates (CCR) for the three machine learning models with three moving window sizes are presented in Fig 6. CCR is defined as the ratio of the correct classified instances to the total instances in a dataset; it is an indicator of overall classification performance. The results in Fig. 6 suggest two general conclusions. First, the larger the window size, the better the observed performance. Second, SVM seems to have slightly higher CCRs compared to RF and DT. For SVM, prediction accuracies are 93.8 %, 92.8 %, and 91.2 % for *W* = 60 s, 32 s, and 16 s, respectively. This statistic demonstrates that with approximately 4 times the detection frequency, there was only a 2.5 % tradeoff on prediction accuracy.

Table 3. Precision, recall, and F1-score for SVM with three moving window sizes considering both OE and OFE data.

Window size	**Class**	**Precision**	**Recall**	**F1-score**
60 s	Normal	96.3%	94.1%	95.2%
	Unattended	89.7%	93.4%	91.5%
32 s	Normal	94.9%	93.8%	94.3%
	Unattended	89.3%	91.1%	90.1%
16 s	Normal	93.6%	92.4%	93.0%
	Unattended	87.2%	89.1%	88.1%

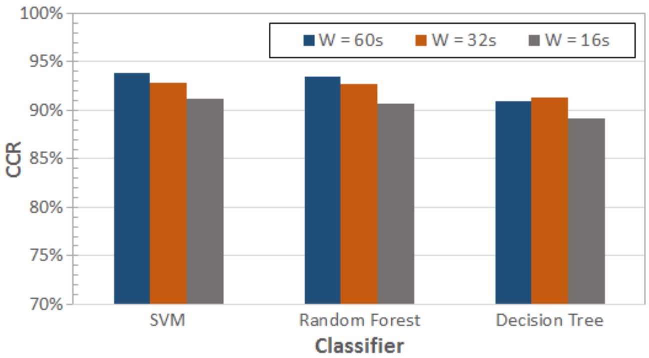

Figure 6. Overall performance classifying normal cooking and pre-ignition for three machine learning models with different moving window sizes considering both OE and OFE data.

4.2 Classification of pre-ignition using an object-specified approach

Sensors in the oil experiments, regardless of oil volume, oil type, and heating conditions, presented monotonic behavior. This trend does not necessarily exist for the cooking experiments with other foods due to a variety of factors including possibly the burner settings used, the water content of the foods, and the shape and deformation of the foods during cooking. If a machine learning model uses data that have similar behaviors, the prediction performance should increase. Therefore, an object-specified approach was also followed, training and evaluating the machine learning models either with only the OE data or only the OFE data.

Figure 7 shows the updated CCRs using the object-specified approach on SVM. For OE data alone, the prediction performance for *W* = 60 s is increased over the combined OE and OFE data to 96.9 %. In general, there is an average 1.9 % improvement in the prediction performance over the combined OE and OFE data for all three moving window sizes. For OFE data alone, the prediction performance for W = 16 s increases by 5.1 % over the combined OE and OFE data. The improved performance for OFE data alone with W = 60 s and W = 32 s is 2 % and 2.8 %, respectively. Table 4 shows the detailed breakdown of the two data sets using statistical measures, showing the enhanced prediction accuracy.

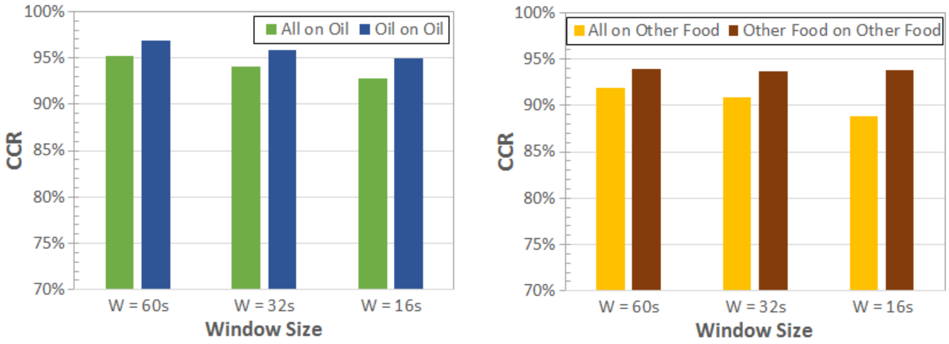

Figure 7. Performance of SVM predictions using both OE and OFE data for training compared to the object-specified approach, where only OE or OFE data is used for training.

Table 4. Precision, recall, and F1-score for SVM with three moving window sizes using the object-specified approach.

Dataset	Class	Precision	Recall	F1-score
Oil (OE)	Normal	98.4%	95.7%	97.0%
	Unattended	95.3%	98.2%	96.8%
Other Foods (OFE)	Normal	96.8%	95.8%	96.2%
	Unattended	82.0%	85.6%	83.8%

4.3. Towards Two-Step Pre-Ignition Detection

Based on the previous section, the object-specified machine learning models built to classify the cooking conditions (normal or pre-ignition) for a specific type of cooking (oil heated on an electric cooktop versus other foods on an electric cooktop) is shown to outperform the more generic machine learning model. This performance enhancement does not require additional data. Instead, to use the object-specified machine learning models, a classifier that discriminates between the oil cooking scenarios and other cooking scenarios is needed. The gas cooktop experiments were not included in the previous analyses, so cooktop type could also be important in determination an optimized model. Nevertheless, the feasibility of use of a two-step architecture for detection of pre-ignition is investigated.

Next, machine learning is used to detect the type of cooktop being used. The cooking oil results from different cooktop types in the dataset are used. The data from heating oil on an electric cooktop (OE) are given the label "*Electric*", and the data from heating oil on a gas cooktop (OG) are given the label "*Gas*". The same features as presented in Section 3.3 are used to build the cooktop type identification models and the same evaluation approach is adopted. As shown in Fig. 8, the attempt leads to very promising performance of cooktop identification. Using SVM as the classifier with W = 60 s, an accuracy of better than 98 % is observed. For a smaller W, which enables a faster time response, an accuracy of 98 % ($W = 32\ s$) and 97.3 % ($W = 16\ s$) is achieved. As shown in Table 5, the models achieve high F1-scores for both cooktop types, indicating that the model does not achieve high CCR by simply selection of the majority side. These results suggest that the proposed method can precisely differentiate an electric cooktop from a gas cooktop, providing verification of the machine learning methods developed here. The results also demonstrate that it may be possible to build a two-step pre-ignition detection model, which first classifies the cooking scenario to recommend a specific model to better predict pre-ignition conditions for a particular type of cooktop.

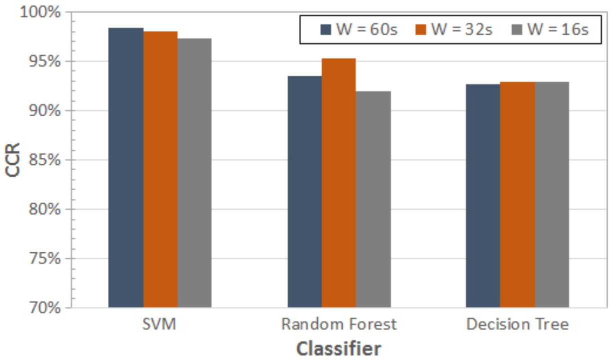

Figure 8. Overall performance on cooktop type classification for the three machine learning models with different *W* using OE and OG data sets.

Table 5. Precision, recall, and F1-score for SVM with three different *W* for cooktop type classification.

Window size	Class	Precision	Recall	F1-score
60 s	Electric	99.5%	98.4%	98.9%
	Gas	95.5%	98.5%	96.9%
32 s	Electric	98.9%	98.4%	98.7%
	Gas	95.4%	96.7%	96.0%
16 s	Electric	98.1%	98.2%	98.2%
	Gas	94.7%	94.5%	94.6%

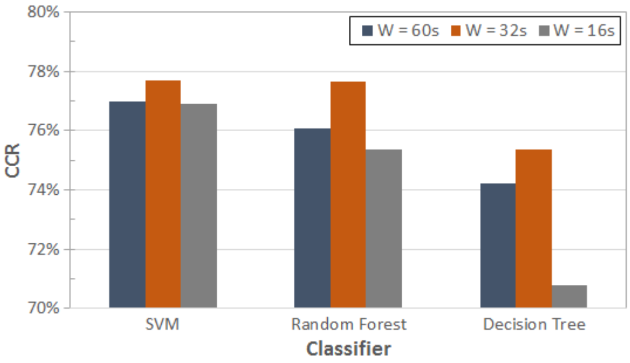

Figure 9. Overall performance on food type classification for the 3 machine learning models with different moving window size on OE and OFE data.

Tam, Wai Cheong; Fu, Eugene Yujun; Mensch, Amy; Hamins, Anthony; You, Christina; Ngai, Grace; Leong, Hong va. "Prevention of Cooktop Ignition Using Detection and Multi-Step Machine Learning Algorithms." Paper presented at International Association of Fire Safety Science 2020, Waterloo, CA. April 27, 2020 - May 01, 2020.

Next, the possibility of using the classifier to identify the heating of oil versus cooking scenarios involving foods is investigated. Both the OE and OFE data sets using the electric cooktop are utilized. The data with oil (OE) is labeled "*Oil*" and the data with other foods (OFE) is labeled "*Others*". The same model features and evaluation approach presented in Section 3.3 to build the oil versus other scenario detection models are adopted here. Table 6 provides the detailed statistical performance for the food type predictions. The numerical results indicate that the models cannot precisely differentiate cooking oil from scenarios involving cooking other foods. A possible reason is that there is insufficient data. The models to detect cooktop type achieved promising performance despite fewer data sets using the gas cooktop because the sensor signals from heating oil with a gas cooktop does not vary as much across different experiments as the varied data sets in the OFE data group. The types of other foods and procedures of cooking other foods are much more diverse than just heating oil on the highest setting, leading to diverse sensor signal patterns that make it difficult for the classifier to learn patterns.

Table 6. Precision, recall, and F1-score for SVM with three moving window sizes on classifying heating oil from other cooking scenarios on electric cooktops.

Window size	Class	Precision	Recall	F1-score
60 s	Oil	74.9%	92.6%	82.8%
	Others	82.9%	53.4%	65.0%
32 s	Oil	75.0%	94.5%	83.6%
	Others	86.2%	51.9%	64.8%
16 s	Oil	74.2%	94.6%	83.2%
	Others	85.7%	49.6%	62.8%

5. Conclusions

The feasibility of building machine learning models to perform real-time cooktop pre-ignition detection is investigated. Machine learning algorithms have the capability to consider multiple sensor signals. Taking advantage of that capability, statistic-based and trend-based features are extracted from the time series signal of six sensors: alcohol, CO, dust, IAQ, smoke, and VOC, to build pre-ignition detection models. The proposed approach achieves encouraging performance, even when using data from diverse cooking scenarios on electric cooktops (OE and OFE data sets) for training with 93.8 % of data instances predicted correctly (using SVM and $W = 60$ s).

Models trained and tested only on data for a specified cooking condition (separating OE and OFE data sets) outperform models trained on the combined set of all electric cooktop data. For instance, the overall accuracy is 96.9 % for the model trained and tested on only the OE data set (using SVM and $W = 60$ s). If the cooking scenario of the target data can be identified, the detection performance of pre-ignition can be improved. This suggests the potential of a two-step approach to obtain a more robust cooking pre-ignition detection model.

Results from calculations to identify cooking scenarios using a multi-step detection approach shows it is possible to precisely differentiate heating oil on electric cooktop from a gas cooktop. However, the method was not as effective in identifying a scenario of heating oil versus cooking other foods on an electric cooktop. In the future, experiments on a wider variety of food types will be considered to test the range of possible improvement of model performance.

Appendix A. Additional Information for Sensor Array.

14 different sensor responses were selected for testing. The sensors were based on various operating mechanisms, including electrochemical, MOS-type, light scattering, and non-dispersive infrared absorption. Sensors were selected to measure CO_2, CO, hydrocarbons, alcohols, H_2, natural gas, volatile organic compounds (VOCs), smoke, air quality, and aerosols/dust. Humidity and temperature were also measured. Table A1 provides the sensor names, their sensitivity, operating principle, measurement range, and units.

Table A1. Summary of sensor information.

	Sensor Name	Sensitivity	Operating Principle	Measurement Range	Units
1	Smoke	combustible gas, smoke	electrochemical	300 -10,000	ppm
2	Alcohol	alcohol	electrochemical	0.04 - 4	mg/L
3	Hydrocarbon 1	methane, propane, butane	electrochemical	300 -10,000	ppm
4	Hydrocarbon 2	liquified petroleum, butane, propane, LPG	electrochemical	300 - 10,000	ppm
5	Hydrogen	H_2	electrochemical	100 - 1,000	ppm
6	Natural Gas	methane	electrochemical	< 10,000	ppm
7	CO 1	CO	electrochemical	0 - 10,000	ppm
8	VOCs	air contaminants, VOCs, odorous gases	metal oxide sensor	not specified	ppm
9	Dust	aerosol	optical	0.1 - 0.5	mg/m^3
10	Humidity	H_2O	electrochemical	2000	ppm
11	CO_2 1	CO_2	electrochemical	2000	ppm
12	IAQ	cooking odors, pollutants, smoke	electrochemical	not specified	ppm
13	CO_2 2	CO_2	electrochemical	5000	ppm
14	CO 2	CO	electrochemical	5000	ppm

Appendix C. Basic Concept for Support Vector Machine, Decision Tree, and Random Forest.

Machine learning (ML) algorithms have been widely used for multi-class classification problems in various fields. Based on recent literature [22-25], it has been demonstrated that support vector machine (SVM), decision tree (DT), and random forest (RT) have the capabilities to handle complex time series data with multi-dimensional feature vectors. Guidelines are lacking for the use of ML algorithms in classification problems involving time series data in fire research, and the performance for these three ML algorithms is unknown. Therefore, SVM, DT, and RF will be used for the development of classification models for prediction of fire hazards. Comparing the results obtained from the different models can serve as a sanity check for the performance of each model. In the next subsection, the basic concepts for SVM, DT, and RT will be presented. Readers can refer to the following references [26-28] for detailed descriptions of the mathematical formulation for each algorithm.

<u>Support Vector Machine (SVM) [26]</u>

SVM is a classifier that finds a decision boundary, known as a hyperplane, to separate instances into two classes. The algorithm maximizes the constrained margin such that the distance between the instances in different classes is optimized to achieve the greatest model generalizability. For example, given a training dataset $T = \{(X_1, y_1), (X_2, y_2), \dots, (X_n, y_n)\}$, which can be linearly separated, the hyperplane denoted as p can be written as:

$$w \bullet X + b = 0 \tag{C1}$$

where X_n is the sample of n^{th} instance, and y_n is the class label. w is the weight of the hyperplane, and b is the bias of the hyperplane. Based on the definition provided in [26], the distance between the instances for different classes is:

$$d = \min_{i=1,2,\dots,n} y_i(\frac{w}{\|w\|} \cdot X_i + \frac{b}{\|w\|}) \tag{C2}$$

where $\|w\|$ is norm of w. For SVM, the distance is known as margin. Therefore, SVM determines the hyperplane with the largest margin by solving the optimization problem:

$$\arg\max_{w,b} (\min_{i=1,2,\dots,n} y_i(\frac{w}{\|w\|} \cdot X_i + \frac{b}{\|w\|})) \tag{C3}$$

For real-life applications, fire data are often more complex and not linearly separable. In order to overcome this numerical difficulty, there are two treatments. The first treatment is called the “kernel trick” [26], which commonly involves four nonlinear kernel functions: 1) polynomial kernel, 2) Gaussian kernel, 3) radial basis function, and 4) sigmoid kernel. The use of a kernel function allows the transformation of data into a higher dimensional space such that a hyperplane exists separating the instances X_n for different classes. The second treatment is introducing a regularization or slack variable. With the implementation of the regularization variable, a small proportion of the data are ignored, and misclassification is allowed. Although there is trade-off for use of the regularization variable treatment, it generally helps to avoid over-fitting and to provide a more generalized model.

Decision Tree (DT) [27]

DT builds classification models in the form of a tree structure. A typical DT is composed of a root node, internal nodes, edges, and leaves. The root node represents the entire population. Internal nodes represent partitioning or splitting conditions, which correspond to a feature vector. Edges can be a specific value or range of values for the splitting condition of the feature. The leaves represent the terminal nodes of a tree with class labels. The hierarchical nature of the algorithm provides detailed information of how a decision is being made. As compared to SVM, DT is more transparent, and the results are easier to interpret.

Given the aforementioned training dataset $T = \{(X_1, y_1), (X_2, y_2), \ldots, (X_n, y_n)\}$, the formulation of a DT involves selecting optimal splitting features. The process starts by splitting the dependent feature, or root node, into binary pieces, where the child nodes have less entropy than the parent node. If the sample is completely homogeneous the entropy is zero, and if the sample is equally divided the entropy is one. Mathematically, entropy is defined as:

$$Entropy = -\sum_{i=i}^{k} P_k log P_k \tag{C4}$$

where P_k is possibility of the instance belonging to class k. In general, DT searches through all candidate splits to find the optimal split that minimizes the resulting entropy of a tree. One effective split strategy is to always select the feature with largest information gain, IG:

$$IG(D_p, f) = Entropy(D_p) - \sum_{i}^{all\ child\ node} \frac{N_i}{N} Entropy(D_i) \tag{C5}$$

where D_p is the dataset of the parent node with N number of samples, f is the feature, and D_i is the dataset of the i^{th} child node with N_i number of instances. This splitting process is continued until all the instances at current level are labeled to the appropriate classes.

Random Forest (RF) [28]

RF is an ensemble learning method for classification. It builds H number of classification trees and provides the prediction of the class of an object based on the averaged results obtained from each of the trees. Mathematically, after H trees are grown, the RF classification predictor is given as:

$$f(x) = \frac{1}{H} \sum_{i=1}^{H} K(i, x) \tag{C6}$$

where x is the input feature.

In general, significant effort is usually needed to tune the model to maximize performance. This process can be accomplished by selecting appropriate hyperparameters, which can be thought of as the “dials” or “knobs” of a machine learning model. There are several automated tuning methods, such as grid search, random search, and Bayesian optimization. In this study, the most basic tuning method, grid search [29], is used. With this technique, we simply build a model for each possible combination of all the hyperparameter values provided, evaluate each model, and select the architecture which produces the best results.

Summary

Table C1 provides the summary of model configurations for the three ML algorithms. For SVM, the radial basis functions (RBF) kernel function is used. The selection of the kernel function depends on both the number of input features and the size of the dataset. In this study, there are up to 12 features and roughly 10000 instances (refer to Table 1). Since the number of samples from the dataset is much larger than the number of input features, it is suggested that RBF will have better performance [30]. With the use of the RBF kernel, the two parameters, C and γ, must be considered. The parameter C is the regularization parameter or slack variable, and it controls the trade-off between misclassification of training examples and simplicity of the decision surface. In general, a low C makes the decision surface smooth, while a high C aims to classify all training examples correctly [31]. The parameter γ defines how much influence a single training example has on other examples. The larger γ is, the less influence a single simple will have. Grid search [29] is used to determine the optimal values for the two parameters.

Table C1: Summary of model configurations for SVM, DT, and RF.

SVM				DT	RF			
	Optimal	**Range**	**Interval**			**Optimal**	**Range**	**Interval**
C	100	0 - 300	10	NA	**Estimator**	10	5 - 100	5
Gamma (γ)	10	0 - 50	1					

The model configurations for DT and RF are simpler. For DT, the entropy method is used to measure the quality of a split, but no parameters were needed to be adjusted. For RF, the setting remains similar except that the optimal number of trees needs to be identified. In theory, the more trees the better. However, based on results obtained for different number of trees ranging from 10 to 100 with an interval of 10 trees, the improvement of prediction accuracy with more trees is negligible (less than 0.1 %). Therefore, the number of trees is set to 10.

Abstract

Faster and more energy efficient hardware accelerators are critical for machine learning on very large datasets. The energy cost of performing vector-matrix multiplication and repeatedly moving neural network models in and out of memory motivates a search for alternative hardware and algorithms. We propose to use streaming batch principal component analysis (SBPCA) to compress batch data during training by using a rank-k approximation of the total batch update. This approach yields comparable training performance to minibatch gradient descent (MBGD) at the same batch size while reducing overall memory and compute requirements.

Introduction

Recent assessment of the energy necessary to train deep networks highlights the high financial and environmental costs associated with this fast growing field (Strubell, Ganesh, and McCallum 2019). New hardware accelerators are needed for efficient local and cloud computing (Ambrogio et al. 2018).

To accelerate training, research has increasingly focused on variable learning rate methods that add additional hyperparameters to the training of neural networks. Though these additional hyperarameters decrease the training time, they double or triple the memory overhead compared to a unit batch size stochastic gradient descent (SGD). These approaches are nevertheless preferred over SGD, however, since they can accelerate training on the rapidly fluctuating gradient vector to provide a superior learning trajectory.

In our approach, we accelerate training and reduce overhead by generating a stochastic low-rank approximation of the gradient using streaming principal component analysis (SPCA). SPCA was proposed by Oja in 1982(Oja 1982), and recent proposals combine SPCA with adaptive algorithms to optimize the learning rate while using only a single pass over the data (Henriksen and Ward 2019). (Burrello et al. 2019) proposed a parallel implementation of streaming History-PCA to save memory when backpropagating. SPCA remains an active research area which is promising for edge computing and other applications where memory usage is critical. To our knowledge, Hoskins et al. are first to use SPCA to compress batch gradients (Hoskins et al. 2019). Here we propose the SBPCA training algorithm, which approximates minibatch gradient descent with a slowly varying thin singular value decomposition of the overall gradient. Initial results show that SBPCA can accelerate training while reducing memory overhead and energy costs.

Method Details

In any SGD-derived method, the weights in a given layer are updated as $\Theta \leftarrow \Theta - \alpha\nabla\Theta$ where Θ is the weight matrix trained for that layer, α is the learning rate, and $\nabla\Theta$ is a stochastic approximation of $\partial\ell/\partial\Theta$ over a batch B, with ℓ the loss function evaluated after the feedforward step.

We consider an alternative calculation of $\nabla\Theta$ through a streaming low rank approximation based on the Singular Value Decomposition (SVD). Using Algorithm 1, the stochastic approximation is given by $\nabla\Theta = X\Sigma\Delta^T$, where X is the left singular matrix, σ is the vector of singular values, $\Sigma = \text{diag}(\sigma)$, and Δ is the right singular matrix. Restricting σ to its top k singular values, the memory cost of Algorithm 1 is $m \times k + k + n \times k$. We generally take $k \ll \min\{m, n\}$ to approximate $\nabla\Theta$ with efficient memory usage. Algorithm 1 updates this approximation using a novel block-averaged bi-iterative implementation of Oja's rule, and uses QR decomposition to re-orthogonalize the singular vectors.

```
Algorithm 1 Streaming Batch PCA (SBPCA) Update
Require: $\sigma$, $X$, $\Delta$ and $b$
  for $i = 1, 2, ..., B/b$ do
    $X$ step:                                   $\Delta$ step:
    $y = \delta_i\Delta/b$                       $z = x_i X/b$
    $X \leftarrow \frac{iX}{i+1} + \frac{x_i^T y}{(i+1)\sigma}$       $\Delta \leftarrow \frac{i\Delta}{i+1} + \frac{\delta_i^T z}{(i+1)\sigma}$
    $X \leftarrow \text{QR}(X)$                  $\Delta \leftarrow \text{QR}(\Delta)$
    $X$-$\Delta$ step: $\sigma \leftarrow \frac{i\sigma}{i+1} + \sum_{\text{rows}} \frac{(\delta_i\Delta)\odot(x_i X)}{(i+1)b}$
  end for
  Calculate $\nabla\Theta = X \cdot \text{diag}(\sigma) \cdot \Delta^T$
```

The X matrix (and Δ respectively) is updated as $X \leftarrow cX + (1-c)d$ where c is a convergence coefficient and d represents the block-averaged update of X over a minibatch of the input data, represented as x (and δ respectively), a matrix

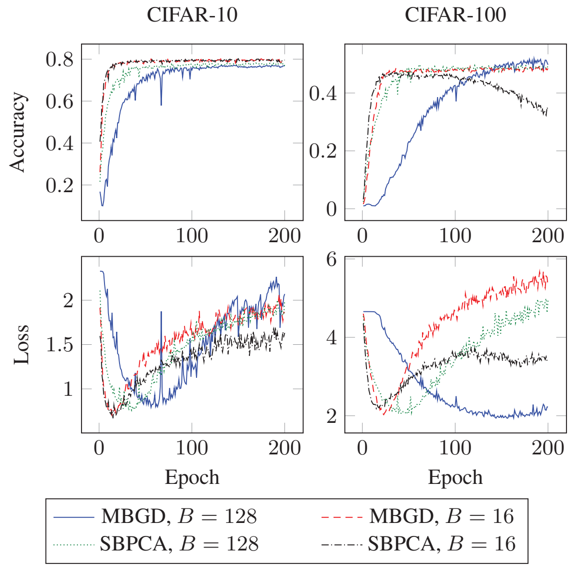

Figure 1: Comparative accuracy and loss for SBPCA and MBGD for CIFAR-10 (rank $k = 3$) and CIFAR-100 ($k = 30$) for $B \in \{16, 128\}$, with $b = B/4$. SBPCA recreates the loss minimum artifact in AlexNet present in MBGD.

with with rows b representing a subset of a minibatch of data with block size b examples. We describe two approaches. In the fixed version of Algorithm 1, we vary the convergence coefficient from block to block as $c_i = i/(i+1)$ while keeping the block size b of the minibatch fixed. However, we find that fixed values of b can lead to poor sampling of the space, so we introduce an alternative version (SBPCA with variable b or SBPCAV), adapted from Algorithm 1, with fixed $c = 1/2$ (implementable in hardware as a single bit-shift) but variable block size $b_i = 2^{(i-1)}$, with i the block index. The rank-1 updates corresponding to each singular vector of X and Δ are rescaled by their respective values in σ.

Experiments

We evaluate the SBPCA and SBPCAV algorithms on the CIFAR-10, CIFAR-100, and ImageNet datasets using an AlexNet modified to accommodate the smaller input size while maintaining the five convolutional and three fully connected layer structure. These algorithms are used only for fully connected layers; convolutional layers have less memory overhead, and so benefit less. We compare with MBGD results.

Since the initialization condition of the gradient approximation for the next batch is the end condition of the prior batch, the gradient estimation includes significant prior gradient history. This acts as a form of momentum, accelerating the training convergence compared to MBGD. In our experiments, we observed this is especially powerful at low learning rates. At high learning rates, the gradient changes more rapidly than the gradient estimation can be updated, destabilizing the training process. As seen in Fig. 1, the SPCA consistently achieves faster convergence than the classic MBGD for equivalent learning rates. Since AlexNet's structure poorly solves CIFAR, it leads to a non-monotonic behavior in the loss due to overtraining and can converge to an undesired local minimum. For small datasets, SBPCA approaches yield-equivalent accuracy to MBGD, shown in Table 1. Even for ImageNet, the algorithm can reach 85% of MBGD accuracy. We also see a dramatic difference in the performance of SBPCAV compared to SBPCA.

Table 1: Accuracy of training methods and ranks for CIFAR-10, CIFAR-100, and ImageNet. CIFAR hyperparameters same as before. For ImageNet, $B = 256$ and $b = 64$. *Fixed* refers to SBPCA and *Varied* to SBPCAV.

	CIFAR-10		**CIFAR-100**		**ImageNet**	
Rank	*Fixed*	*Varied*	*Fixed*	*Varied*	*Fixed*	*Varied*
1	0.7644	0.7391	0.4103	0.4163	0.3382	0.3660
3	0.7817	0.7729	0.4288	0.3783	0.3747	0.4065
10	0.7913	0.7840	0.4652	0.4252	0.4329	0.4454
30			0.4988	0.4563	0.4698	0.4602
100			0.5159	0.4712		
MBGD:	**0.7712**		**0.5185**		**0.5434**	

Conclusions

Our proposed SBPCA and SBPCAV can produce stochastic approximations of the gradient updates sufficient to train functionally relevant neural networks. We find that approximations of rank less than about ten are typically good enough to capture most relevant information about the local loss function. We verify these methods' effectiveness on three image datasets. While results are better on CIFAR-10 and CIFAR-100, even on ImageNet, SBPCAV can reach 85% of MBGD accuracy at significantly lower memory overhead. These results suggest future research exploring detailed memory analysis, impact of dropout and low rank approximations of more sophisticated training algorithms.

Aggregating Atomic Clocks for Time-Stamping

T. Saidkhodjaev (UMD), J. Voas (NIST), R. Kuhn (NIST), J. DeFranco (PSU), and P. Laplante (PSU)

Abstract

A timestamp is a critical component in many applications, such as proof of transaction ordering or analyzing algorithm performance. This paper reports on a method called Verified Timestamping (VT) that improves the standard timestamp protocol. VT was developed at the National Institute of Standards and Technology (NIST) for use in algorithms where timestamp accuracy is critical. VT is an aggregation of the outputs from various atomic clocks to create a Timestamping Authority (TsA). The motivation for this research effort included malicious delay issues in Networks of Things [NIST SP 800-183] as well as race conditions associated with the inclusion of new blocks into blockchains. This paper presents the TsA design and the results of VT, which indicate that atomic clock aggregation is not only possible, but a viable means to produce higher integrity timestamps at the ms level of performance. Tests showed that this is sufficient to preserve event ordering, using only a conventional PC with no dedicated connection or specialized hardware.

1.0 Introduction

The term “timestamping” refers to marking the time when a certain event occurred, such as when a message was sent or received. Unfortunately, computer clocks are generally not precise enough for some types of data, such as in a financial transaction where it is essential to determine if a stock purchase occurred during the period of a particular price, for example. In the current environment of high frequency trading, accuracy on the order of µs is needed for audit and market surveillance by regulators (SR FINRA 2016-005). European Commission regulations announced in 2016 for the accuracy of business clocks require clock granularity of one µs or better, with a maximum allowed divergence from Coordinated Universal Time (UTC)

Saidkhodjaev, Temur; Voas, Jeff; Kuhn, D. Richard; DeFranco, Joanna; Laplante, Phil. ”Aggregating Atomic Clocks for Time-Stamping.” Paper presented at 2020 IEEE International Conference on Service Oriented Systems Engineering (SOSE), Oxford, UK. August 03, 2020 - August 06, 2020.

of no more than 100 µs (Annex, Directive 2014/65/EU). Similar regulations from the U.S. Financial Industry Regulatory Authority have an even tighter clock synchronization requirement with no more than a 50 µs (SR FINRA 2016-005) divergence. General purpose computer clocks are not a good choice when accurate time is needed as they are known to have poor accuracy, with a possible drift of 5 s to 15 s per day (Lombardi, 2019). The Network Time Protocol (NTP) and atomic clocks are routinely used to synchronize actions and provide more accurate time for internet applications. However, even NTP and atomic clocks are not precise enough for some applications such as those that use blockchain technology where timestamp verification and transaction order is critical (Stavrou & Voas, 2017). In addition, a timestamp that is trusted and verifiable is needed to accurately sequence the blocks for blockchain consensus protocol (Kuhn et al., 2019). The purpose of this project is to propose a general purpose system called Timestamping Authority (TsA), which would be able to provide reliable, real-time, high precision timestamps preserving the order of events regardless of their number and time when they were processed. In this paper we will discuss the TsA motivation and design with blockchain technology as a use case.

2.0 Background

The most accurate and precise time is kept by atomic clocks, which measure the frequency of oscillations of atoms that happens to be very close to a constant number. For most applications, *accuracy* refers to the closeness of measurements to a particular true value (such as a physical location), while *precision* is the closeness of measurements to each other. UTC, as its name implies, involves *coordination* among a set of cooperating systems. In the context of timekeeping, accuracy refers to traceability to UTC, while precision is the degree of synchronization among a set of clocks.

As noted previously, financial regulators require highly accurate timestamps, with UTC traceability. Within financial systems, continuous monitoring of clock synchronization stability is required, with realtime comparisons to UTC references. Global Positioning System (GPS) signals are typically used to provide UTC traceability to a national institution such as NIST, the Research Institutes of Sweden, or others. UTC combines time scales known as International Atomic Time (TAI) and Universal Time (UT1), which rely on a weighted average time from

450 atomic clocks in 70 nations (for TAI) and observations of rotations of the Earth (for UT1). To reduce potential vulnerability to GPS jamming or spoofing, financial institutions may employ specialized high-power encrypted signal transmission to protect systems providing UTC traceability. NTP is commonly used to provide synchronization of clocks within variable-latency packet switched networks. For NTP implementations, atomic clocks are connected to servers that deliver time over the network. These servers in turn are connected to other servers, and so on (Mills, 2003). This tree-like design (Figure 1) is needed to reduce the load on the top-level servers.

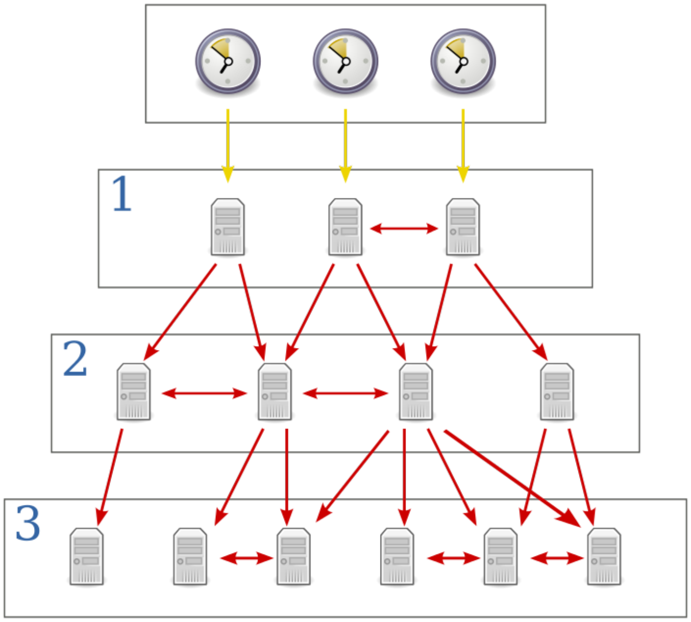

Figure 1: NTP Network Structure.

Yellow arrows indicate a direct connection; red arrows indicate a network connection.

This protocol operates over User Datagram Protocol (UDP), which is a transport layer network protocol. NTP version 3, used in the project, was standardized as Internet Engineering Task Force RFC-1305 (Mills, 1992), and is compatible with the latest version 4, RFC-7822 (Mizrahi & Mayer, 2016). The typical device might use one of the bottom-layer NTP servers to synchronize time. However, using the bottom layer can be insufficient in some situations, since some precision is lost on the way from the top. Improving precision becomes extremely expensive as the required level increases. The cause of this imprecision is due to the asymmetric network routes and network conditions (Mills, 2012).

A blockchain is an example of an application where timestamp accuracy is critical for verification and security. A blockchain is a series of timestamped immutable records that are managed by multiple computer entities. In order to add a new block to the chain, the candidate that wants to insert the block needs to perform a computation (e.g., calculate a hash of the concatenation of the previous block hash and a hash of the current data) and submit the result to the system for verification. The need for accurate timestamps comes into play when there are multiple candidates at the same time. In this case, only the candidate that finishes the hash calculation first will be added. All other candidates must start over with the new last block. This is a time consuming and expensive process. Figure 2 illustrates the addition of a timestamp using the basic methodology where only one candidate will succeed in being added to the chain and all others will have to start the hash calculation over – creating a type of race condition.

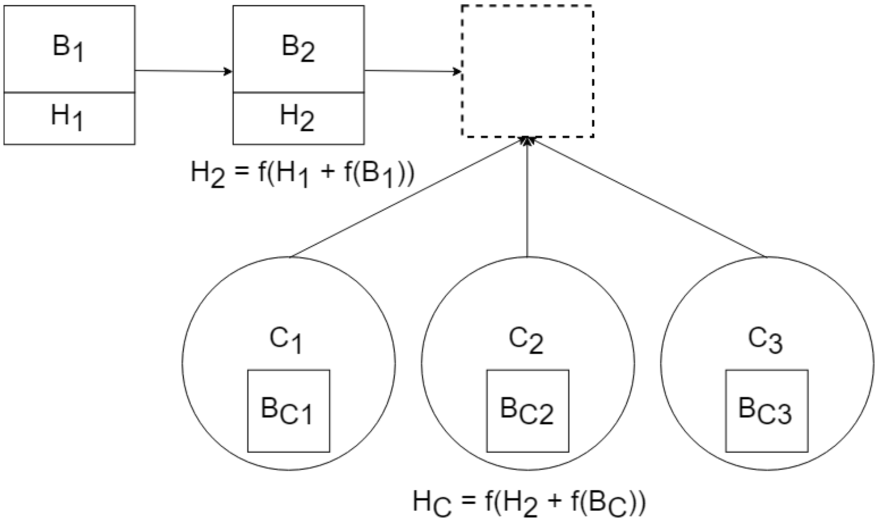

Figure 2: Adding a block to the blockchain with a basic timestamp (B – block; H – hash; f - hash function; C – candidate)

A possible solution to this problem is integrating a single TsA service into the system as shown in Figure 3.

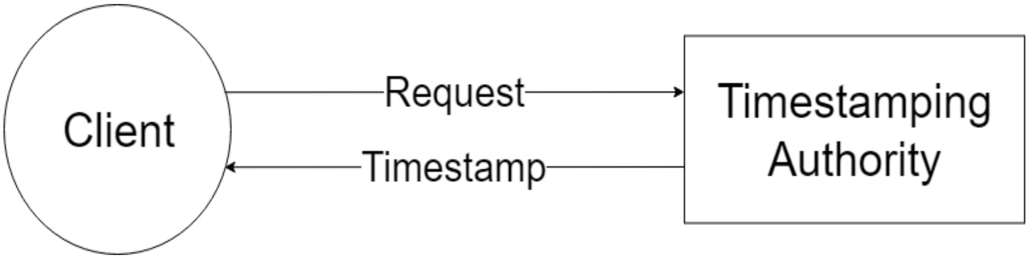

Figure 3: A Timestamping Authority Service

A TsA service could provide an accurate time on demand over a network. However, this does not resolve the situation where events happen simultaneously. As mentioned earlier, transaction order is critical in many applications. Figure 4 shows a single timestamping authority with the requests coming sequentially, thus keeping the accurate order of the requests. However, this design does not scale well and would work only for transactions that occurred geographically close to the TsA.

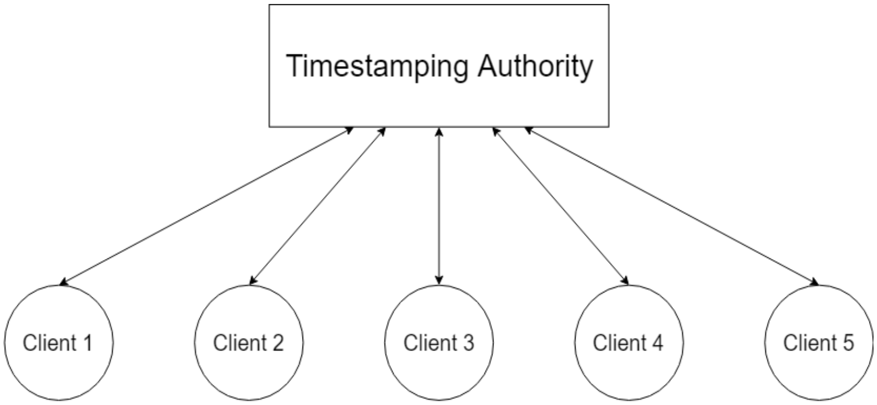

Figure 4: A single timestamping authority

A scalable timestamping solution would use several TsA servers, but then the question of time synchronization between them arises. An open specification called Chainpoint uses blockchain technology and the NIST randomness beacon to tackle this problem. A Chainpoint client stores a hash of the NIST randomness beacon and the timestamp on the blockchain:*Chainpoint (Timestamp + hash(random beacon))* → *blockchain*

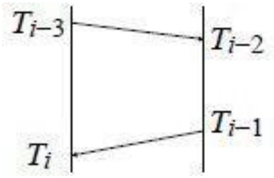
The NIST randomness beacon (beacon.nist.gov) produces a purely random 512-bit string every minute. Every random value is then stored in a blockchain and can be verified at any time.

Inserting the random number facilitates proving the authenticity of the timestamp at any minute on the timeline. This approach will both guarantee transaction order and provide verifiability to the timestamps. However, the time resolution of Chainpoint timestamps depends on the randomness beacon, which is one minute, so we need to look for a different approach.

3.0 TsA Design

To ensure accurate time and order, when a time request is made, the timestamp will be determined by using an aggregation from several atomic clocks. Specifically, the atomic clocks that are used as time sources for this project have publicly available NTP servers, which are synchronized to the clocks, thus providing precise time to the clients (see Sect. 3.1 for details of this process). The communication with the client also works over NTP. NTP can provide up to 1 ms precision under ideal network conditions, and the precision deteriorates as asymmetric network routes are introduced (see RFC-1305, Appendix F). When a network route is asymmetric, the time for a request to get to the server is different from the time to get the response. This situation usually happens when long-distance requests are made or when the network condition is unsatisfactory. Since only the nearest atomic clocks are used, to provide high precision, NTP also accounts for latency automatically (see RFC-1305). Figure 5 shows the transition of 4 timepoints in the UDP message that allows the calculation of correct network delay and local clock offset from the server clock.

The testing procedure consists of using one PC, running the Timestamping Authority Server locally, and running from one to three clients also locally. Due to everything running on the same PC, time for the request to get from the client to the server and from the server to the client is negligible, so the precision of the aggregation procedure can be tested. The server starts up, gets time from three atomic clocks, and the clients are run when the server is ready to respond, (i.e. it has calculated an average time from all three clocks). Then, since we may assume that network delays are not an issue, we can collect all the timestamps received by the clients and compare them to the order they were sent. The tests showed that the correct order is preserved when the requests are spaced out by 10 ms or more.



$$\delta = (T_i - T_{i-3}) - (T_{i-1} - T_{i-2})$$
$$\theta = \frac{(T_{i-2} - T_{i-3}) + (T_{i-1} - T_i)}{2}$$

Figure 5: Network Delay calculation from RFC-1305

Figure 6 shows an example time request from Event X. The TsA is retrieving the time from several atomic clocks and returns the precise time to the client.

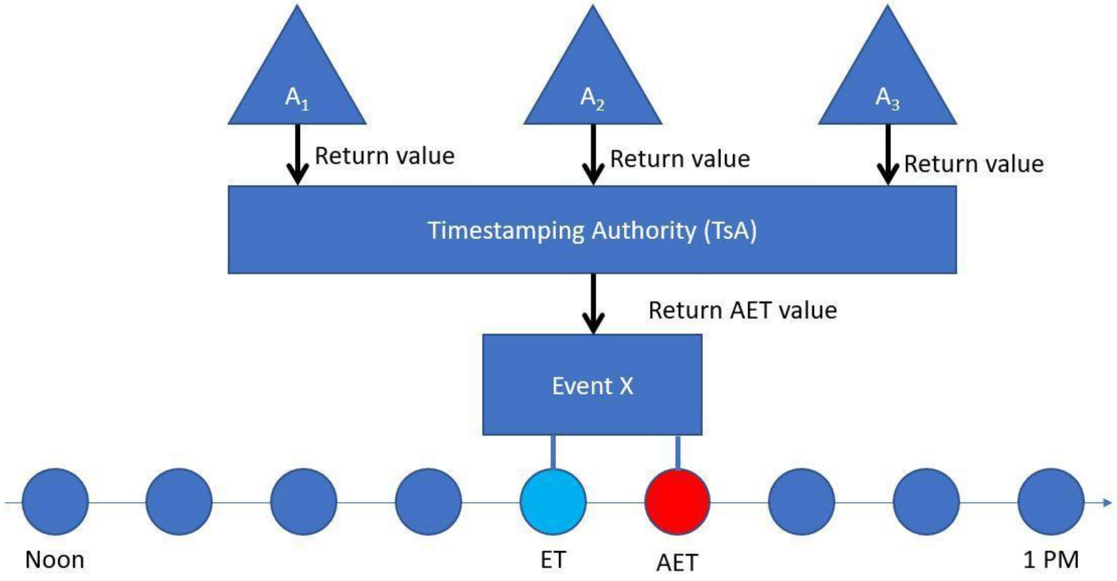


Figure 6: Scheme of TsA operation.
(ET - exact time of the event; AET - approximate exact time; A - atomic clock)

The timestamps are assigned to the candidates and form a queue, giving some time to the first-comer and notifying all other process candidates to wait (Figure 7). That is, the queue is formed among the candidates and each one is given some time to do the hash computation. If the client fails, the opportunity is given to the next candidate. This approach could reduce CPU time spent by the candidates, because they now have an opportunity to wait for the first arrival to finish before continuing their own computations. Timestamps will serve as a proof that the

candidate was indeed first to arrive. This approach would be especially useful if there are multiple servers accepting blocks and they need to be coordinated. In this case, they could query the TsA and receive timestamps that could be used across the servers.

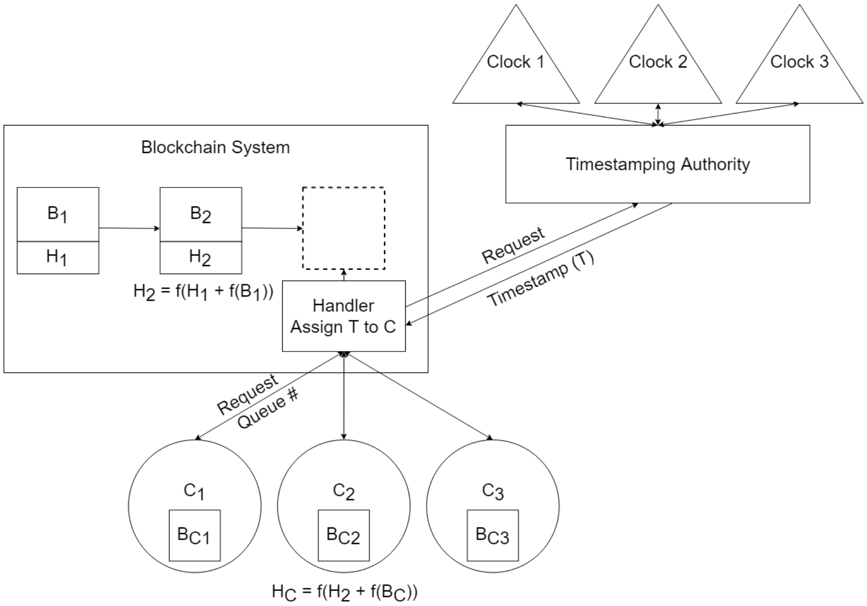

Figure 7: Adding a block to the blockchain with a TsA.

(B – block; H – hash; f - hash function; C – candidate)

It is important to note that the clients are not permitted to use local time due to possible imprecision. Maintaining accurate UTC time is difficult, and TsA does not claim that the time provided is accurate. Instead, the Time Stamping Authority establishes a common timescale for the system that would preserve order of timestamped events. In other words, Time Stamping Authority is precise, but not necessarily accurate. The project described in this paper was designed to demonstrate the effectiveness of an authority by aggregating time from several official reliable atomic clocks and use it to produce the common timescale. The prototype currently aggregates time from three nearby atomic clocks and computes the average of their times. (This is currently implemented as simple averaging, but some form of weighted average may be used in the future.) More effective formulae can be used after the aggregation. Tests with local server and client show that using this approach preserves the order of timestamps.

3.1 Clocks Used and Their Reliability

The International Bureau of Weights and Measures (IBWM) or Bureau International des Poids et Mesures (BIPM) in French, the organization that defines the International System of Units (SI) units, also provides the UTC time standard (https://www.bipm.org). This standard is created based on over 400 participating laboratories measuring time with their atomic clocks and reporting the measured time every 5 days to IBWM, which then calculates the weighted average based on the clock precision and produces UTC. The problem is that it is difficult to transmit clock data in real-time without losing accuracy, hence all calculated time points are in the past. Nevertheless, the data from the atomic clocks spread across the globe suggests that most of them are synchronized up to hundreds of nanoseconds (ns) (https://www.bipm.org/en/bipm-services/timescales/time-ftp/Circular-T.html), which is more than enough for the problem at hand. Within the U.S., the difference between UTC and the two commonly used clocks (NIST and Naval Observatory) is only a few ns. IBWM also publishes the Annual Report on Time Activities (https://www.bipm.org/en/bipm-services/timescales/time-ftp/annual-reports.html), which lists laboratories participating in creation of the time standard, and are known to be reliable. Some of those laboratories have publicly available NTP servers linked to the clocks, which are used in this project as time sources. For the North American region, possible clock servers are the National Institute of Standards and Technology NTP (https://tf.nist.gov/tf-cgi/servers.cgi), the United States Naval Observatory NTP (https://tycho.usno.navy.mil/NTP/) and the National Research Council of Canada NTP (https://nrc.canada.ca/en/certifications-evaluations-standards/canadas-official-time/network-time-protocol-ntp). One problem with using these clocks is that the public servers are vulnerable to distributed denial of service (DDoS) attacks, and therefore all clients making too frequent requests to them are banned (e.g., the NIST clock encourages no more than one request every 4 s). This problem has been solved by maintaining an offset from local time to each of the used clocks, and updating it every 10 s (this interval can be configured). Per Lombardi's estimations, most hardware clocks gain or lose about 5 s to 15 s per day (Lombardi, 2019), so with simple calculations, we see that the hardware clocks can gain or lose at most 2 ms every 10 s. While not perfect, the period of 10 s was chosen as a trade-off to both have acceptable precision, and not get the server banned by the atomic clock NTP servers. Therefore, even if a local clock is imprecise, it is very unlikely that any significant deviation will happen in 10 s.

4.0 Implementation Description

The NTP utilities library from Apache Commons Net was used in the project (https://commons.apache.org/proper/commons-net/). Some code was modified and everything else was used as a library. The project consists of four executables written in Java. The first and primary executable is the server, which can be configured and started via command line, specifying the NTP servers to be used at run time. The server periodically updates local time offsets of the used clocks and services client requests. There is a class *TimeStampingAuthorityServerRunner* with a main method that is compiled to the executable server. There are also two other classes that can be used as library code. One of these (*TimeStampingAuthority*) simply requests time from the clocks, maintains clock offsets and can provide aggregate time via the application programming interface (API), and another one (*TimeStampingAuthorityServer*) also runs an NTP server on a specified port. There is a separate Clock class that contains logic for maintaining the clock offsets and network communication with the atomic clock servers.

The second executable is the client for testing. It can be configured and started via command line, and it logs the time points received from the server to a .txt file. The client makes requests to the server at the specified address with a given frequency. Tests show that an interval of 10 ms or more should preserve events ordering on the TsA side. Even though such precision might not be enough for some applications, it has a benefit of simplicity: no need for advanced equipment or dedicated connections, just one program on any PC. Moreover, we would note that this is a proof-of-concept, so future developments may achieve higher precision.

The third executable takes the log file produced by the client and checks if timestamps the client received are in the ascending order. It can check multiple files at the same time and is also usable from a command line. The fourth executable takes several log files and combines them. This executable was used when several clients were run simultaneously to test how well TsA preserves order of events with its timestamps. All the executables are configurable. VT uses the Maven framework for dependency management and build automation. It also uses Git for tracking changes (https://github.com/usnistgov/blockmatrix/tree/master/TimeStampingAuthority).

Executables can be used on their own, but it is suggested that an interactive development environment (IDE) supporting Maven and Git is used in development, e.g. IntelliJ IDEA or Eclipse (both are free). There are four Maven modules corresponding to four executables in the project. 3 contain just one class with a main method, and one contains several classes mentioned above. There is a directory called "testing" which contains all the executables, a file with the clock data and a script for testing. Maven is configured in such a way that when the "package" command is run, all the modules are assembled into .jar files. When the "verify" command is run after that, the .jar files are moved into the correct directories for convenience. The "out" directory contains all 4 executables bundled with their dependencies as well as a library .jar, containing non-executable server-side classes without dependencies. This library jar can be used in other projects as a dependency, assuming that the Apache Commons Net library is included.

4.1 Installation

This project uses Java Development Kit (JDK) 12.0.1 (the current version as of this writing), but is tested to be backward-compatible with JDK 1.8.0_21.

If used as a .jar, the executables do not have any dependencies except for the Java runtime environment.

If used as Java classes, the Apache Commons Net library needs to be downloaded, which provides implementation of many network protocols, including NTP, along with utilities that make it easier to use these protocols in the program. You can include this library as a dependency in a Maven project using the information on

https://mvnrepository.com/artifact/commons-net/commons-net/3.6 or download the libraries as source code or as binaries on

https://commons.apache.org/proper/commons-net/download_net.cgi. The libraries are open source and are available under the Apache License, Version 2.0.

It is suggested that you use an IDE with support of Maven and Git if you would like to use them in the development of the project, because Maven downloads the dependencies for you and makes building and packaging easier and Git helps revert any changes and keep track of the history of the project. If not, a simple solution would be to rip out the classes of all 4 modules and put them in a new project together. Do not forget to add the Apache Commons Net library as a dependency.

5.0 Limitations

The order-preserving property of the current TsA implementation has been tested only locally. Namely, the procedure was to run the Time Stamping Authority server locally, together with one or more clients that would request timestamps from the server. Since the time on the PC is the same, more tests are needed to determine the reliability of TsA. Namely, clients could be located far from the server, and have their own reliable time source to compare the timestamps with. Based on this kind of testing, the conclusion about order-preservation can be made.

Sometimes several subsequent timestamps get "merged" and have the same value, even though it is known that the events were supposed to have a time interval between them. For example, there could be several timestamps with values 1, 1, 1, 4, 5, while the events were supposed to happen at times 1, 2, 3, 4, 5. It is likely that this happens due to low computing power of the development machine used, and as a consequence of running several processes for actual testing of the program and other processes running in the background. If the events are spaced out with the stated time difference - 10 ms, then the weak order is always preserved. By weak order we mean the sequence of numbers where two numbers can be equal, not strictly increasing.

Implementation factors are a consideration in this merging phenomenon. The prototype was implemented in Java, which sometimes has unpredictable runtime due to garbage collection, and it was not the only program running on the PC, so the operating system (OS) could take away processor time for a fraction of a second, corrupting the timestamps. It is expected that if the implementation had adequate performance and priority is given to the time-stamping server, these anomalies should not be present, and the resulting timestamps should form strictly increasing sequence. Additional testing will be used to evaluate this condition.

1. NTP assumes that the offset from the client clock is to be calculated by the client, so the TsA has no way to know if the client completed the timestamp calculation correctly.
2. When requesting time from the clocks and serving time to the client, only one NTP-request is made, since acceptably low latency network conditions are assumed. It is suggested to make several NTP-requests and take the one with the lowest round trip time to exclude asymmetric route errors.
3. RFC-1305 suggests a formula for combining several clock times to increase accuracy and precision. This could be used instead of a simple average of all the clocks, which is currently used.

6.0 Conclusion

In the real estate community, it is said that property value is based on “location, location, location.” But we also know that timing is everything. In sports, the end of a game can be decided in a single second. In financial transactions, it comes down to milli- and microseconds. Here, we have shown that atomic clock aggregation is possible and that it works better if the clocks are somewhat geographically co-located due to latency. We have argued that a Timestamping Authority (TsA) is a feasible approach to creating timestamps of higher integrity.

We plan to continue this research to better understand the impact of latencies on the accuracy of the aggregated clock results.

Multiple Changepoint Analysis of Noisy Nonlinear Data with an Application to Modeling Crack Growth in Additively Manufactured Titanium

Lucas Koepke[*][†] Jolene Splett[‡] Timothy Quinn[‡] Nikolas Hrabe[‡]
Jake Benzing[‡] Michael Frey[‡]

Abstract
Noisy measurement data pose a challenge for changepoint analysis, especially in the presence of multiple changepoints and when the model is nonlinear. We explore various approaches to estimating changepoints and their standard errors under these conditions. We consider whether adding a monotonicity constraint improves the changepoint estimates and reduces their standard errors. We finish with a novel application to material science using crack growth data from additively manufactured titanium. As cyclic loading is applied to a test specimen, crack growth can be partitioned into three regimes: slow-growth, mid-growth, and high-growth. We improve estimates of the transition points between these regimes versus those made by experts in the field by adding confidence bounds to the changepoint locations, allowing for designed experiments to study treatment effects on changepoint location.

Key Words: changepoint, isotonic regression, nonlinear least squares, pool-adjacent-violators algorithm

1. Introduction

As a material is subjected to cyclic fatigue loading, cracks can form and grow over time even when the maximum applied force is well below the yield strength of the material. To measure the resistance of a material to fatigue crack propagation, a notched sample is cyclically loaded for many thousands of cycles. For each force cycle, the crack size a is estimated and the cyclic force range, $\Delta P = P_{max} - P_{min}$ is recorded. For analysis, the stress intensity factor, ΔK, is calculated from ΔP, a, and the geometry of the specimen, since during fatigue testing the force range is constant, while ΔK increases as the crack propagates. The stress intensity can be calculated for any part where the forces and geometry are known. ΔK is plotted against the change in crack length per cycle or fatigue crack rate, $\frac{da}{dn}$ (see Figure 1).

Figure 1a shows data on the linear scale. For lower values of ΔK, the crack shows minimal growth. This transitions to an elbow region as ΔK increases, where the crack growth rate can be predicted with a power law (Hertzberg, 1996, p. 614). This in turn leads to a short period of rapid crack growth. The transitions between these three regimes (slow-growth, mid-growth, and high-growth) can be used to characterize the fatigue properties of the material. Because the transitions are difficult to identify on the linear scale, both $\frac{da}{dn}$ and ΔK are typically transformed by taking the log (base 10) (Figure 1b). The transformation changes the elbow region into a linear region, with a lower changepoint occurring at the transition into the linear region and an upper changepoint at the transition out of the linear

(a) Original data.

(b) Log-transformed data.

Figure 1: Example of fatigue crack growth data from additively manufactured titanium on the linear scale (left) and after taking the log (base 10) of both the stress intensity factor ΔK and the crack growth rate $\frac{da}{dn}$ (right). Possible changepoint locations are shown by the vertical red lines.

region. These changepoints are typically determined through inspection by experts in the field. Our challenge is to estimate these two changepoints objectively.

We proceed as follows. Since we don't know the true changepoints for the experimental data, we start with a simulation study both to compare methods using data with a known changepoint and to explore how aspects of the data might bias the estimates. Additionally, we investigate whether it is possible to reduce noise in the data knowing that crack growth should always increase as ΔK increases. We finish by estimating the changepoints on experimental data and comparing results with changepoints estimated using inspection by expert engineers. All computation was performed using R (R Core Team, 2018).

2. Methods

We assume that the model should be linear between the changepoints, so we concentrate on methods that can be made to accommodate this constraint. Specifically, we focus on fitting models using nonlinear least squares (NLS). We can parameterize the function that we fit to approximate different shapes below, between, and above the two changepoints. In each case, the function segments are constrained to meet at the changepoints, and the changepoint locations are estimated as parameters. The approach also has the advantage of providing standard errors on the parameter estimates and model fit diagnostics. For example, the model for estimating one changepoint with one linear and one quadratic segment is

$$\begin{aligned}\hat{y} =&I_{x\leq \text{changepoint}}(a_1 + b_1 * x)+ \\ &I_{x>\text{changepoint}}(b_2 * x + c_2 * x^2)\end{aligned} \tag{1}$$

If c_2 is set to zero this model reduces to one with two linear segments meeting at the changepoint.

2.1 Noise reduction

We know that $\frac{da}{dn}$ should be monotonically increasing with ΔK (cracks do not decrease in size in engineering materials under cyclic force), so it is natural to consider the benefit of isotonic regression (Barlow and Brunk, 1972; Dykstra, 1981; Robertson et al., 1988). Isotonic regression is unique in that it is guaranteed to reduce

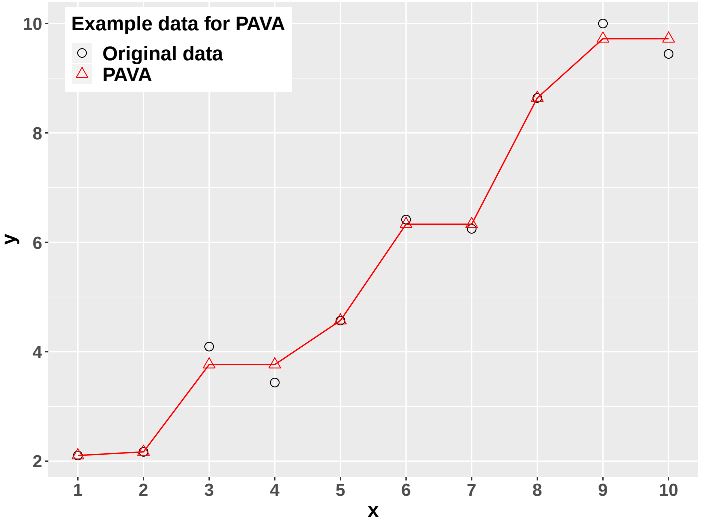

Figure 2: Example of PAVA using simulated data. Black circles are the original data points, the red triangles show the result after PAVA. If the original data is already increasing, PAVA does nothing, but the pooling is evident whenever a y value decreases.

mean-squared error when estimating a monotonic mean function. We consider the isotonic regression calculated using the pool-adjacent-violators algorithm (PAVA) (Ayer et al., 1955). PAVA is implemented in R in the `isotone` package (Mair et al., 2009).

PAVA works as follows. Start with the data (x_i, y_i) for observations $i \in 1, \ldots, n$ ordered such that $x_i \leq x_{i+1}$. At this point the y_i's have not been touched. We assume equal weights. Start at $i = 1$ and check whether y_2 is less than y_1. If this is the case, the monotonicity constraint is violated, so pool y_1 and y_2 by replacing both with their average $\frac{y_1+y_2}{2}$. Then proceed as follows for $i \in 2, \ldots, n-1$:

1. Check for a monotonicity violation (y_{i+1} is less than y_i). If that is the case, pool y_{i+1} and y_i.

2. If the new value of y_i is now less than y_{i-1}, pool all three (y_{i-1}, y_i, and y_{i+1}) by replacing the three values with their average. Then for $j \in i-1, \ldots, 1$ repeat until $j = 1$ or $y_j < y_{j+1}$.

3. Proceed to the next i.

After the PAVA computation has completed, the y's are monotonically non-decreasing (Figure 2). Even though PAVA appears to naturally apply to fatigue crack growth data due to the monotonicity, it is not clear whether PAVA will bias the changepoint estimates, or to what extent the associated standard errors will be affected.

3. Simulation study

The simulation study is set up to explore different situations that might arise in the experimental data in a controlled way. We simulate data using (1) for the one

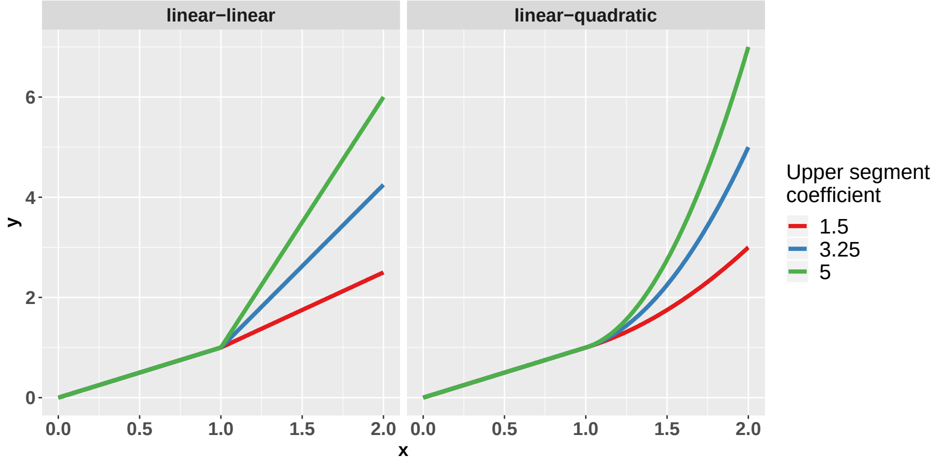

Figure 3: Data generation models shown without noise. Both have a linear first section with $b_2 = 1$ up to the changepoint at $x = 1$. Multiple parameter values for the upper segments are shown, corresponding to the slope on the upper segment (b_2) in the linear-linear model and the coefficient on the quadratic term (c_2) for the linear-quadratic model.

changepoint case since including a second changepoint is a straightforward extension of the NLS function. The first segment is a line with b_1=1 for x between 0 and 1. The changepoint is at $x = 1$. For x between 1 and 2, we consider both a linear and a quadratic segment, the quadratic is chosen because it represents the simplest nonlinear case.

Two parameters are varied when simulating data. The first is the amount of additive noise. In the experimental data, the error relative to the range of the y measurements is about 1 %, so we consider a range of additive noise values including: 1 %, 2 %, 3 %, and 5 %. The other parameter we vary is the shape of the second segment after the changepoint. In the linear-linear model where c_2=0, this parameter is the slope of the second segment (b_2), and will range between 1.5 and 5. For the linear-quadratic model, we fix the slope of the quadratic segment to be 1 at the changepoint (b_2=1) so the function is continuous and smooth, but we vary the coefficient on the quadratic term (c_2) between 0.5 and 5. Changing c_2 is equivalent to changing the second derivative (differing by a factor of 2). Examples of these data generation models with different parameter values are shown in Figure 3.

For each model, parameter value, and relative noise level, we simulate 10,000 data sets, each with 200 points below the changepoint and 200 points above, and fit linear-linear and linear-quadratic models using NLS. The output of each iteration is an estimated changepoint location, and we use these to compute the bias and standard error of the changepoints. The second part of the simulation will treat noise reduction using PAVA. Although PAVA should reduce the noise in the data with no penalty in overall model fit, it is not clear whether PAVA will introduce bias in the specific parameter estimate for the changepoint. Thus for each simulated data set, we also fit the model to PAVA smoothed data, and compare the bias and standard error of the changepoint parameter estimates for unsmoothed and PAVA-smoothed data.

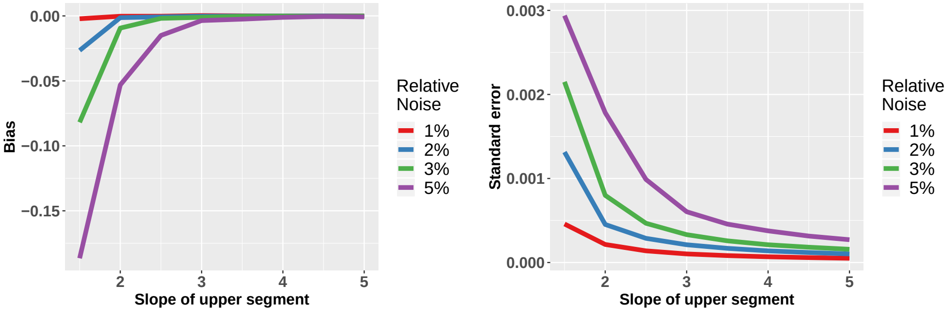

Figure 4: Bias (left) and standard error (right) for the estimated changepoint obtained by fitting the linear-linear model to linear-linear data versus the value of b_2 used to simulate the data.

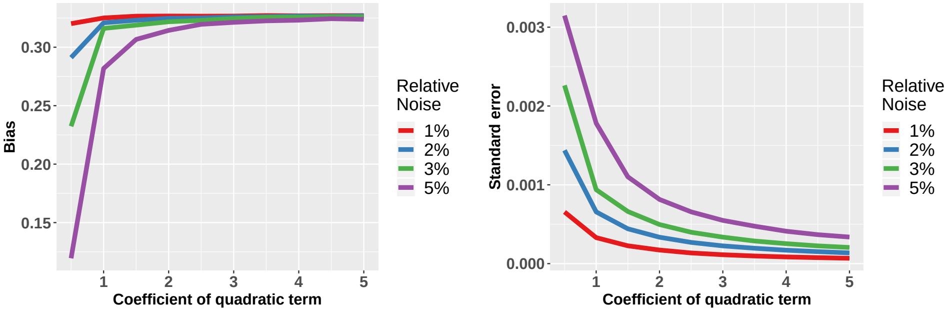

Figure 5: Bias (left) and standard error (right) for the estimated changepoint obtained by fitting the linear-linear model to linear-quadratic data versus the value of c_2 used to simulate the data.

3.1 Bias and standard error

Figure 4 shows the bias (left) and standard error (right) of the estimated changepoint for the linear-linear model fit to the linear-linear data. On the x-axis is the slope of the upper segment, ranging between 1.5 and 5. In the noisiest scenario (5 % relative noise) with the least slope difference ($b_2 = 1.5$), the bias is -0.18. When $b_2 = 2$, the bias drops to just -0.05 and keeps improving as the slope increases. The standard error follows a similar pattern.

Results for bias and standard error of the estimated changepoint for the linear-linear model fit to linear-quadratic data are shown in Figure 5. The shape of the curves for bias and standard error are similar to the previous case (fitting a linear-linear model to linear-linear data) but now instead of the bias trending towards zero it settles at roughly 0.32. The standard error decreases for all relative noise levels as the coefficient on the quadratic term increases.

Results for bias and standard error of the estimated changepoint for the linear-quadratic model fit to linear-quadratic data are shown in Figure 6. When c_2 is between 0.5 and 1.5, the biases are near zero but the standard errors at the four relative noise levels are highest at the 0.5 value, decreasing as c_2 increases. The bias is negative for coefficients 2 through 5. A negative bias here indicates that the transition to the quadratic segment, the changepoint, is estimated to be too low, so the quadratic segment consistently takes over part of the linear segment.

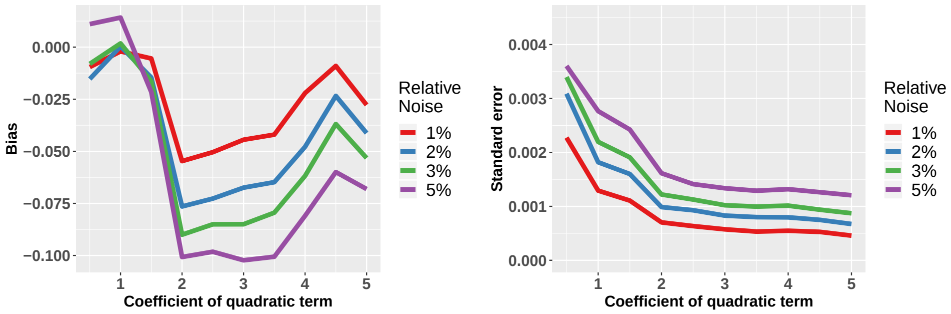

Figure 6: Bias (left) and standard error (right) for the estimated changepoint obtained by fitting the linear-quadratic model to linear-quadratic data versus the value of c_2 used to simulate the data.

The results of the simulation show that fitting a linear-linear model to linear-linear data performs well. The recommendation is not as clear for the linear-quadratic data, since fitting a linear-quadratic model does not perform consistently. The parameter combinations with biases near zero have the largest standard errors, and there are erratic jumps in the bias for some coefficient values. Fitting a linear-linear model to the linear-quadratic data shows higher bias in the changepoint estimate, but the results are consistent over different coefficient values, and the standard errors are consistently lower compared with the linear-quadratic fit.

3.2 PAVA results

In the simulation study, we explore two ways that PAVA can influence the analysis. The first is to show the improvement in model fit, and the second is to explore the effect on the changepoint estimates themselves.

In terms of model fit, the reduction in mean-squared error from unsmoothed to PAVA-smoothed data is shown in Figure 7. The percent change was calculated going from unsmoothed to PAVA-smoothed data, relative to the unsmoothed data. For both cases where the model fit matches the data model, PAVA reduced the mean-squared error of the NLS fit by over 80 %. This reduction is larger at high relative noise levels, and decreases as the upper segment becomes steeper. The third case, fitting a linear-linear model to linear-quadratic data, shows similar improvement (over 80 %) when b_2 is 0.5 or 1, but offers less of an improvement as b_2 increases. When $b_2 = 5$, PAVA reduced the mean-squared error by less than 40 % at the lowest relative noise level.

The effect of PAVA on the bias of the changepoint estimates is shown in Figure 8. This plot shows the difference in absolute values, $|\text{bias}_{\text{unsmoothed}}| - |\text{bias}_{\text{PAVA}}|$. A positive value means that PAVA reduces the bias, while a negative value means the opposite. We chose to use this difference instead of calculating a percentage change since many values are close to zero, leading to unstable relative changes.

For a linear-linear model fit to linear-linear data, PAVA reduces the magnitude of the bias when $b_2 = 1.5$ for the three highest relative noise levels (2 %, 3 %, and 5 %). When $b_2 = 2$, PAVA reduces the magnitude of the bias only for the 5 % relative noise case. PAVA increases the bias for the other combinations of slope and relative noise, but only by 0.01 or less.

PAVA does not improve the bias when fitting a linear-linear model to linear-

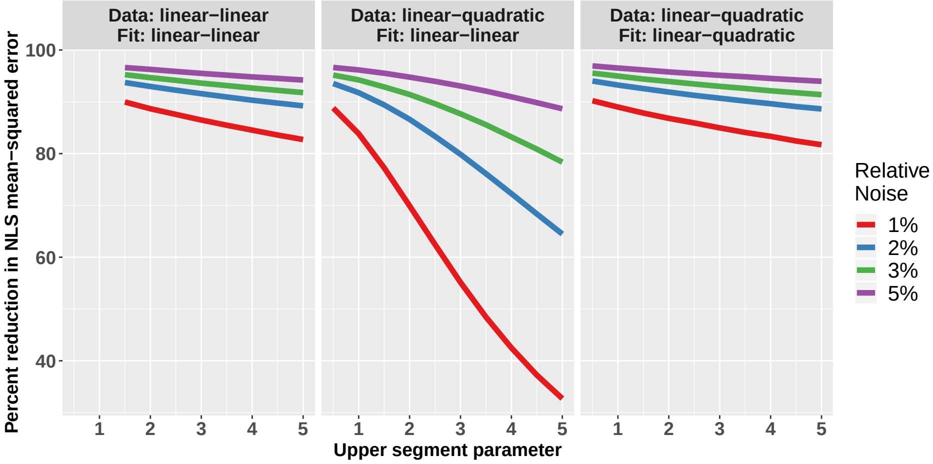

Figure 7: Percent change in mean-squared error of the NLS fit going from unsmoothed to PAVA smoothed data. (left) linear-linear model fit to linear-linear data, (center) linear-linear model fit to linear-quadratic data, and (right) linear-quadratic model fit to linear-quadratic data.

quadratic data. Bias is actually increased for all combinations of relative noise and the coefficient on the quadratic term (c_2), although this increase is 0.02 or less for relative noise of 1 %. The difference in bias decreases for all relative noise levels as c_2 increases.

When fitting a linear-quadratic model to linear-quadratic data, PAVA reduces the bias at all noise levels for c_2 values from 1.5 to 4, although by less than 0.025 in all cases. Bias increases for a quadratic coefficient of 1, but by less than 0.01.

While PAVA substantially reduces the overall error in the model fit, it does not offer a consistent reduction in bias for the changepoint estimate. However, in cases where PAVA increases the magnitude of the bias, the increase is less than 0.01 when the correct model is fit to the data. The bias increase is more than 0.02 when fitting the linear-linear model to linear-quadratic data when the c_2 is less than 2. Although PAVA does not consistently reduce the bias of the changepoint estimates, the reduction in mean-squared error from the model fit means that PAVA could be a useful step in estimating changepoints with NLS under the right conditions (for example, the linear-linear model fit to linear-linear data with high noise and a small change in slope). PAVA should not be used for the case where a linear-linear model is fit to linear-quadratic data.

4. Analysis of experimental data

We turn now to the problem of estimating the two changepoints on the experimental data. We extend the linear-linear and linear-quadratic models from the simulation study to now include two changepoints. For simplicity we call the linear-linear-linear model the “1-1-1” model and the quadratic-linear-quadratic model the “2-1-2” model, from the order of the polynomials in each segment. The equation that

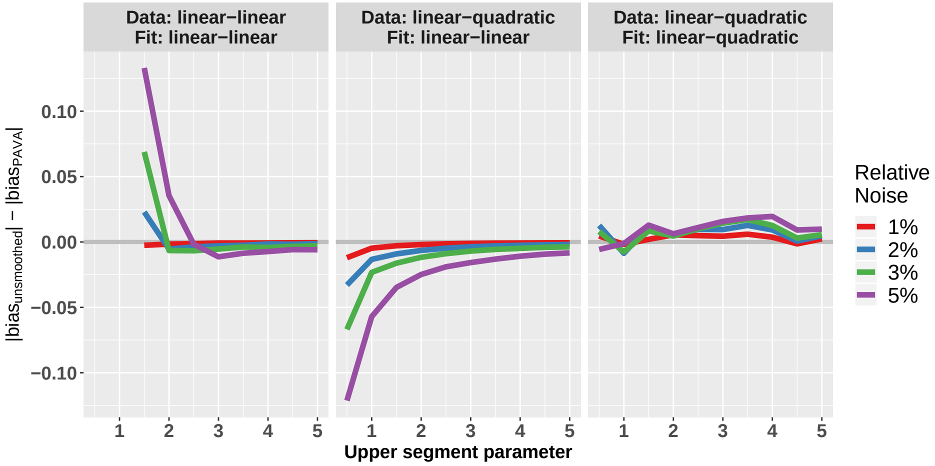

Figure 8: Difference in the absolute value of the bias for unsmoothed data and the absolute value of bias for PAVA-smoothed data. A positive value indicates that the magnitude of the bias is smaller after PAVA, while a negative value indicates the opposite.

Parameter	1-1-1 model	2-1-2 model	Expert
Lower changepoint	1.087 (0.00579)	1.152 (8.735)	1.06 (0.0107)
Upper changepoint	1.735 (0.00469)	1.667 (0.0283)	1.75 (0.00974)
b_0	5.180 (0.162)	2.710 (161.622)	N/A
c_0	N/A	-9.268 (1.756)	N/A
a_1	-7.333 (0.0252)	-7.299 (0.0368)	N/A
b_1	2.735 (0.0179)	2.712 (0.0261)	N/A
b_2	6.893 (0.353)	1.865 (0.783)	N/A
c_2	N/A	21.821 (3.954)	N/A

Table 1: Parameter estimates for the 1-1-1 and 2-1-2 models, and the mean values from the expert engineers. Standard errors for each point estimate are shown in parentheses. Units on the changepoint estimates are $\log_{10}(\text{MPa} * \text{m}^{1/2})$.

we fit using NLS is given by

$$\begin{aligned}\hat{y} =& I_{x<\text{lower changepoint}}(b_0 * x + c_0 * x^2) + \\ & I_{\text{lower changepoint}\leq x\leq \text{upper changepoint}}(a_1 + b_1 * x) + \\ & I_{x>\text{upper changepoint}}(b_2 * x + c_2 * x^2)\end{aligned} \tag{2}$$

where c_0 and c_2 are set at zero for the 1-1-1 model. There are no intercept terms estimated for the lower and upper segments because they are not free parameters. Since we do not know the true changepoints, we first had three expert engineers provide their best guess of the changepoint locations, independent of one another, for comparison with our results. Results for the 1-1-1 and 2-1-2 models are compared with the expert estimates in Table 1. This comparison illustrates why we use the 1-1-1 model for fitting even though the fatigue crack growth data appears to follow a 2-1-2 model. The 2-1-2 model fails to produce a lower changepoint with a reasonable standard error, and the 2-1-2 estimates are not as close to the expert changepoints as the 1-1-1 estimates. The experimental data may correspond to a high bias,

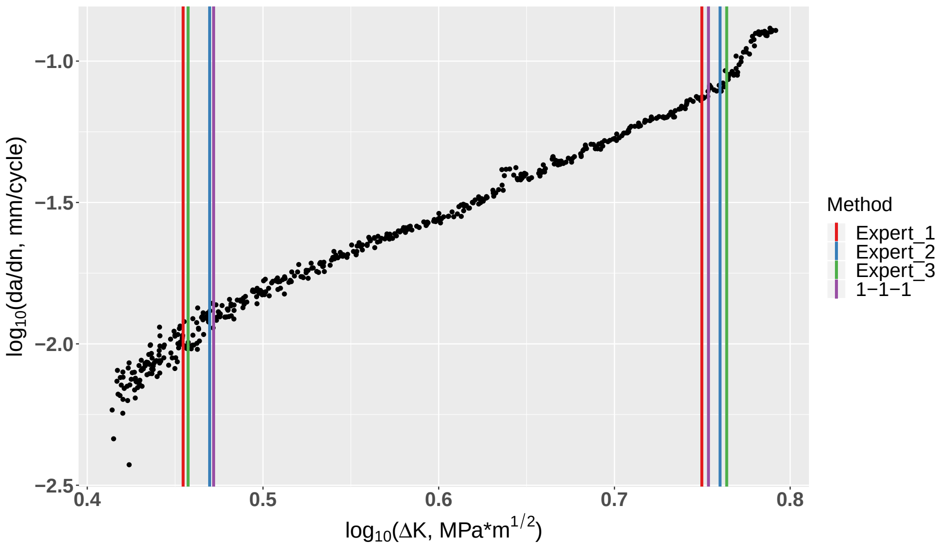

Figure 9: Experimental data with changepoints from each of the three experts and the 1-1-1 model. The 1-1-1 estimates agree almost exactly with at least one expert for both the upper and lower changepoints.

high standard error case in the simulation study where a linear-linear model is fit to linear quadratic data. In addition, the 2-1-2 model may not be a good fit to the experimental data. The 1-1-1 estimates are much closer to the average values from the experts for both changepoints, and the estimates have reasonable standard errors. Note that the 1-1-1 and 2-1-2 models estimate almost identical values for the slope and intercept of the central linear segment.

Individual estimates from the three experts and the 1-1-1 model are shown in Figure 9. The expert estimates show variability in the changepoint locations, but the estimates from the 1-1-1 model are both in the right area and very close to at least one expert for both the upper and lower changepoints. Results for data from other fatigue tests are similar, so we conclude that the 1-1-1 method is at least as reliable as an expert engineer in estimating the two changepoints.

For the experimental data, Figure 10 shows the point estimates and 95 % confidence intervals for three methods: experts (mean ± 2×standard error), the 1-1-1 model, and the 1-1-1 model with PAVA. While PAVA isn't recommended for fitting a linear-linear model to linear-quadratic data, we estimate changepoints for PAVA-transformed experimental data for completeness. Based on the simulation results for the case where a linear-linear model is fit to linear-quadratic data, the upper changepoint should be biased high; however, the 1-1-1 model produces an upper changepoint that is less than the average computed for the experts. Although the point estimates for the 1-1-1 method with and without PAVA are similar, PAVA does reduce the widths of the confidence intervals.

5. Conclusions

The simulation study provides insight into the behavior of changepoint estimation using NLS for a variety of scenarios. Fitting a linear-linear model to linear-linear data produces the most consistent changepoint estimates, with biases smaller than

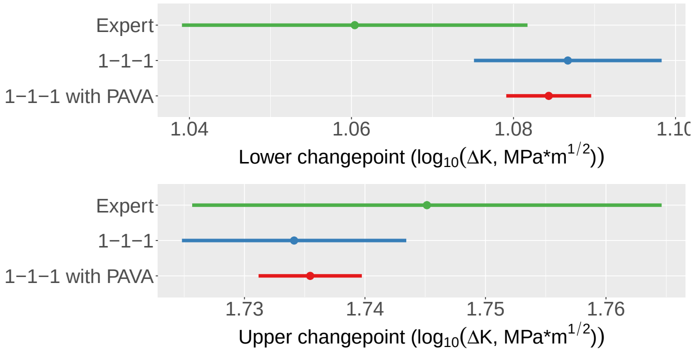

Figure 10: Comparison of point estimates and 95 % confidence intervals for the lower changepoint (top) and the upper changepoint (bottom).

0.01 in most cases. When fitting a linear-quadratic model to linear-quadratic data, many biases were in the range of -0.025 to -0.1. Changepoint estimates are biased, converging to a bias of 0.32, for all cases considered when fitting a linear-linear model to linear-quadratic data. Additionally, PAVA always reduces the mean-squared error for the model fit, but did not always reduce the bias in the changepoint estimates and should be used with caution.

The application to fatigue crack growth data shows that the 1-1-1 model provides realistic changepoint estimates even though the model doesn't accurately represent the data in the lower and upper segments. This method performs quite well compared with changepoint estimates made by experts in the field.

Future work will focus on two areas. First, we will estimate changepoints in the context of a designed experiment to evaluate how material conditions affect the changepoint locations. The second area of work involves missing data. Because valid data can only be collected while the crack is below a certain percentage of the sample width (ASTM E647), a particular test may only provide data on one of the two changepoints. Utilizing data from these tests would be useful, since fatigue tests are expensive.

This work builds the foundation for a methodical, data-driven approach to the analysis of fatigue crack growth data. The objectivity provided by our statistical approach will be useful to the scientific community.

Highlights:

- The heat release rates determined by calorimetry and mass loss compared favorably
- Temperature profiles in the radial and axial directions were measured
- Gas temperatures were estimated considering radiative loss and thermal inertia effects
- The radiative fraction was calculated as 0.22 ± 16 % from heat flux measurements

Abstract:

A series of measurements was made to characterize the structure of a 1 m diameter methanol (CH_3OH) pool fire steadily burning with a constant lip height in a quiescent environment. Time-averaged local measurements of gas-phase temperature were conducted using 50 μm diameter, Type S, bare wires, with a bead that was approximately spherical with a diameter of about 150 μm. The thermocouple signals were corrected for radiative loss and thermal inertia effects. The mass burning rate was measured by monitoring the mass loss in the methanol reservoir feeding the liquid pool. The heat release rate was measured using oxygen consumption calorimetry. The heat flux was measured in the radial and vertical directions and the radiative fraction was estimated, which corresponded to previous results.

Keywords: Heat release rate; Temperature distribution; Burning rate; Heat flux distribution; Radiative fraction

1. Introduction

The focus of this study is to characterize the burning of a 1 m diameter pool fire steadily burning in a well-ventilated quiescent environment. Pool fires are a fundamental type of combustion phenomena in which the fuel surface is flat and horizontal, which provides a simple and well-defined configuration to test models and further the understanding of fire phenomena. In this study, methanol is selected as the fuel. Fires established by methanol are unusual as no carbonaceous soot is present or emitted. This creates a particularly useful testbed for fire models and their radiation sub models that consider emission by gaseous species - without the confounding effects of radiative exchange due to soot.

Many studies have been reported on the structure and characteristics of 30 cm diameter methanol pool fires, including the total mass loss rate [1-3], mean velocity [4], pulsation frequency [4] and gas-phase temperature field [4, 5]. With so many measurements

Sung, Kunhyuk; Chen, Jian; Bundy, Matthew; Hamins, Anthony. "The Characteristics of a 1 m Methanol Pool Fire." Paper presented at 13 International Symposium on Fire Safety Science (IAFSS 2020), Waterloo, CA. April 26, 2020 - May 01, 2020.

characterizing the 30 cm methanol pool fire, it is a suitable candidate for fire modeling validation studies [3, 6-8]. On the other hand, research on the detailed structure and dynamics of larger pool fires is limited. Tieszen, *et. al.* [9, 10] used particle imaging velocimetry to measure the mean velocity field in a series of 1 MW to 3 MW methane and hydrogen pool fires burning in a 1 m diameter burner. Klassen and Gore [11] reported on flame height and the heat flux distribution near 1.0 m diameter pool fires burning a number of fuels including methanol. They used the same burner as this study, but with a 5 mm (rather than 10 mm as used here) lip height. This study complements Ref. [11] by also measuring the local flame temperature throughout the flow field, the heat release rate using oxygen consumption calorimetry, and the radiative fraction determined by a single location measurement.

Use of fire modeling in fire protection engineering has increased dramatically during the last decade due to the development of practical computational fluid dynamics fire models and the decreased cost of computational power. Today, fire protection engineers use models like the Consolidated Fire and Smoke Transport Model (CFAST) and the Fire Dynamics Simulator (FDS) to design safer buildings, power plants, aircraft, trains, and marine vessels to name just a few types of applications [6, 12]. To be reliable, the models require validation, which involves a large collection of experimental measurements. An objective of this report is to provide data for use in fire model evaluation by the fire research community. Also, it is of interest to compare the burning characteristics of the 30 cm methanol pool fire with the results presented here for a 1 m diameter methanol pool fire.

2. Experimental Methods

Steady-state burning conditions were established before measurements were initiated. A warm-up period of 10 min was required for the mass burning rate to be steady. Since back diffusion of water slowly accumulates in the fuel pool in methanol fires, fresh fuel was used between experiments. The purity of the methanol was 99.99 % by mass and the density was 792.7 kg/m^3 at 20 °C, according to a report of analysis provided by the supplier. Experiments were conducted under an exhaust hood located 4 m above the burner rim. The effect of ambient convective currents on the fire were minimized by closing all inlet vents in the laboratory. The exhaust consisted of a large round duct (1.5 m diameter) located 6.0 m above the floor [13]. The smallest exhaust flow possible (about 4 kg/s) was used, helping to avoid perturbations (such as flame lean) and minimizing the influence of the exhaust on fire behavior. This led to the establishment of an unusually symmetric and recurring fire. The experiments were repeated three times.[*]

[*] Certain commercial entities, equipment, or materials may be identified in this document in order to describe an experimental procedure or concept adequately. Such identification is not intended to imply recommendation or endorsement by the National Institute of Standards and Technology, nor is it intended to imply that the entities, materials, or equipment are necessarily the best available for the purpose.

2.1. Pool Burner Setup

A circular steel pan with an inner diameter (*D*) of 1.00 m, a depth of 0.15 m, and a wall thickness of 0.0016 m held the liquid methanol. An image of the burner is seen in Fig. 1. The bottom of the burner was water cooled. The burner was mounted on cinder blocks such that the burner rim was about 0.3 m above the floor. A fuel overflow basin included for safety extended 3 cm beyond the burner wall at its base. The fuel inlet was insulated and covered with a reflective foil to prevent preheating of the fuel.

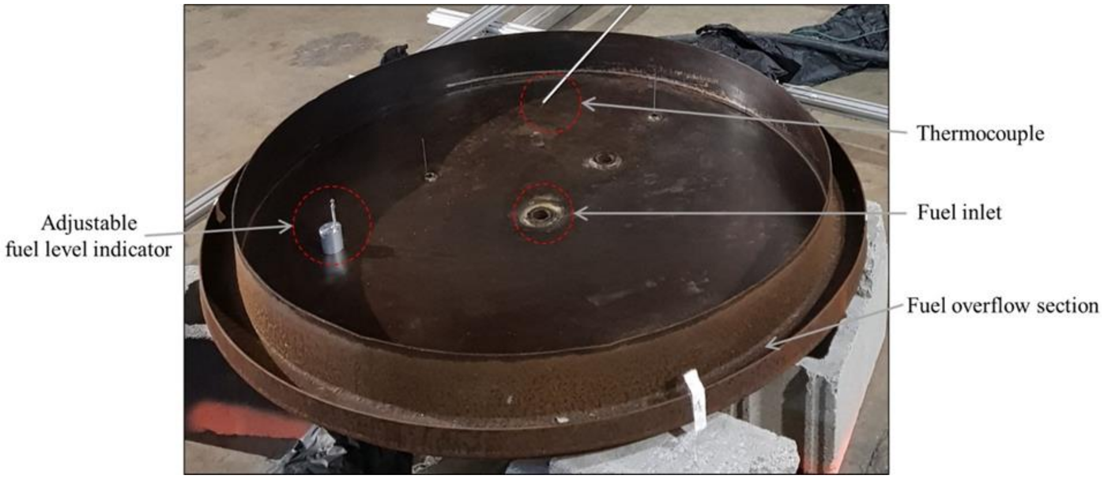

Fig. 1. The 1 m diameter, water-cooled, round steel burner with fuel level indicator and fuel overflow section. The S type thermocouple used to measure the gas phase temperature is also shown.

2.2. Measuring Heat flux

The radiative heat flux by the fire emitted to the surroundings was measured using a wide view angle, water-cooled, Gardon type total heat flux gauges with a 1.3 cm diameter face. The gauges were positioned as shown in Fig. 2. Radial heat flux gauges oriented upward were aligned with the burner rim to measure the heat flux towards the floor. Vertical heat flux gauges were used to measure heat flux to the surroundings.

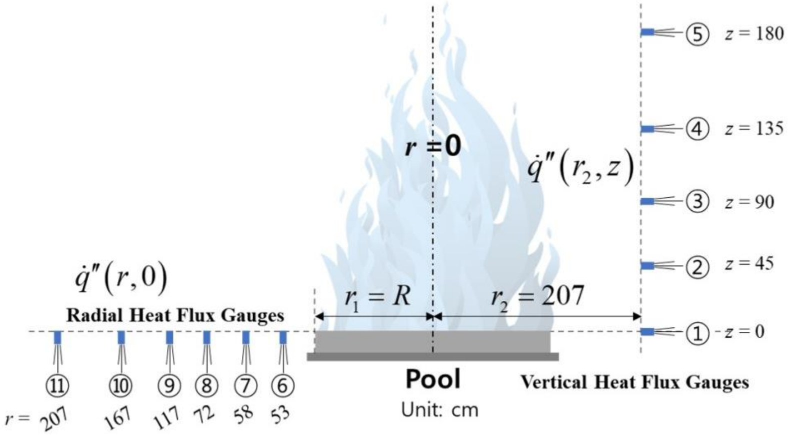

Fig. 2. A schematic diagram of the heat flux gauge set-up. All units in the figure are in cm.

2.3. Measuring Temperature

The local temperature was measured using a Type S (Pt, 10 % Rh/Pt), bare-wire, fine diameter thermocouple. The thermocouple was inserted into a (2-hole) 3 mm outer diameter ceramic tube with about 1 cm of the thermocouple wire including its bead, extending beyond the end of the ceramic tube. Selection of the diameter of a fine wire thermocouple must consider trade-offs between the durability of the instrument and measurement needs. The finer the wire, the smaller the radiative exchange with the environment and the faster the measurement time response, but the more difficult it is to configure. In this study, a 50 µm diameter S-type thermocouple was employed with an approximately spherical bead as observed using an optical microscope. The measured signal was acquired at a rate of 60 Hz for 120 s using a data acquisition module (SCXI-1600, National Instruments Inc.), which represents about 170 flame puffing cycles.

A computer-controlled translation device was used to adjust the position of the thermocouple along a vertical axis aligned with the pool centerline. The vertical rail was aligned with the centerline of the burner and the thermocouple/ceramic tube assembly was attached to the tip of a horizontal rod connected to the moving rail. The connection region between the thermocouple and the rod was well-insulated and covered with aluminum foil.

The energy balance on the thermocouple bead considers convective, radiative, and conductive heat transfer, and can be expressed as:

$$\dot{Q}_{conv} + \dot{Q}_{rad} = \rho_b \cdot c_{p,b} \cdot V_b \frac{dT_b}{dt} \tag{1}$$

where $\dot{Q}$ is the net rate of heat transfer. ρ, $c_{p,b}$, and V_b are the density, specific heat and volume of the bead, respectively. In addition, if the response time of the thermocouple is much larger than the fire fluctuation frequency, then thermal inertia effects can impact the measurement variance, although there is little influence on the mean [4]. The thermal inertia is related to the thermocouple time constant (τ), and the energy balance becomes:

$$T_g(t) = T_b(t) + \tau \frac{dT_b(t)}{dt} + \frac{\varepsilon\sigma}{h}\left(T_b^4(t) - T_{surr}^4\right) \tag{2}$$

$$\tau = \frac{m_b c_{p,b}}{hA_b} \tag{3}$$

where T_b is the bead temperature, T_g is the gas temperature, T_{surr} is the effective temperature of the surroundings, A_b is the surface area of the bead, σ is the Stefan-Boltzmann constant ($5.67 \cdot 10^{-8}$ W/m^2/K^4), ε is the thermocouple emissivity. Here, the flame is taken as essentially optically thin based on estimates using the radiation subroutine in Ref. [6]. The convective heat transfer coefficient of gas flow near the bead is defined as h = Nu $\cdot\ \lambda_g/d_b$, where λ_g is the thermal conductivity of gas, d_b is the thermocouple bead diameter. In Eq. (2), the second and third terms on the right side represent the thermal inertia correction and radiation correction, respectively. The Nusselt number is empirically associated with the Reynolds and Prandtl numbers. Solving the thermal inertia correction term, the time derivative of bead temperature was calculated using a second-order polynomial fit of three consecutive data points of the temperature time series with a curve fit window size of 33.3 ms.

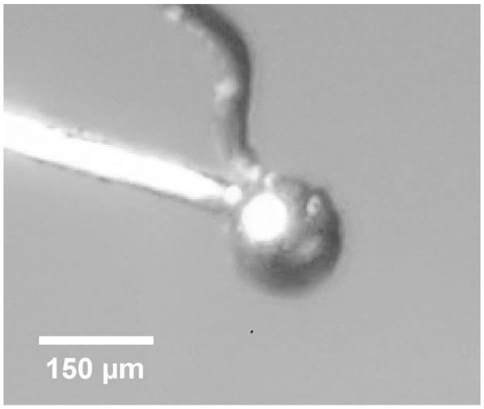

Fig. 3. Magnified image of thermocouple bead.

Fig. 3 shows an image of the thermocouple bead, which was approximately spherical with an eccentricity of about 0.97. The bead diameter was measured using Image-J image processing software from a photo taken with an optical microscope. The uncertainty of the bead diameter was multiplied by the image resolution (2.7 µm/pixel) and the number of pixels needed to determine the edge of the bead. The measured bead diameter was 153.3 µm ± 7.7 µm, which was approximately three times the wire diameter. The time constant for heat transfer to a sphere [14] can be written as:

$$\tau = \frac{\rho_b c_{p,b} {d_b}^2}{6\mathrm{Nu}\lambda_g} \qquad (4)$$

Following Shaddix [15], the Nusselt number for a sphere is calculated using the Ranz-Marshall model:

$$\mathrm{Nu} = 2.0 + 0.6\ \mathrm{Re}^{1/2}\ \mathrm{Pr}^{1/3}; \qquad 0 < \mathrm{Re} < 200 \qquad (5)$$

where Re is the Reynolds number of the bead and Pr is the Prandtl number. The temperature-dependent gas properties for Re and Pr, are taken as those of air [16], and the temperature-dependent emissivity and thermophysical properties of platinum are taken from Refs. [15, 17]. The average ambient temperature during the experiments was 298 K ± 5 K, which was taken as the surrounding temperature, T_{surr}, in Eq. (2). A FDS simulation of the fire was conducted to validate the temperature correction method used to solve Eq. (2) and to obtain the gas velocity distribution above the burner to better represent Re in Eq. (5). The FDS input code was based on the FDS Validation Guide's [6] input file for the 1 m methanol pool fire case. Details are explained in Ref. [18]. The average difference in the mean gas temperature along the centerline between FDS and the experimental results was 4 %. FDS yielded Re ranging from 1 to 24 along the centerline. In Eq. (2), the radiation correction and thermal inertia correction terms mainly affect the mean and variance values, respectively, in agreement with Refs. [4, 15]. For example, correction of the mean temperature due to radiative loss along the centerline was 1 % on average, varying from near zero at the top of the fire plume to 1.7 % at the hottest fire locations. The thermal inertia correction term has a negligible influence on the mean gas temperature, but does amplify the value of its instantaneous extremes, which affects the local standard deviation. The average contribution of the thermal inertia correction term for locations along the centerline represents 54 % of the standard deviation of the gas temperature. In contrast, the radiative loss term has little influence. For these reasons, the uncertainties of the mean and standard deviation of the gas temperature were separately analyzed. The uncertainties of each term of the gas temperature in Eq. (2) were determined based on Ref. [19]. The calibration error of a Type S thermocouple is 0.25 % in 273 K $< T_b <$ 1733 K [20]. The measurement uncertainty of the data acquisition (DAQ) system was approximately 0.60 % for the application range of the thermocouple [21].

3. Results and Discussion

The shape of the fire dramatically changed during its pulsing cycle. The fire was blue with no indication of the presence of soot. Fig. 4 shows four images of the methanol pool fire during different phases of its puffing cycle. Repeating puffing cycles occurred in which orderly curved flame sheets anchored at the burner rim were connected to the central fire plume, rolled towards the fire centerline, and necked-in to form a narrow and long visible fire plume. The flame height was recorded with 30 Hz video. Analysis of the video record showed that the average flame height and its standard deviation was 1.10 m ± 0.22 m and the primary pulsation frequency was 1.37 Hz ± 0.03 Hz.

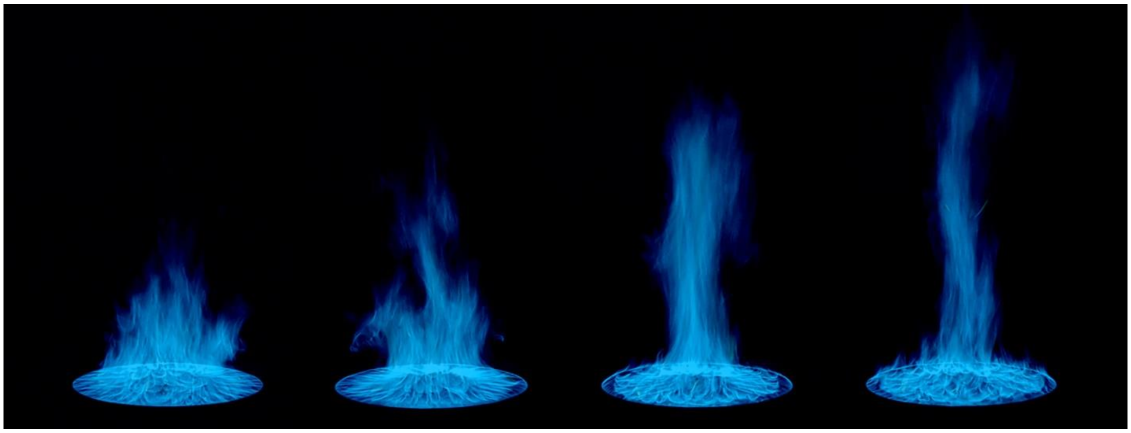

Fig. 4. Instantaneous digital images 132 ms apart in the pulsing 1 m diameter methanol pool fire.

3.1. Mass Burning Rate

With a steady liquid level in the fuel pool, the mass burning rate was measured by monitoring the mass loss in the 20 L methanol reservoir feeding the liquid pool, using a calibrated load cell. Fig. 5 shows the time-varying fuel mass in the reservoir during Test 3. When the fuel was low in the reservoir, it needed to be replenished. The periods when the reservoir was refilled are indicated by the white (unshaded) regions in Fig. 5. During these periods, the fuel was still fed to the burning pool and the fuel level in the pool was maintained constant as verified by a video camera focused on the relative level of the fuel compared to the fuel level indicator (see Fig 1). The burning rate is estimated during the gray regions in the figure, that is, after an initial warm-up and avoiding periods when fuel was added to the reservoir. The total mass loss rate for each period is noted (by the numbers in the gray regions) by considering the ratio of the mass loss to the duration of the period. The time-weighted mean mass burning rate during the three tests was 12.8 g/s ± 0.9 g/s, where the uncertainty here is reported as the combined expanded uncertainty, representing a 95 % confidence interval (a coverage factor of two).

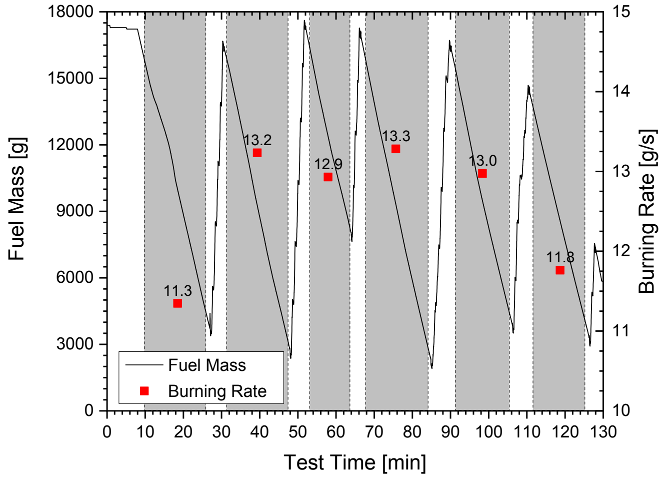

Fig. 5. Mass of fuel reservoir and average fuel burning rate during Test 3. The unshaded regions after 10 min represent times when the reservoir was being refilled with methanol.

3.2. Heat Release Rate

The heat release rate was measured using oxygen consumption calorimetry and compared with the ideal heat release rate ($\dot{Q}$) calculated from the mass burning rate, i.e., $\dot{m}\Delta H_{c,}$ where ΔH_c is the net heat of combustion of methanol equal to 19.9 kJ/g [16]. The heat release rate from calorimetry was averaged for the three tests once the fire reached steady-state burning.

The measured mass burning rate, the ideal heat release rate, and heat release rate measured via the oxygen consumption calorimetry are presented in Table 1. As expected, the ideal heat release rate agrees well with the measured calorimetric heat release rate since the combustion efficiency is expected to be nearly 1. The heat release rate measured by calorimetry was 256 kW ± 45 kW, where the combined expanded uncertainty was based on repeat measurements, the results described in Ref. [13], and additional natural gas calibrations (at a measured heat release rate of about 250 kW).

Table 1. Measured mass burning rate in the 1 m methanol pool fire, the ideal heat release rate determined from the measured mass burning rate, and the heat release rate determined using calorimetry. The uncertainty is expressed as the combined expanded uncertainty with a coverage factor of two, representing a 95 % confidence interval.

Mass burning rate $\dot{m}$ [g/s]	Ideal Heat Release Rate $\dot{Q}$ [kW]	Heat Release Rate from calorimetry $\dot{Q}_a$ [kW]
12.8 ± 0.9	254 ± 19	256 ± 45

3.3. Heat Flux Distribution

Fig. 6 shows the mean radial radiative heat flux as a function of the radial distance from the burner centerline. As expected, the radiative heat flux rapidly decreases with distance from the centerline. The maximum measured radial heat flux was 5.1 kW/m^2 ± 1.0 kW/m^2. The heat flux consistently decreased in a manner proportional to 1/r^2. Fig. 7 shows the mean vertical radiative heat flux as a function of the axial distance above the burner. There was little change in radiative heat flux in the axial direction. The radial heat flux has a maximum value of 1.0 kW/m^2 ± 0.1 kW/m^2 at 0.9 m above the burner. Fig. 6 also shows the results from Ref. [11], which are in agreement with the current measurements within experimental uncertainty.

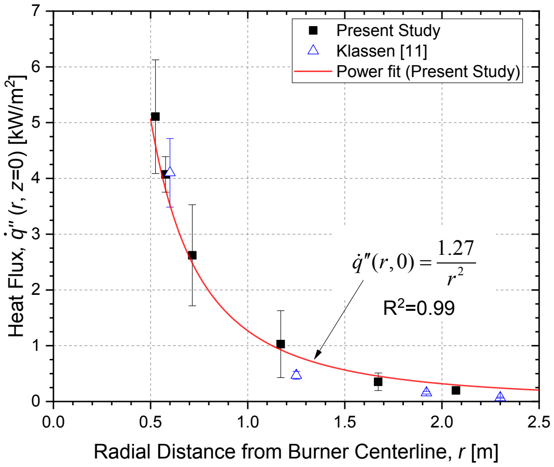

Fig. 6. Mean and standard deviation of the radial radiative heat flux as a function of the radial distance from the burner centerline at the plane defined by the burner rim (z = 0).

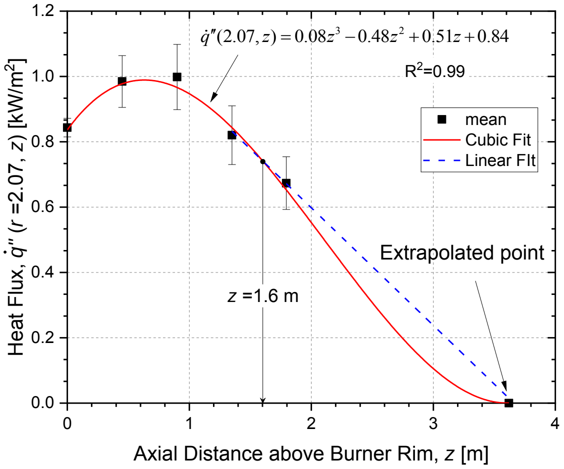

Fig. 7. Mean and standard deviation of the vertical radiative heat flux as a function of the axial distance above the burner for gauges facing the pool fire.

The fraction of energy radiated from the fire (χ_{rad}) was calculated as shown in Eqs. (6) and (7) , considering the overall enthalpy balance explained in Ref. [22], where its value is equal to the ratio of the total radiative emission from the fire $\dot{Q}_{rad}$ normalized by the idealized fire heat release rate ($\dot{Q}$). The radiative fraction can be broken into the sum of the radiative heat transfer to the surroundings (χ_r) and onto the fuel surface (χ_{sr}) such that:

$$\chi_{rad} = \chi_r + \chi_{sr} = \dot{Q}_{rad}/\dot{Q} \tag{6}$$

$$\chi_r = \dot{Q}_r/\dot{Q} \text{ and } \chi_{sr} = \dot{Q}_{sr}/\dot{Q} \tag{7}$$

where $\dot{Q}_r$ is the radiative energy emitted by the fire to the surroundings except to the fuel surface and $\dot{Q}_{sr}$ is the radiative heat feedback to the fuel surface. Assuming symmetry, integrating the measured local radiative heat flux in the *r* and *z* directions (see Fig. 2) yields the total energy radiated by the fire, $\dot{Q}_{rad}$, considering the flux through a cylindrical control surface about the pool fire:

$$\dot{Q}_{rad} = \dot{Q}_r + \dot{Q}_{sr} = \left(2\pi\int_{r_1}^{r_2}\dot{q}''(r,0)\cdot rdr + 2\pi r_2\int_0^{z_2}\dot{q}''(r_2,z)dz\right) + \pi r_1^2\bar{\dot{q}}_{sr}'' \tag{8}$$

where r_1 and r_2 are 0.5 m and 2.07 m, z_2 is 3.62 m, and $\bar{\dot{q}}_{sr}''$ is the average radiative heat flux incident on the fuel surface. In the energy balance for a steadily burning pool fire following Ref. [22], the total heat feedback ($\dot{Q}_s$) to the fuel surface is broken into radiative and convective components ($\dot{Q}_s = \dot{Q}_{sr} + \dot{Q}_{sc}$). Normalizing this by $\dot{Q}$, $\chi_s = \chi_{sr} + \chi_{sc}$. Kim *et al.* [22] measured the distribution of local heat flux incident on the fuel surface in a 30 cm methanol pool fire. The fractional total heat feedback (χ_s) was 0.082 ± 24 % with about 67 % attributed to radiation, that is, χ_{sr}= 0.055 ± 21 %. χ_s in the 1 m pool fire is assumed to be the same as in the 30 cm pool fire. Convective heat transfer to the fuel surface ($\dot{Q}_{sc}$) was calculated using the thin film theory following [23]. As a result, χ_{sr} was 0.065 ± 31 % and χ_{sr}/χ_s was 0.80, which is about 20 % larger compared than in 30 cm pool fire. The fitting function seen in Figs. 6 and 7 was used to integrate the heat flux in the radial and vertical directions. The zero-heat flux position (z_2 = 3.62 m) was extrapolated from the values of the highest two locations in Fig. 7. In previous studies [11, 22], the heat flux peaked at a vertical position equal to approximately one-half the characteristic flame height and decreased almost linearly above the visible flame tip regardless of pool diameter and fuel type, until it reached zero. The vertical radiative heat flux (the second term in Eq. (8)) was integrated using the cubic function from 0 to z_1 (1.6 m) and either the cubic function or a line in the region from z_1 to z_2. The energy difference associated with the fitting functions was treated as uncertainty.

The results show that $\dot{Q}_{rad}$ was 56 kW ± 11 % and χ_{rad} was 0.22 ± 16 %. The radiative fraction of the total heat release rate emitted to the surroundings in previous studies for methanol pool fires is listed in Table 2. The radiative fraction reported here agrees with the value in Ref. [11] within expanded uncertainty. The radiative fraction of the 1 m pool fire was similar to its value in the 30 cm fire, and agreed with the result in Ref. [22] which suggested that the radiative fraction was fairly constant as a function of pool size for diameters less than 2 m.

Table 2. Comparison of the radiative fraction in steadily burning 30 cm and 100 cm methanol pool fires. The combined expanded uncertainty is also shown, representing a 95 % confidence interval.

Research	Pool diameter	χ_{rad}
Present study	100 cm	0.22 ± 16 %
Klassen and Gore [11]	100 cm	0.19[a,b]
Kim *et al.* [22]	30 cm	0.24 ± 25 %
Hamins *et al.* [24]	30 cm	0.22 ± 10 %

[a] $\bar{\dot{q}}_{sr}''$ in Eq. (8) was assumed equal to the heat flux measured next to the burner ($\dot{q}''$(51 cm, 0) = 4.1 kW/m^2), which yields χ_{sr} = 0.01, which is smaller than expected [22]. χ_{rad}, therefore, was recalculated with χ_{sr} = 0.055, yielding χ_{rad} = 0.19.

[b] Recalculated χ_{rad}, using ΔH_c = 19.918 kJ/g [16], not 22.37 kJ/g, assuming gaseous water as a product of combustion.

3.4. Temperature Distribution

Fig. 8 shows the measured time series of uncorrected bead temperature (T_b), the radiation corrected temperature (T_r) considering only the radiation correction term (not the thermal inertia) in Eq. (2), and the (radiation and inertia) corrected gas temperature (T_g). There is no time-delay between the bead temperature and the radiation corrected temperature. The radiative correction became larger as the bead temperature increased with the maximum correction equal to 55 K, when T_b =1694 K. The minimum correction was 7 K, when T_b =1070 K in Fig. 8. The corrected gas temperature was 617 K lower than the bead temperature at 40.35 s, whereas it was 313 K higher than the bead temperature at 40.68 s. The mean time constant was calculated as 57 ms ± 3 ms. As the Nusselt number increases with bead temperature, the time constant decreases, as indicated by Eq. (4).

Fig. 9 shows the measured mean and standard deviation of the bead temperature, corrected gas temperature and time constant as a function of distance above the burner along the centerline of the fire in Test 3. As expected, the mean gas temperatures were very similar to the mean bead temperature for all positions. On average, the combined expanded uncertainty of the mean gas temperature was 8 %, considering all 46 temperature measurement locations. On average, the combined expanded uncertainty of the standard deviation of gas temperature as 26 %.

The mean and standard deviation of the gas temperature as a function of distance above the burner along the centerline are shown in Fig. 10. The maximum value of the mean temperature was about 1371 K, which occurred at 0.3 m above the burner rim. The gradient near the fuel

294 surface in Fig. 10 is steep. At 0.05 m above the burner, the gas temperature was about 1144 K ±
295 424 K. The temperature at two locations on the fuel surface was measured to be at the boiling
296 point of methanol, 338 K, yielding a temperature gradient near the fuel surface of about
297 161 K/cm ± 85 K/cm.

299 Fig. 8. Instantaneous temperature at (z, r) = (30 cm, 0 cm) in Test 3; T_b is the bead temperature,
300 T_r is the corrected temperature considering only radiative loss, and T_g is the gas temperature
301 corrected for radiative loss and thermal inertia.

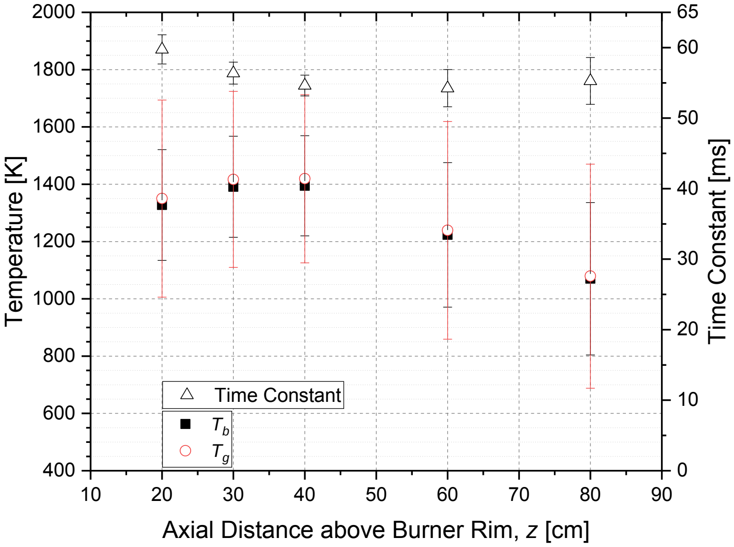

Fig. 9. Mean and standard deviation of the measured bead temperature profile, and calculated gas temperature and thermocouple time constant as a function of axial distance above the burner rim in Test 3.

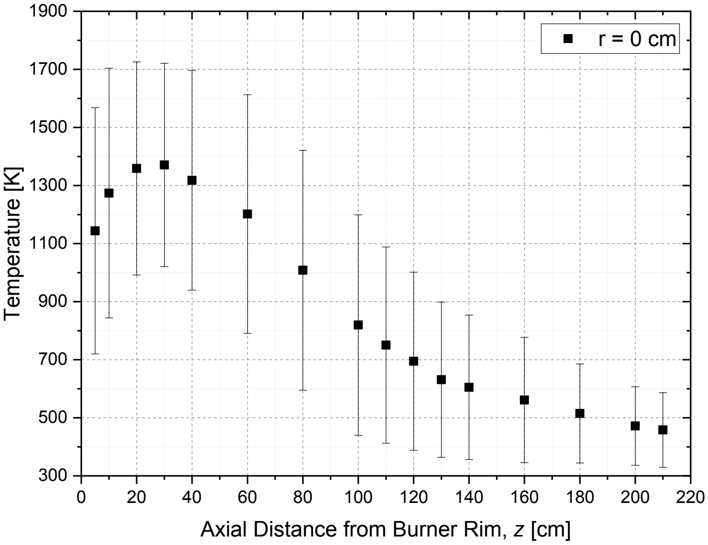

Fig. 10. Mean and standard deviation of the gas temperature profile as a function of axial distance above the burner rim along the centerline of the fire.

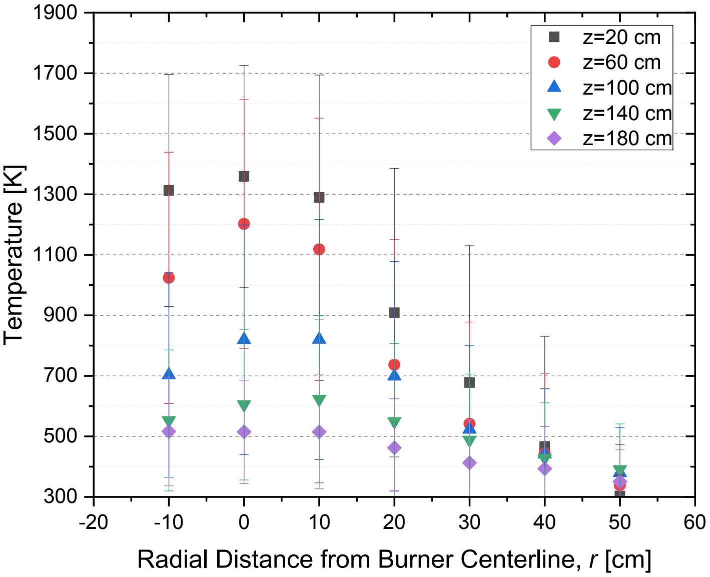

Fig. 11. Mean and standard deviation of the gas temperature profiles as a function of radial distance from the burner centerline at various heights above the burner rim.

Fig. 11 shows the mean and standard deviation of the gas temperature profile in the radial direction for various axial distances above the burner rim (20 cm ≤ z ≤ 180 cm). The maximum temperature occurs near the centerline for each elevation. The gradient diminished with distance from the fuel surface. A complete discussion of the uncertainty analysis for the temperature and other results is given in Ref. [18].

Sung, Kunhyuk; Chen, Jian; Bundy, Matthew; Hamins, Anthony. "The Characteristics of a 1 m Methanol Pool Fire." Paper presented at 13 International Symposium on Fire Safety Science (IAFSS 2020), Waterloo, CA. April 26, 2020 - May 01, 2020.

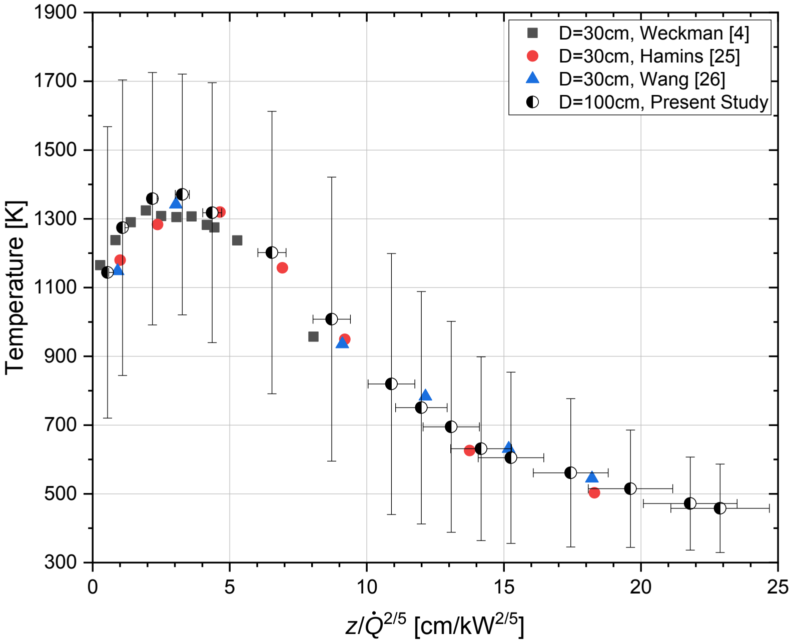

Fig. 12. Mean and standard deviation of the axial temperature profiles as a function of distance above the burner rim normalized by $\dot{Q}^{2/5}$ and compared to previous results in 30 cm methanol pool fires.

Fig. 12 shows the mean and standard deviation of the temperature profile as a function of scaled axial distance. The results are compared to previous measurements in 30 cm diameter methanol pool fires from Refs. [4, 25, 26]. Axial distance above the burner is normalized by $\dot{Q}^{2/5}$ following Baum and McCaffrey [27]. Weckman and Strong [4] measured temperature in a 30.5 cm diameter methanol pool fire with a lip height of 1 cm using a 50 µm wire diameter, bare bead, Type S (Pt, 10% Rh/Pt), thermocouple similar to the thermocouples used in this study. The measurements from Ref. [25] are also shown, where temperature was measured using a 75 µm wire diameter, bare bead, Type S thermocouple in a steadily burning 30.1 cm diameter methanol pool fire with a 0.6 cm lip. The radiation corrected thermocouple measurements in Wang *et al.* [26] are also shown, using a 50 µm wire diameter, bare bead, Type S thermocouple in a steadily burning 30.1 cm diameter methanol pool fire with a 1 cm lip height. A comparison of the results in Fig. 12 shows that the 1 m and 30 cm pool temperatures are similar when the axial distance above the burner is normalized by $\dot{Q}^{2/5}$.

4. Summary and Conclusions

A series of measurements for temperature, burning rate and heat release rate were conducted to characterize a 1 m diameter, well-ventilated methanol pool fire steadily burning in a quiescent environment. The measured heat release rate determined by oxygen consumption calorimetry was 256 kW ± 45 kW, which was consistent with the heat release rate calculated from the fuel mass burning rate measurements. The gas-phase thermocouple temperature measurements were corrected considering radiative loss and thermal inertia effects. Instantaneous temperatures as large as 1800 K were measured in the fire. The maximum value of the time-averaged gas temperature was measured as about 1371 K, which occurred about 0.3 m above the burner. As expected, the corrected profile of mean axial temperature was shown to be similar to previous results for methanol pool fires when scaled by $\dot{Q}^{2/5}$. The heat flux was measured in the radial and vertical directions, and the radiative fraction was estimated as 0.22 ± 16 %, which corresponded to previous methanol pool fire results in 1 m and 0.3 m diameter pools. The present results help provide an understanding of the structure and character of the 1 m diameter methanol pool fire and provide data useful for the evaluation of fire models.

AccuPIPE: Accurate Heavy Flow Detection in the Data Plane Using Programmable Switches

Yang Guo, *NIST*

An Wang, *Case Western Reserve University*
Hang Liu, *The Catholic University of America*

***Abstract*—Identifying heavy flows, i.e., flows with large packet counts during a pre-defined time window, is vital for many network applications. The task of real-time heavy flow detection in data plane is challenging due to high switching speed (100 Gbps), a large number of concurrent flows (millions of concurrent flows), and small memory footprint requirement. In this paper, we dissect the key factors that affect the existing detection scheme's accuracy, and propose AccuPipe, a new detection scheme with intelligent flow entry replacement strategies. The simulation results show that the new scheme is able to efficiently utilize all flow entries in the detection pipeline, and detects more than 850 heavy flows (out of top 1,000) using a small amount of memory (1,000 flow entries, roughly equivalently to 18KB memory) with reasonable reporting overhead. This represents a 76% improvement over HashPIPE scheme, which detects on average 484 heavy flows (out of top 1,000) in the same setting. In addition, we investigate the performance of different flow entry replacement strategies, and report their pros and cons.**

I. Introduction

In the Internet, a small set of heavy flows, flows with extremely large number of packets or bytes, often accounts for a disproportionate share of the total traffic. Real-time detection of such heavy flows at small time scales is useful for many applications, e.g., DDoS detection, dynamic traffic routing [14], dynamice flow scheduling [15], etc. Real-time heavy flow detection in the data plane, however, is challenging due to stringent speed, accuracy, and memory requirement.

Heavy flow detection is well studied in streaming algorithms literature [6], where packets are processed as they pass through the measurement point. Packet sampling [5], [8], sketching [7], [9], [17], and counter-based algorithms [11] are representative techniques that tackle the trade-off between measurement accuracy, speed, and momory usage. For instance, sample and hold [8] imporves the sampling accuracy by keeping counters for flows that have been sampled. Count-min sketch [7] hashes on packet headers and increments counters in hash tables. The minimum counter is used to approximate the flow packet counts. FlowRadar [9] improves upon count-min sketch by allowing keys (flow IDs) to be decoded from the hash. More recently, UnivMon [10] and Elastic Sketch [18] develop sketch based techniques where one sketch satisfies multiple tasks' requirements.

HashPipe [16] is the first to investigate the real-time heavy flow detection problem in a switch's data-plane. HashPipe takes advantage of emerging programmable switch's programmability [1]–[3] and designs a measurement pipeline that implements modified space saving [12] algorithm to capture heavy flows. Elastic sketch [18] is another in-data-plane flow measurement scheme that utilizes more memories than HashPipe but provides the flow rate estimations for all flows.

In this paper we strive to improve upon HashPipe to achieve better heavy flow detection accuracy with small memory footprint. We analyze two key factors that affect HashPipe's measurement accuracy, namely *flow entry wastage* in the measurement pipeline and *packet arrival pattern*. Our analysis and simulation results show that the flow entry wastage contributes less than 8% to the accuracy loss, while the packet arrival pattern plays a major role in the measurement inaccuracy due to dramatic time-varying packet arrival pattern at fine time scale.

We propose AccuPipe that integrates frequency-based caching replacement strategies into heavy flow measurement pipeline. Instead of using the accumulated packet count as the indicator of potential heavy flows as in HashPipe, *AccuPipe utilizes flow entries inside the measurement pipeline to opportunistically capture short-term packet bursts and reports them to the measurement server.* At the end of each measurement cycle, the measurement server aggregates the reported packet counts to identify the top heavy flows. Our results show that the proposed scheme improves the identification accuracy from 48% to more than 85% with reasonable reporting overhead.

The rest of the paper is organized as follows. Section II introduces HashPipe and analyzes key factors that affect HashPipe's measurement accuracy. Section III describes AccuPipe and flow entry replacement strategies. Section IV presents the performance evaluation results. Section V concludes the paper.

II. HashPipe and Its Accuracy Analysis

HashPipe uses the measurement pipeline that implements modified space saving [12] algorithm to capture heavy flows. The measurement pipeline is defined using the programming language, e.g., P4 [2] [1] and runs in a programmable switch's data-plane [1]. The pipeline consists of multiple stages, with each stage working as a hash table. The entries in the hash

[1] Certain commercial equipment, instruments, or materials are identified in this paper in order to specify the experimental procedure adequately. Such identification is not intended to imply recommendation or endorsement by the National Institute of Standards and Technology, nor is it intended to imply that the materials or equipment identified are necessarily the best available for the purpose.

Guo, Yang; Liu, Franklin; Wang, An; Liu, Hang. "AccuPIPE: Accurate Heavy Flow Detection in the Data Plane Using Programmable Switches." Paper presented at IEEE/IFIP Network Operations and Management, Budapest, HU. April 20, 2020 - April 24, 2020.

table are called *flow entries*. In HashPipe, a flow entry contains two fields, key field and val field. The key field holds the flow id, e.g., five tuple {`srcIP, dstIP, srcPORT, dstPORT, Protocol`} as defined by the measurement. The val field holds the accumulated packet count of the corresponding flow. Programmable switches use *packet metadata* to communicate the results of packet processing between different stages. The metadata traverses the pipeline together with the packet. In HashPipe, the packet metadata also contains two fields, $cKey$ (*carried Key*) and $cVal$ (*carried value*). The first stage hashes on the key of incoming packet ($iKey$), while the rest of stages hash on $cKey$.

The first stage in HashPipe always allows the incoming packet to be inserted into the hash table. Let $h_i(\cdot)$ be the hash function at stage i. The incoming packet is hashed to flow entry l, $l = h_1(iKey)$. If the entry l is empty and not used, we set $key_l = iKey$ and $val_l = 1$. The packet finishes the measurement and exits the pipeline. If key_l matches $iKey$, the value of val_l is increased by one and the packet also exits the pipeline. If $iKey$ does not match key_l, $(cKey, cVal) \quad (key_l, val_l)$ and $(key_l, val_l) \quad (iKey, 1)$. The packet carries the metadata and goes to the next stage.

The rest of the stages keep heavy flows in the pipeline and push out small flows. Upon the arrival of a packet, the stage i hashes on $cKey$ and gets flow entry l, where $l = h_i(cKey)$. If the flow entry l is empty or $key_l = cKey$, the entry is updated as in the first stage and the packet exits the pipeline. If, however, the key_l does not match $cKey$, $cVal$ is compared with val_l. Whichever key with larger value will be kept in the hash table, and the smaller one is saved in the metadata and moved to the next stage. In the end the flow with the smallest *val* is washed out of HashPipe. The detailed algorithm is included in the Section 3.4 in [16].

A. Accuracy analysis of HashPipe

Flow entry wastage, traffic arrival pattern, and duplicates negatively affect HashPipe's accuracy. Consider a N flow-entry, K stage HashPipe pipeline. We define *heavy flows* to be the flows ranked in the top N based on their packet counts during a pre-defined time window. The rest of flows are called *light flows*. Ideally HashPipe should be able to capture all heavy flows, with one flow entry for one heavy flow. However, since flows are hashed randomly to flow entries, some flow entries may not "see" any heavy flows, and are thus wasted. We denote such behavior as *flow entry wastage*. Also, flow entries can be occupied by light flows instead of heavy flows. A light flow can overtake competing heavy flows with favorable *traffic arrival pattern*, as shown later in this section. Finally, a heavy flow may be hosted at multiple flow entries at different stages. Such *duplicates* also negatively affect HashPipe's accuracy. The simulation study in [16] shows that duplicates account for from 5% to 15% towards inaccuracy. In this section we focus on the effects of *flow entry wastage* and *traffic arrival pattern*.

- **Effect of flow entry wastage.** Below we derive a model that estimates S, the average number of wasted flow entries.

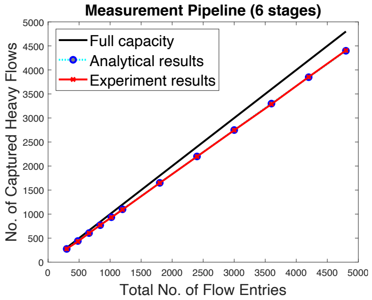

Fig. 1: HashPipe hash collision error analysis.

In the derivation, we ignores the *duplicates* effect and *traffic arrival pattern* effect. We also assume that the first HashPipe stage behaves the same as the later stages. These assumptions favor HashPipe and the analysis offers a lower bound of S.

Given N flow entries and K stages, the average number of flow entries per stage is N/K. Denote by s_i the average number of wasted entries at stage i, and by n_i the average number of incoming heavy flows that are looking to be hosted at stage i. We have $n_1 = N$, and

$$n_i = n_{i-1} - N/K + s_{i-1} \tag{1}$$

for $i = 2, ..., K$. Stage $(i-1)$ has N/K entries with s_{i-1} being wasted. Hence the average number of heavy flows captured at stage $(i-1)$ is $N/K - s_{i-1}$. The number of incoming heavy flows at stage i is thus $n_{i-1} - N/K + s_{i-1}$.

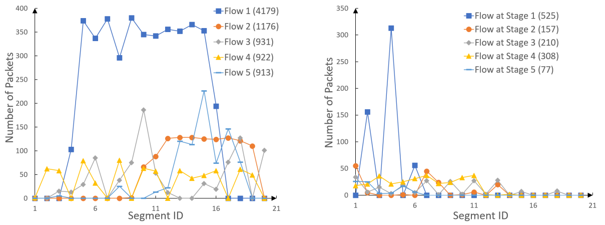
We next derive the formula for s_i. Consider a heavy flow that is randomly hashed to a flow entry at stage i. The probability that a flow entry is not chosen by this heavy flow is $1 - \frac{1}{N/K}$. The probability that a flow entry is not chosen by any n_i heavy flows is $(1 - K/N)^{n_i}$. Hence the average number of wasted entries at stage i is:

$$s_i = (N/K) \cdot (1 - K/N)^{n_i} \tag{2}$$

for $i = 1, 2, ..., K$. Starting with $n_1 = N$, $(\{s_i\}, \{n_i\})$ can be computed iteratively using Eqn.(1) and (2).

Denote by C the average number of captured heavy flows by HashPipe, i.e., $C = N - \sum_{i=1}^{K} s_i$. Figure 1 depicts the average number of captured heavy flows with varying number of total flow entries, The number of stages is set to be six, shown to be optimal in [16]. Varying the number of stages does not change our conclusions. We also conduct the simulations to verify the analytic model. We use a two-second CAIDA trace [4] with one million packets and over 100k flows to drive the simulation. Five-tuple {`srcIP, dstIP, srcPORT, dstPORT, Protocol`} is used as the flow id through out the paper. The simulation results are consistent with the analysis. The HashPipe's measurement pipeline wastes no more than 8% of the flow entries. Using the same trace with 1,000 flow entries, HashPipe only captures about 484 heavy flows, or 48% of top 1,000 heavy-flows. This raises the question if *traffic arrival pattern* plays a more important role than *flow entry wastage* and *duplicates*.

- **Effect of traffic arrival pattern.** We next examine the impact of traffic arrival pattern to the HashPipe accuracy.



(a) Top five heavy flows missed by HashPipe

(b) Flows occupy the flow entry at different stages in HashPipe

Fig. 2: Effect of traffic arrival pattern to the HashPipe accuracy.

To observe the traffic arrival pattern, the two-second trace is divided into 20 segments (0.1 second per segment). Fig. 2a plots the number of packet arrvials per segment for the top five heavy flows missed by HashPipe. The flows are ranked from one to five in the decreasing order of their packet counts, which is included in the parenthesis. Furthermore, Fig. 2b depicts the flows that occupy the flow entries that Flow 1 is hashed to at five pipeline statges (we ignore HashPipe's first stage since it is used for staging the measurement). Flow 1, with the packet count of 4,179, is a much heavier flow than any of the five flows hosted in HashPipe. Flow 1, however, does not arrive until 4th segment, when the other flows already have established a healthy packet count in the pipeline. Flow 1 fails to accumulate a big packet count in the initial stage of HashPipe and loses the competition with smaller flows. We also examine other heavy flows that are not captured by the HashPipe. The results show that the majority of the missed heavy flows are caused by the traffic arrival pattern instead of flow entry wastage and duplicates. It has long been observed that the network traffic is very bursty due to underlying protocol such as TCP, and packet burst varies dramatically at small time scale. A large packet count is not a robust indicator that a flow is heavy. The design of HashPipe favors flows with early burst packet arrival, not necessarily heavy flows.

III. Design of AccuPipe

In this section, we introduce *AccuPipe (Accurate HashPipe)* to accurately captures heavy flows. Unlike HashPipe where packet count is used to predict the heavy flows, AccuPipe uses the measurement pipeline as a cache to opportunistically captures ongoing heavy flows. When an ongoing flow is deemed not heavy anymore, its packet count is evicted from the measurement pipeline and reported to the server. The emptied flow entry continues to capture next heavy flow burst. At the end of a measurement window, the server aggregates collected packet counts and obtains top heavy flows.

In Caching technology, contents are stored in temporary storage, so-called cache, to reduce the service delay or the workload on servers [13]. To maximize the caching hit ratio, various cache replacement strategies have been developed, e.g., recency-based strategies (e.g. LRU), frequency-based strategies (e.g. LFU), function-based strategies, randomized strategies, etc. AccuPipe use the measurement pipeline as a cache to capture the heavy flow packet burst. A set of flows being hashed to the same flow entry compete for its occupancy; replacement strategies are designed to store heavy flows with frequent packet arrivals. Hence frequency-based caching strategies are most suitable for our design. Below we describe several replacement strategies used in AccuPipe.

•**Aging based strategy**: An *age* field is added to flow entries. Upon the arrival of a packet, if $iKey$ matches flow entry key, the packet count is increased by one and the *age* field is reset to be zero, regardless of the current value. The packet then exits the pipeline. If the packet $iKey$ does not match flow entry's key, the *age* field is increased by one. The *age* is then compared to a pre-set threshold α. If the *age* is less than α, the packet continues to traverse the pipeline. On the other hand, if the *age* is greater than $alpha$, the current flow in the flow entry is deemed to be infrequent and evicted. Its packet count is reported to the server. The newly arrived packet is cached into the flow entry and exits the pipeline.

•**Frequency based strategy**: Frequency based strategy was first proposed in [18]. In frequency based strategy, a new field called *total_packet_count* is added to each flow entry. The *total_packet_count* is initialized to be zero, and increased by one whenever a packet is hashed to this flow entry. The ratio of *total_packet_count / packet_count* is computed and compared to the preset threshold λ. The rest of the process is the same as in the Aging based strategy.

•**Segment based strategy**: In segment based strategy, AccuPipe works the same as HashPipe. The measurement time window is divided into equal size small measurement sub-windows, or segment. At the end of each segment, the measurement results in the pipeline are reported to the server. The pipeline is re-initialized and continues the measurement for the next segment.

•**Hybrid strategy**: Hybrid strategy is a combined scheme of aging based strategy and frequency based scheme. If the packet count is less than or equal to the pre-set threshold β, frequency based strategy is applied. If the packet count surpasses β, the aging based strategy is applied. As shown in Section IV, hybrid strategy offers best performance.

IV. Evaluations

In this section, we evaluate AccuPipe with different caching strategies. The measurement pipeline consists of six stages and 1,000 flow entries. The pcap trace is from [4] and is pre-processed to extract ten 5-second traces based on packet time-stamp information. Each 5-second trace contains more than 2.5 million packets and over 200K flows. The results presented here are the average over ten traces. Two metrics are examined: *accuracy*, the number of heavy flows that are correctly identified, and *reporting overhead*, the amount of reports that are sent to the server. Note that heavy flows are the flows being ranked in the top 1,000.

• **Performance comparison of Aging, Frequency, and Segmented AccuPipe.** The aging threshold, frequency threshold, and number of segments are varied in evaluating the

Guo, Yang; Liu, Franklin; Wang, An; Liu, Hang. "AccuPIPE: Accurate Heavy Flow Detection in the Data Plane Using Programmable Switches." Paper presented at IEEE/IFIP Network Operations and Management, Budapest, HU. April 20, 2020 - April 24, 2020.

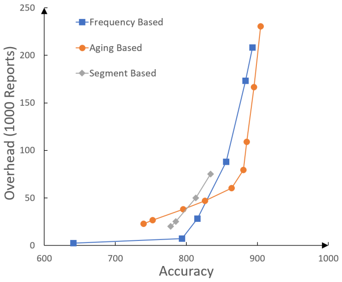


Fig. 3: Performance comparison of Aging, Frequency, and Segmented AccuPipe. Each dot represents the average results over ten traces for one experiment setting. The aging thresholds (α) from the right to the left are 8, 16, 32, 48, 64, 80, 96, 128, and 144. The frequency thresholds (λ) from the right to the left are 2, 4, 8, 16, 32, and 64. In Segmented AccuPipe experiments, the number of segments are 20, 25, 50, and 75, respectively from the left to the right.

accuracy and the reporting overhead of Aging AccuPipe, Frequency AccuPipe, and Segmented AccuPipe. Fig. 3 depicts the reporting overhead vs. accuracy with different thresholds and number of segments, where accuracy represents the number of heavy flows that are correctly identified. As expected, smaller aging and frequency thresholds offer higher accuracy than larger ones as AccuPipe captures smaller traffic bursts and report more frequently. Aging scheme can capture more than 850 heavy flows accurately as long as the aging threshold is smaller than 64, while Frequency scheme can do so if the frequency threshold is no greater than eight. The reporting overhead for Aging and Frequency AccuPipe are 60.1k and 87.9k reports, respectively, which favors aging scheme.

However, as the threshold decreases, frequency based scheme starts to outperform aging scheme. At the frequency threshold of 32, the *accuracy percentage*, the percentage of heavy flows that are correctly identified, reaches 79.3% with only 7.1k reports in Frequency AccuPipe; the similar accuracy percentage (79.5% with the aging threshold of 96) requires 60.1k reports in Aging AccuPipe. In general, aging based scheme performs well in high accuracy percentage ($> 85\%$) region while frequency scheme performs better in medium accuracy region, as shown in Fig. 3.

In Segmented AccuPipe, the packet counts in the pipeline are reported to the switch controller at the end of each segment, and the measurement is restarted for the next segment. We assume that each flow entry requires one report. In general, using more segments in Segmented AccuPipe leads to higher accuracy since the measurement is able to keep track of traffic pattern at the finer time scale. In terms of reporting overhead, Segmented AccuPipe incurs more overheand than Frequency AccuPipe to achieve the same accuracy. Compared to Aging AccuPipe, Segmented AccuPipe incurs more overhead when the accuracy is greater than 800 heavy flows. It, however, starts to outperforms Aging AccuPipe as the accuracy decreases to be smaller than 800 heavy flows. Note that the packet counts in Segmented AccuPipe are periodically reported. Hence these reports form a batch and can potentially be compressed. Compression can drastically reduce the reporting overhead and make Segmented scheme desirable.

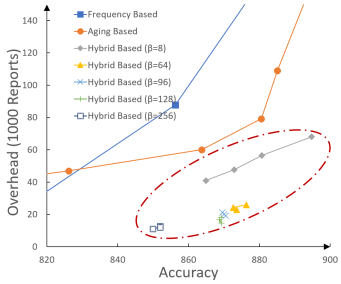

Fig. 4: Performance of Hybrid AccuPipe. The value of α is set at 32 for all cases. The value of β is shown in the figure. The value of λ are set at 32, 64, 96, and 128 from the right to the left. We retain the results of Aging and Frequency AccuPipe for the purpose of comparison.

- **Performance of Hybrid AccuPipe.** Compared to Frequency AccuPipe, Aging AccuPipe is more accurate and requires less reporting overhead in high accuracy region (accuracy percentage $> 85\%$). Frequency AccuPipe, however, is able to bring down the reporting overhead without significantly sacrificing the accuracy in lower accuracy region. Hybrid AccuPipe strives to combines Aging scheme's accuracy with Frequency scheme's reporting efficiency. In the Frequency AccuPipe with the threshold of λ, a flow with the burst arrival of n packets at the beginning can occupy the flow entry for the period of $\lambda \cdot n$ packet arrivals hashed to the same flow entry. A large value of λ could casues the overstay of unheavy flows. In contrast, Aging AccuPipe always examines the most recent α packets. If no packet belonging to the flow entry key arrives during the most recent α packet arrivals, the packet count in the flow entry will be evicted.

To avoid the overstay of a unheavy flows in Frequency AccuPipe, a new threshold β is introduced in Hybrid AccuPipe. Hybrid AccuPipe has three parameters, α, β, and λ. When a flow entry's packet count is less than β, AccuPipe employs Frequency scheme. Otherwise AccuPipe employs Aging scheme. Fig. 4 depicts the accuracy vs. overhead of Hybrid AccuPipe with different values of β. Hybrid AccuPipe consistently outperforms Aging and Frequency AccuPipe. For instance, when $\beta = 64$, Hybrid AccuPipe achieves 87.3% accuracy percentage with 22.9k reports.

V. Conclusions

In this paper, we study the accuracy issue of the real-time heavy flow detection using programmable switch. We investigate two factors that contribute to the measurement inaccuracy, and identify traffic arrival pattern is the main contributor to the inaccuracy in the existing scheme. We propose AccuPipe that employs caching techniques to capture short-term traffic bursts. The simulation results show that the AccuPipe improves the heavy flow detection rate by over 70% over the existing scheme.

Options for Low-GWP Refrigerants in Small Air-Conditioning Systems[†]

Mark O. McLinden, Andrei F. Kazakov, J. Steven Brown, Riccardo Brignoli, Ian H. Bell, Piotr A. Domanski

Abstract

We summarize a systematic examination of possible low-GWP (global warming potential) replacements for the HFC (hydrofluorocarbon) refrigerants currently used in small air-conditioning systems. The methodology identified the optimal thermodynamic parameters for a refrigerant; this was based on an ideal-cycle analysis, which indicated a tradeoff between efficiency (COP) and refrigeration capacity depending largely on the refrigerant critical temperature. A more realistic analysis, which included an optimization of the heat exchangers, however, revealed that there was a maximum in COP at a relatively high refrigeration capacity, corresponding to refrigerants with a relatively low critical temperature and operating at moderately high pressures. A search in an exhaustive chemical database for fluids having the identified thermodynamic parameters as well as acceptable chemical stability, toxicity, and GWP identified a list of 29 candidate refrigerants. But none of these are a direct, nonflammable, low-GWP replacement for the R-410A currently used in the majority of small air-conditioning systems.

Introduction

The Kigali Amendment to the Montreal Protocol, which phases down the production and consumption of hydrofluorocarbon (HFC) refrigerants, entered into force January 1, 2019. But even before this milestone was reached numerous regional and national regulations concerning the use of HFCs were already in place. For example, the "F-gas" regulations in the European Union[1] mandate maximum values of GWP (global warming potential) for refrigerants in various applications, as well as specifying training and reporting requirements. In the United States, the Significant New Alternatives Program (SNAP) of the U.S. Environmental Protection Agency[2] prohibits or allows specific refrigerants in various applications. The need to identify alternative fluids is obvious.

This paper starts with a brief perspective on the environmental impacts of the HFCs and other refrigerants. The main discussion considers options for low-GWP fluids. First, the methodology of our search for replacement fluids is summarized, and the resulting candidate fluids are presented. Some of the limitations and tradeoffs inherent with replacement fluids are discussed. Finally, brief conclusions are presented. Much of the present paper is drawn directly from our previous works[3,4,5,6,7,8,9,10,11], and the reader is referred to those references for complete details.

Background—Environmental Properties of Refrigerants

Emissions of HFCs currently account for only a small fraction of anthropogenic climate change—about 1 % of the total radiative forcing due to all greenhouse gases, including CO_2, CH_4, and N_2O, according to the 2018 Scientific Assessment of Ozone Depletion.[12] The Kigali Amendment and other regulations are driven by estimated large increases in future emissions predicted under "business as usual" scenarios as laid out by Velders *et al.*[13,14] With the HFC phasedown of the Kigali Amendment, Velders[15] estimates that the surface temperature increase from HFCs will be limited to 0.06 K by the end of the century compared to (0.3 to 0.5) K with "business as usual."

The environmental characteristics of selected refrigerants, as compiled by the WMO,[12] are listed in Table 1. The GWP parameter was first presented by the Intergovernmental Panel on Climate Change[16] in 1990 as a simple

metric for comparing the impact of different gases on the climate system. The GWP of a gas is relative to that of carbon dioxide; furthermore, it is calculated over some time interval, or "time horizon." A time horizon of 100 years is most commonly used (including in regulations) and is referred to as GWP_{100}. Other time horizons are sometimes used, and Table 1 also lists the GWP_{20}—the value for a 20-year time horizon. For long-lived gases, such as R-12, the GWP_{100} and GWP_{20} are similar. For gases with lifetimes on the order of a few decades or less (*e.g.*, the HFCs), however, the GWP_{20} is substantially higher than the GWP_{100} because the climate impact of such gases is concentrated in the initial years following their release into the atmosphere. When calculating over a longer time horizon, the impact in the later years is small, and the GWP_{100} basically "averages out" the impacts. This indicates that the short-term climate impact of the HFCs can be understated by their GWP_{100}. But this also underlies an opportunity for a positive impact on the climate by mid-century by phasing down the HFCs: CO_2 is long-lived in the atmosphere, and so the benefits of any reduction in its emissions are damped by its existing concentration in the atmosphere. A phase-down of HFC emissions, on the other hand, has much more immediate benefits.

Table 1. Environmental characteristics of selected refrigerants.[†]

R-number	Formula	T_{NBP} (˚C)	Lifetime (years)	ODP	GWP_{20}	GWP_{100}
CFCs and HCFCs						
R-12	CCl_2F_2	–29.8	102	0.73–0.81	10800	10300
R-22	$CHClF_2$	–40.8	11.9	0.024–0.034	5310	1780
R-123	$CHCl_2CF_3$	27.8	1.3	0.01	290	80
HFCs						
R-32	CH_2F_2	–51.7	5.4	0	2530	705
R-125	CHF_2CF_3	–48.1	30	0	6280	3450
R-134a	CH_2FCF_3	–26.1	14	0	3810	1360
R-152a	CH_3CHF_2	–24.0	1.6	0	545	148
HFOs and HCFOs						
R-1233zd(E)	$CF_3CH{=}CHCl$	18.3	0.071	<0.0004	13.5	3.7
R-1234yf	$CF_3CF{=}CH_2$	–29.5	0.029	0	1	<1
R-1234ze(E)	$CF_3CH{=}CFH$	–19.0	0.045	0	4	<1
Natural fluids						
R-290	$CH_3CH_2CH_3$ (propane)	–42.1	0.041	0	<1	<1
R-717	NH_3 (ammonia)	–33.3	"few days"	0	<1	<1
R-744	CO_2 (carbon dioxide)	–56.6[‡]	–	0	1.00	1.00

[†] Environmental data from WMO[12]; T_{NBP} from REFPROP[17]; table from ref[10].
[‡] Triple-point temperature

While the many of the HFCs do have high values of GWP it must be kept in mind that they were developed and implemented to replace substances with high ozone-depletion potential (ODP), the so-called ozone-depleting substances or ODSs, primarily the CFCs and HCFCs. Many of the CFCs and HCFCs also have high values of GWP (see Table 1); for example, the GWP_{100} of the most common refrigerant in automotive systems was reduced by a factor of 7.5 (10300 to 1360) when R-12 was replaced with R-134a. Thus, the Montreal Protocol, which was originally targeted at stratospheric ozone protection, has already had a tremendously positive effect on climate, as reported by Velders *et al.*[18] In that analysis, Velders *et al.* consider a scenario in which the 1987 Montreal Protocol (and subsequent amendments) was not implemented. Without any action, the radiative forcing (*i.e.*, impact on climate) of the ODSs would have been comparable to CO_2 emissions by 2010. Instead, the actual yearly GWP-weighted emissions of the ODSs peaked in 1988 at an equivalent equal to 43 % of that of CO_2. By

2010, the Montreal Protocol had avoided emissions of approximately 10 Gt CO_2[eq] (*i.e.*, emissions with a warming impact equivalent to 10 gigatonnes of CO_2) per year; by comparison, global CO_2 emissions from fossil fuels and industrial processes were 32 Gt per year in 2010.[19] Put another way, the Montreal Protocol has delayed climate change by 7–12 years, according to Velders *et al.*[18]

Thus, by rapidly phasing out the CFCs and other ODSs in the 1990s, the refrigeration industry has already avoided significant climate impacts, and with the HFC phasedown called out in the Kigali Amendment to the Montreal Protocol the industry will make further substantial contributions.

The Search for Replacement Fluids

The present paper summarizes the results of a comprehensive search for the best single-component, low-GWP replacement fluids for use in small air-conditioning systems, as presented by McLinden *et al*.[9] We searched for suitable replacement fluids by applying thermodynamic and environmental screening criteria to a comprehensive chemical database. The fluids passing these screens were then simulated in an air-conditioning system, with the calculated volumetric refrigeration capacity and COP (*i.e.*, energy efficiency) serving as additional screens.

A refrigerant is the essential working fluid in a vapor-compression refrigeration cycle; it absorbs heat at a relatively low temperature in the evaporator (*e.g.*, the cooling coil in an air conditioner) and releases it at a higher temperature in the condenser (*e.g.*, the outside coil). To identify replacement refrigerants one must first consider the characteristics required of any refrigerant and then also consider the optimal properties for the particular application of interest.

General requirements of a refrigerant. The requirements of a replacement refrigerant have been considered by numerous authors including McLinden and Didion,[20] Calm and Didion,[21] and Kujak and Schultz.[22] Always at the top of the list is the need for chemical stability within the sealed refrigeration system; next are health and safety considerations. Existing safety codes (*e.g.*, ASHRAE Standard 15[23]) require nonflammable refrigerants for many applications, but that requirement is being reconsidered. Environmental considerations (*e.g.*, ODP and GWP) are obviously important—they are the reason new fluids are currently under consideration. Practical requirements such as cost and materials compatibility also factor in.

A refrigerant must also possess certain thermodynamic characteristics for it to function. Since a refrigerant absorbs and releases heat primarily through evaporation and condensation, a high latent heat of vaporization might seem to be desirable. A boiling-point temperature low enough that air will not leak into a system is desirable; but the boiling point should not be so low that the system pressures are "too high." A high discharge temperature upon compression will lower the efficiency of the cycle, but conversely, "wet compression" must be avoided in most types of compressors.

The "Exploration of Thermodynamic Space." But how are these seemingly disparate thermodynamic characteristics related, and how is one to identify a refrigerant satisfying them? McLinden *et al.*[4] and Domanski *et al.*[5] approached this problem by defining fluids in terms of a small number of fundamental thermodynamic characteristics and then searching for optimal values of those parameters. Thus, they considered the full range of possible thermodynamic behaviour, rather than scanning a finite number of known fluids (which would reveal no new fluids). They termed this approach the "exploration of thermodynamic space."

The fluid thermodynamic properties were modeled by the "extended corresponding states" (ECS) approach laid out by Huber and Ely.[24] Corresponding states is the observation that the properties of fluids are similar when scaled by their critical point parameters, T_{crit} and p_{crit}, where the critical point is the state where the saturated liquid and saturated vapor approach one another. Key to this method is a "reference fluid" to which the properties of the unknown fluid are scaled. This method is "extended" by additional parameters; the most significant were the heat capacity of the vapor ($C_p{}^0$) and the acentric factor, ω, which is related to the slope of the vapor pressure curve. The range of the parameters considered is given in Table 2. The critical temperature is not as familiar as the normal boiling point temperature, T_{NBP}, but the two are related, and here both are used here. (Other parameters were considered, but they were found to be of minor importance.[5])

Table 2. Fluid parameters varied in the optimization runs and their ranges.

Parameter	Range
reference fluid	propane –or– R-32
T_{crit}/K	305 – 650
p_{crit}/MPa	2.0 – 12.0
ω	0.0 – 0.6
$C_p{}^0$(300 K)/J·mol^{-1}·K^{-1}	20.8 – 300

Optimum Thermodynamic Characteristics. Any optimization requires objective function(s), and here the coefficient of performance (COP) and volumetric capacity (Q_{vol}) were selected for a cycle operating between an evaporation temperature of 10 ˚C and a condensation temperature of 40 ˚C. The hypothetical fluids were simulated in three cycles (shown in Figure 1): (a) the simple (basic) four-component vapor-compression cycle, (b) a cycle with a liquid-line/suction-line heat exchanger (LL/SL HX), and (c) a two-stage economizer cycle. All three cycles were modelled assuming isentropic compression, no pressure drop in the heat exchangers, and saturated liquid and vapor exiting the condenser and evaporator, respectively. Sets of thermodynamic parameters within the ranges defined in Table 2 defined a series of hypothetical fluids. By varying these parameters according to an evolutionary algorithm, optimal values were determined; see McLinden *et al*.[4] and Domanski *et al*.[5] for details.

This exploration of thermodynamic space indicated a trade-off between efficiency and volumetric capacity. Refrigerants with a high critical temperature gave high efficiency, but low capacity; fluids with a relatively low T_{crit} resulted in the converse. A critical pressure at the upper limit of the range resulted in both higher efficiency and increased capacity, while an acentric factor near the lower limit was optimal. The optimum value of the vapor heat capacity varied with the cycle; a relatively low value was best for the simple vapor-compression cycle, while a higher value was optimal for a cycle with internal heat exchange between the condenser outlet and compressor inlet. These results are presented in Figure 2; a clear efficiency-versus-capacity tradeoff is seen for all three cycles. Figure 2 also shows the "Pareto front" comprising the set of hypothetical fluids having thermodynamic parameters offering the highest COP for a given Q_{vol} and vice-versa; this defines the upper limit of performance that is allowed by thermodynamics. (The inverse of COP and Q_{vol} are plotted to yield a minimization, which is the convention for this type of problem.) For selected "real" refrigerants, the cycle with the LL/SL heat exchanger (Figure 2(b)) shows a much smoother variation of COP versus Q_{vol} compared to the simple cycle (Figure 2(a)); some refrigerants, notably ammonia and R-32, have a lower COP with the LL/SL HX. The economizer cycle (Figure 2(c)) shows a higher COP for both the Pareto front and the current refrigerants compared to the simple vapor-compression cycle. The relative benefit of the LL/SL heat exchanger cycle versus the economizer cycle compared to the simple cycle varied with the fluid.

Database Screenings. Having defined a desired set of thermodynamic parameters, we next set out to identify fluids having those characteristics. Our search relied on screening a comprehensive database of molecules by applying filters representing different refrigerant selection criteria. The search was carried out in the PubChem database—a listing with more than 60 million chemical structures.[25] A first screening of this database is described by Kazakov *et al*.[3]; we summarize here a second screening.[9] All current refrigerants are small molecules, and McLinden[26] provides a thermodynamic basis for this. Thus, we limited our search to molecules with 18 or fewer atoms and comprising only the elements C, H, F, Cl, Br, O, N, or S. The choice of elements follows the observation by Midgley[27] that only a small portion of the periodic table would form compounds

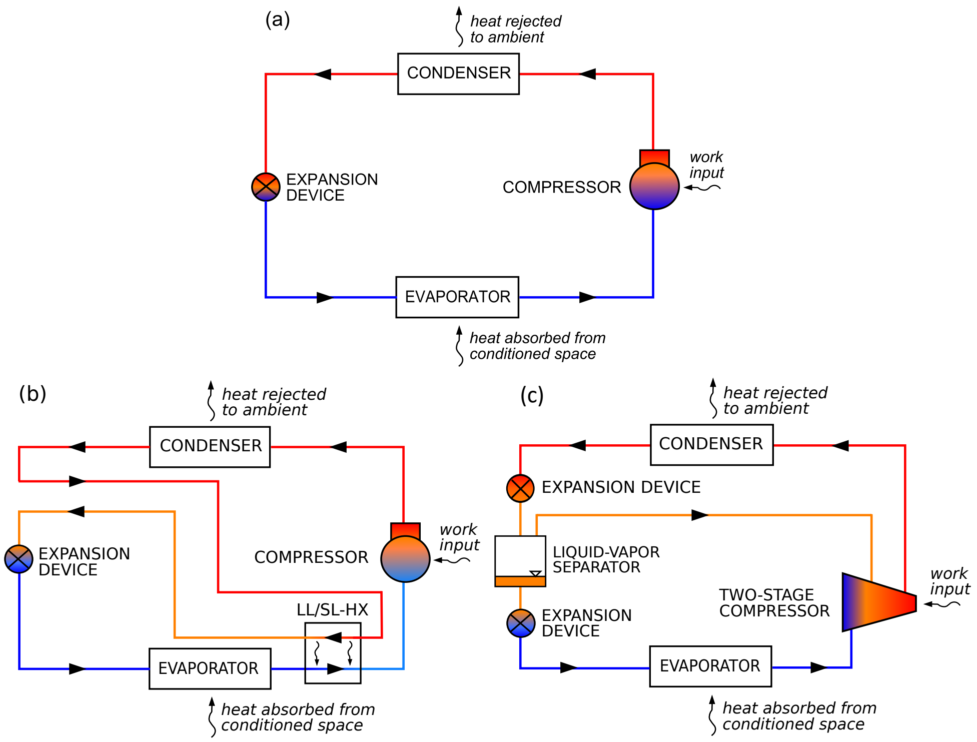

Figure 1. Cycles simulated: (a) simple vapor-compression cycle; (b) cycle with 100 % effective LL/SL heat exchanger; (c) economizer cycle; figure from ref [9].

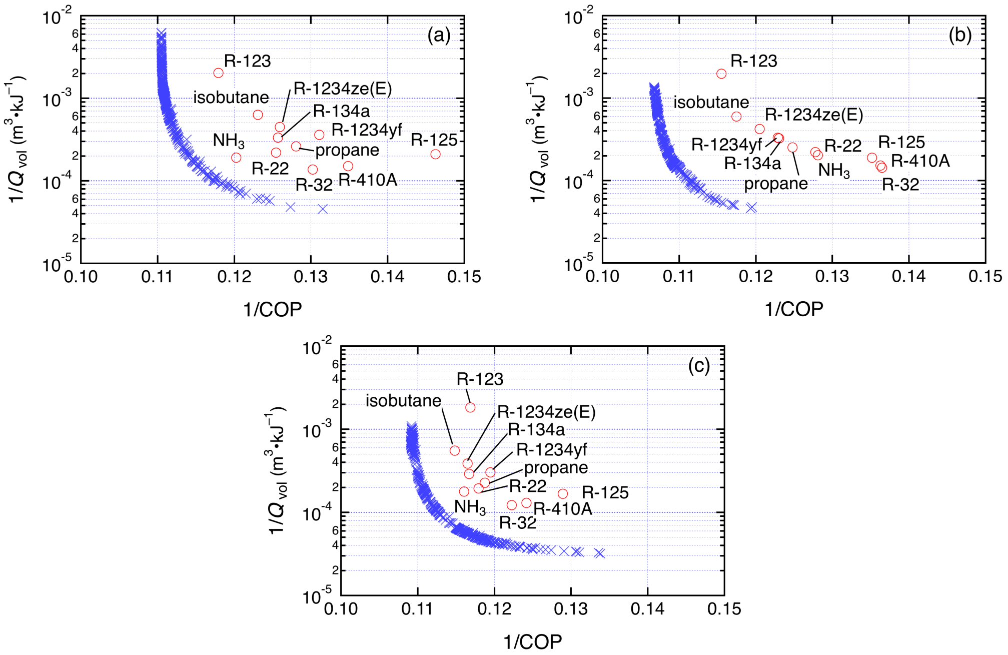

Figure 2. Pareto front (×) and selected current refrigerants (○) for different cycle options: (a) simple vapor-compression cycle; (b) cycle with 100 % effective LL/SL heat exchanger; (c) economizer cycle; figure from ref.[4].

volatile enough to serve as refrigerants. Despite their ability to deplete stratospheric ozone, chlorine and bromine were included since molecules including Cl or Br might have a negligible ODP and might be acceptable if they had a very short atmospheric lifetime. These restrictions on elements and molecular size resulted in 184 000 molecules to be considered further.

Further screens for 320 K < T_{crit} < 420 K and GWP_{100} < 1000 yielded 138 fluids. The PubChem database does not provide T_{crit} and GWP_{100} values for the vast majority of the compounds, so they were estimated using methods based solely on molecular structure; these estimations constituted a major effort of the project.[28,3,4,29] The limits on critical temperature correspond to fluids usable in small AC systems, with an allowance for the uncertainty in the estimated values of T_{crit}. While refrigerants with values of GWP as low as possible are obviously desirable, fluids with GWP_{100} < 750 are, for example, permitted under E.U. regulations in AC systems with less than 3 kg of refrigerant.[30] (The full list of 138 fluids is given in the Supplementary Information of McLinden *et al*.[9], which also lists the estimated T_{crit} and GWP_{100} for each fluid.)

The next screens were for chemical stability and toxicity. Compounds with generally unstable functional groups were dropped from further consideration. For example, peroxides (compounds with the –O–O– group) are unstable. Ketenes (compounds with the –C=C=O group) are generally very reactive, and three such compounds were dropped. Allenes have the –C=C=C– group and are characterized as "difficult to prepare and very reactive."[31] Compounds with a carbon-carbon triple bond are generally less stable than those with a double bond; for example, fluoroethyne (FC≡CH) is described as "treacherously explosive in the liquid state."[32] There are exceptions, however, and trifluoropropyne was retained.

Attempts to automate the screening of toxicity were not successful. Fortunately, at this point, the number of compounds was sufficiently small to allow a "manual" examination of toxicity data. We considered published toxicity data, where available, making use of a variety of sources, including safety standards, compilations of toxic industrial chemicals, regulatory filings, and safety data sheets of chemical manufacturers. We also dropped compounds with two specific groups. Molecules that included the $=CF_2$ group were deemed "not viable candidates" on the basis of Lindley and Noakes[33] who discuss the "$=CF_2$ structural alert" in regards to R-1225zc ($CF_3CH=CF_2$); this is the observation that the $=CF_2$ group has a high reactivity which is often associated with toxic effects. The presence of a $=CF_2$ group does not assure that a molecule is toxic, but we are aware of only one possible counterexample of R-1123 ($CHF=CF_2$), which has an acute toxicity similar to that of the commercialized refrigerant R-1234ze(E).[34] (The chronic toxicity of R-1123 has not been reported in the public literature.) The absence of a $=CF_2$ group does not, however, imply that a molecule is of low toxicity. Fluids having the –OF group were also dropped. The –OF group is analogous to the –OH group that defines an alcohol. The bond dissociation energy of the O–F bond, however, is less than one-half that of the O–H bond in an alcohol,[35] and the fluorine would likely be reactive with water, forming HF (hydrofluoric acid—a highly toxic compound).

Performance in the Ideal Vapor-Compression Cycle. The 138 candidates identified in the database screening were simulated in the simple (ideal) vapor-compression cycle. For the representation of refrigerant properties we used detailed equations of state (EOS) implemented in the NIST REFPROP database[36] where available. However, for a majority of fluids we used the extended corresponding states (ECS) model,[4,24] as discussed above. This screening proceeded in two rounds. The first round of cycle simulations made use of the theoretical CYCLE_D model[37] and provided a first estimate of volumetric capacity and COP.[7] These simulations assumed an ideal cycle with 100 % compressor efficiency and no pressure drops. At this stage, we dropped fluids with a volumetric capacity less than one-third that of R-410A or a COP < 5. (For R-410A in the ideal cycle Q_{vol} = 6.62 $\mathrm{MJ{\cdot}m^{-3}}$ and COP = 7.41.)

Candidate Fluids

The database search combined with the performance simulation in the ideal cycle resulted in a list of 27 fluids with the assertion that it would be "highly unlikely that any better-performing fluids will be found."[9] The list already included several fluids that failed the stated screening criteria, but were added because of commercial interest. These included R-1123, which was identified as unstable by Tanaka *et al.*[38], but a blend with R-32 may be stable.[39] Have any additional fluids been identified in the intervening time? Domanski *et al.*[8] added R-1132a to the list. This fluid was among the 138 fluids passing the original screening but was rejected based on an indication of high toxicity[40]; later data resulted in a "class A" toxicity rating.[41]

The iodine-containing CF_3I has generated considerable interest recently as a low-GWP option that might be used to suppress the flammability of blends (see, for example, McGowan[42]). CF_3I was recently classified as "A1" (low-toxicity, nonflammable) under ASHRAE Standard 34 and designated as R-13I1.[43] This fluid was considered early on by Kazakov *et al.*[3] The C–I bond is very weak and is readily photolyzed by UV light; thus, it did not fit within the estimation scheme for GWP developed by Kazakov. CF_3I and other iodine-containing compounds were investigated in the 1990s during the search for CFC replacements (see Calm[44] and Nimitz and Lankford[45]) and again in the early 2000s in the program sponsored by the Society of Automotive Engineers to identify replacements for R-134a in automotive air-conditioning systems.[46] Interest waned in the iodine-containing compounds on both occasions because of stability and toxicity concerns. Thus, iodine was not included in the list of eight elements making up the fluids in the database searches of Kazakov *et al* [3] and McLinden *et al.*, [6,9] but we include it here.

The final list of 29 candidates is given in Table 3. This list is a subset of the 138 candidates having 320 K < T_{crit} < 420 K and GWP_{100} < 1000, with the deletion of those that have low Q_{vol}, low COP, or are unstable or toxic. The list comprises four hydrocarbons and the closely related dimethylether; five fluorinated alkanes (*i.e.*, HFCs); ten fluorinated alkenes and an alkyne; two fluorinated oxygen-containing molecules; three fluorinated nitrogen or sulfur compounds; CF_3I; and two inorganic molecules (ammonia or NH_3 and carbon dioxide). The list includes a small number of novel molecules that have not been previously considered as refrigerants (at least publicly), but a majority of the fluids are well known, including ammonia (R-717) and propane (R-290), or are the focus of current research in the refrigeration industry, *i.e.*, the fluorinated alkenes (also known as hydrofluoroolefins or HFOs).

Refrigerant blends are currently in common use, and the fluids in Table 3 also constitute the components of future blends. Several of the fluids have low critical temperatures and would operate in a transcritical cycle for our investigated conditions; thus, they were not simulated. These fluids might, however, be useful as a component in a refrigerant blend, and they were included in Table 3 for this reason. The table also includes an additional four current HFCs and HCFCs for comparison purposes. Despite their high values of GWP_{100} R-134a and R-125 might also find use as blend components. Some of the reasons behind this paucity of candidates are discussed below.

Simulations in an Optimized Cycle. The second round of simulations made use of a more advanced "optimized" cycle model that provided a more realistic representation of an air conditioner employing typical forced-convection, air-to-refrigerant heat exchangers, which were optimized for a particular refrigerant.[47] In this type of heat exchanger, the refrigerant undergoes a phase change as it flows down the inside of a tube and exchanges heat with air on the outside of the tube. Specifically, the model accounted for the effect of optimized refrigerant mass flux, which enhances the refrigerant heat transfer coefficient at an acceptable penalty of the pressure drop. These simulations included the effects of the transport properties (thermal conductivity and viscosity) on the heat transfer coefficient and pressure drop, which were not included in the ideal cycle simulations. The simulation model maintained the same heat flux in the evaporator through all simulations, which is a prerequisite for a fair rating of competing refrigerants.[48] The isentropic efficiency of the compressor was a function of the refrigerant properties and averaged 70 %.[49] Here, the relative ranking of fluids differs from a ranking based only on thermodynamic properties; it is, however, more representative of a fluid's performance in an AC system in commercial production, which would be optimized for the refrigerant being used.

The COP and Q_{vol} of the candidate fluids, based on the optimized model, are presented in Table 3 and Figure 3. Unlike the COP versus Q_{vol} tradeoff observed for the ideal analysis (Figure 2), the results of the optimized cycle simulations in the simple cycle (Figure 3) show a maximum in COP corresponding to Q_{vol} of approximately 60 %

Table 3. COP and volumetric capacity of selected low-GWP fluids and current HFC and HCFC fluids. Results are presented for the basic, liquid-line/suction-line heat exchanger (LL/SL), and economizer (Econ.) cycles. Values are for the "optimized" cycle model and are relative to the performance of R-410A in the basic cycle. GWP_{100} are from WMO[12] or E.U. regulation[30] unless noted. The fluids are grouped by chemical class and, within classes, listed in order of increasing critical temperature; table adapted from ref [9].

*Values are relative to those for R-410A in the basic cycle; $COP_{R\text{-}410A} = 5.35$ and $Q_{vol,R\text{-}410A} = 6.93\ MJ{\cdot}m^{-3}$.
†Value estimated by the method of Kazakov *et al.*[3]
‡This fluid has cis (Z) and trans (E) isomers; the predicted values of both were the same.
§Fluid would be near-critical or supercritical in the condenser and was not simulated.

to 110 % that of R-410A. Although there is considerable scatter, a polynomial curve fitted to the fluids shown in Figure 3 indicates the general trend. Relative to fluids with low values of Q_{vol}, the high-Q_{vol} fluids have lower values of T_{crit} and operate at higher pressures; the result is that the cycle operates near the critical point and suffers increased irreversibilities in the expansion process. This effect applies to both the ideal and more-detailed analyses. However, the ideal analysis neglects the fact that the pressure drop in the heat exchangers (condenser and evaporator) extracts a smaller COP penalty on the high-Q_{vol} (*i.e.*, high-pressure) fluids when the heat exchangers are optimized. An additional effect is that the low-Q_{vol} fluids tend to be more complex molecules. For example, R-32 (one of the best fluids in Figure 3) is based on a single carbon atom, and R-410A is a blend of the single-carbon R-32 and two-carbon R-125. In contrast most of the fluids with $Q_{vol} < 0.4 \cdot Q_{vol,R\text{-}410A}$ are three-carbon compounds; greater molecular complexity is associated with higher values of viscosity, which would increase the pressure drop and lower the COP.

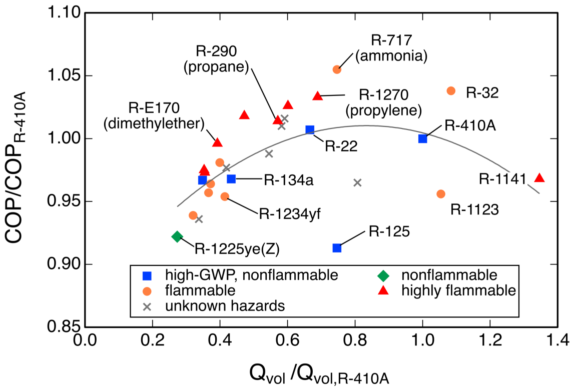

Figure 3. COP and Q_{vol} of selected low-GWP fluids relative to R-410A in the basic vapor-compression cycle including pressure drop and heat-transfer limitations; the curve indicates the general trend; figure adapted from ref [9].

The COP ranged from –7.8 % to +5.5 % relative to that of R-410A in the basic vapor-compression cycle. Ammonia showed the highest COP, better than that for R-410A by 5.5 %. Beyond ammonia, which is toxic, mildly flammable, and presents materials compatibility issues, the COPs of R-32, propene (R-1270), R-161, R-1132(E), propane (R-290), cyclopropane (R-C270) and difluoromethanethiol are also above the R-410A baseline. The COPs of the remaining fluids are lower. Mildly flammable R-32 has a COP and Q_{vol} higher than that of R-410A, but this advantage comes with a GWP_{100} of 705. R-134 and R-E143a have GWP_{100} values of 1135 and 540, respectively. Three fluids have GWPs within the 80 to 150 range, and GWPs for the remaining fluids do not exceed 20. Except for R-32, R-1123, and R-1141 the listed fluids have Q_{vol} lower than R-410A and would thus require a larger compressor—by at least 25 % and, for a majority of the candidates, more than twice as large—to provide the same capacity as R-410A. Table 3 does not provide COP and Q_{vol} for carbon dioxide, ethane, R-41, and R-1132a because their T_{crit} are low and they may require a different (*i.e.*, transcritical) cycle, depending on operating conditions. We list them because they may be suitable as a component of a blend. In general, fluids with a low T_{crit} (corresponding to high Q_{vol}) suffer performance degradation at high ambient temperatures.

The results for the LL/SL-HX and economizer cycles are qualitatively similar to the basic cycle and are listed in Table 3. The LL/SL-HX cycle provides a performance benefit to fluids with a high vapor heat capacity and degrades the performance of fluids with a low vapor heat capacity (which are best performers in the basic cycle). Consequently, the spread of COP values is smaller than that shown in Figure 3. The economizer cycle increases the COP for all refrigerants, although the increase is larger for the fluids having a high vapor heat capacity.

Refrigerant Blends. Given the lack of an obvious low-GWP, nonflammable, pure-fluid candidate with a volumetric capacity similar to R-410A there is considerable interest in refrigerant blends; see, for example, Schultz[50] and Spletzer *et al.*[51] Mixing high-GWP, but non-flammable fluid(s) with low-GWP, but flammable fluid(s) can yield a mildly flammable refrigerant with a GWP_{100} on the order of 500 or, with a different composition, a non-flammable fluid with a higher GWP_{100}.

Bell, *et al.*[11] considered the problem of finding a nonflammable replacement for R-134a in an air-conditioning application. They considered blends composed from a slate of 13 candidate fluids with a range of pressure, flammability, and GWP values that might produce a blend with the desired characteristics of a R-134a replacement. The blend components included hydrofluoroolefins (HFOs), which have very low GWP values (≈ 1 relative to CO_2), but that are mildly flammable; hydrofluorocarbons (HFCs) with moderate-to-high GWP values that were nonflammable and thus, might serve to suppress the flammability of a blend; additional mildly flammable HFCs; and carbon dioxide (CO_2), which is nonflammable with GWP ≡ 1, but which would raise the working pressure of a blend and may produce a large two-phase temperature glide in the heat exchangers. All the selected fluids were of low toxicity, *i.e.*, having an "A" classification under ASHRAE Standard 34.[52] Additional considerations were the commercial availability of the fluid and the availability of property data (in the form of an accurate equation of state), so that cycle simulations could be carried out with some measure of confidence. The blend components were the HFCs: R-134a, R-227ea, R-125, R-143a, R-32, R-152a, R-134, and R-41; the HFOs: R-1234yf, R-1234ze(E), R-1234ze(Z), and R-1243zf; and R-744 (CO_2). Hydrocarbons were not included because the objective was to find a nonflammable blend, and a blend containing only a few percent of a hydrocarbon would be flammable.

A simplified cycle model was used, but it did include the effects of compressor efficiency, pressure drop in the condenser and evaporator, subcooling at the condenser outlet, and superheat at the evaporator outlet. The basic cycle conditions were an evaporator dew-point temperature of 10 ˚C and condenser bubble-point temperature of 40˚C. In contrast to the exploration of thermodynamic space, which employed an optimization based on an evolutionary algorithm, Bell *et al.*[11] simulated all possible combinations of the 13 components, for a total of 100 387 binary and ternary mixtures to be evaluated. All possible four-component mixtures were also considered, for an additional 1.4 million evaluations (although none of the four-component blends were superior to the binary or ternary blends). The flammability of the blends was estimated with a new scheme developed by Linteris *et al*.[53] which yields a "normalized flammability index" $\overline{\Pi}$, which varies from $\overline{\Pi} = 100$ for highly-flammable hydrocarbons (*i.e.*, containing no fluorine); $\overline{\Pi} = 0$ at the limit of flammability (*i.e.*, the boundary of the ASHRAE "1" (nonflammable) and "2L" (mildly flammable) classes); and $\overline{\Pi} < 0$ for nonflammable fluids. Note that $\overline{\Pi}$ is based on the ASTM E-681 test method[54] specified in the ASHRAE standard,[52] and its estimates of flammability versus nonflammability may differ for other test methods.

Figure 4 provides an overview of the results for the binary and ternary blends. Here the COP is plotted versus GWP_{100} and sorted into four "bins" of estimated flammability; each dot represents one blend composition. Starting at the right-most bin, which includes blends which are predicted to be clearly nonflammable, all of the blends have substantially lower COP compared to the R-134a baseline, indicated with the red dashed line. (Note that only blends with GWP_{100} less than or equal to R-134a are plotted.) The next bin to the left shows the blends that are predicted to be nonflammble, but near the flammability limit (*i.e.*, $-10 < \overline{\Pi} < 0$). Here, only blends with $GWP_{100} > 535$ have COPs within a few percent of R-134a, and the upper bound of the COPs increases with GWP_{100}, approaching the COP of R-134a at high values of GWP_{100}. The second bin from the left contains blends that are estimated to be slightly flammable (*i.e.*, $0 < \overline{\Pi} < 10$). (For comparison, $\overline{\Pi} = 4.8$ for R-1234yf and $\overline{\Pi} = -10.5$ for R-134a.) This bin "fills in" the upper-left quadrant of the bin to the right, that is, blends with $GWP_{100} < 535$ and COP approaching that of R-134a. Only the left-most bin, comprising blends that are somewhat more flammable, but still estimated to be in the "2L" flammability classification, contains fluids which have both low values of GWP_{100} and COPs equal to, or greater than, the R-134a baseline.

The yellow boxes in the middle two bins indicate the relatively small number of blends that would be of interest in the search for a nonflammable R-134a replacement, *i.e.*, those with COPs similar to that of R-134a and that are nonflammable or only mildly flammable. The blends identified in this study are applicable only for its specific objectives, but it hints at the difficulty of finding a suitable blend.

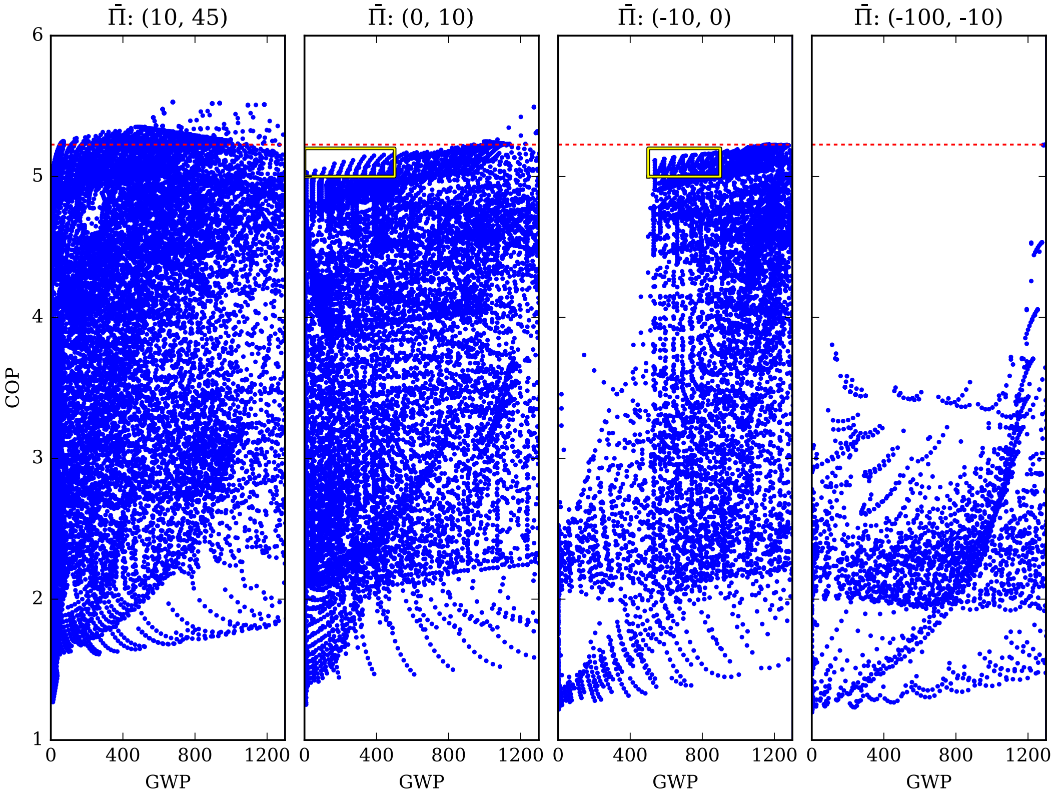

Figure 4. Overview of cycle simulation results sorted into bins of estimated flammability. The flammability decreases moving from left to right; the two right-most bins are predicted to be non-flammable. The red dashed line indicates the COP of the R-134a baseline system, and the yellow boxes indicate the blends of greatest interest. Figure from Bell *et al*.[11]

Limitations and Tradeoffs

When Midgley famously introduced R-12 at the 1930 meeting of the American Chemical Society by inhaling a lungful of the refrigerant and using it to extinguish a burning candle,[55,56] it seemed that the perfect refrigerant had been found. It was nonflammable, of low toxicity, and was simple and cheap to manufacture. It had good thermodynamic properties, and, in fact, its properties were nearly a perfect match to the simple vapor-compression cycle.[26] But, of course, it was later found to deplete stratospheric ozone and have a high GWP. Even today, R-12 remains the fourth-most powerful greenhouse gas, behind CO_2, methane, and N_2O because of past emissions.[12] Since the mid-1970s the task of identifying suitable refrigerants has faced an increasing list of constraints. And, while these constraints have restricted the choice of fluids (*e.g.*, CFCs and HCFCs are no longer available), they have also opened up interest in other fluids. The phaseout of the ozone-depleting fluids, for example, sparked a resurgence of interest in the long-known natural fluids (*e.g.*, ammonia, hydrocarbons). Likewise, the lack of an obvious low-GWP, nonflammable, high-pressure replacement for some of the HFCs has opened a discussion on how fluids with at least some degree of flammability might be safely implemented in a wider variety of systems.

Constraints on molecular structure. As environmental regulations became ever more restrictive, the constraints on the molecules suitable for use as refrigerants correspondingly increased. When the CFCs were first introduced in the 1930s, the constraints were to find a molecule that was nonflammable, of low toxicity, cheap to manufacture and with suitable thermodynamic characteristics. The halogenated alkanes can be represented on

McLinden, Mark O.; Kazakov, Andrei F.; Brown, J; Brignoli, Riccardo; Bell, Ian; Domanski, Piotr A. "Options for Low-GWP Refrigerants." Paper presented at Institute of Refrigeration, London, UK. November 06, 2019 - November 06, 2019.

a triangular grid, with a separate grid for molecules based on one, two, etc. carbons. The base hydrocarbon (methane, ethane, etc.) is at the top of the triangle, and the bottom corners represent molecules with the hydrogens fully substituted with either chlorine or fluorine. With no environmental constraints, CFCs and HCFCs based on methane (one carbon), namely R-12 and R-22, were available to meet a variety of applications, as shown in Figure 5(a). There was no need to search further. With the discovery that the CFCs and HCFCs depleted stratospheric ozone, the entire lower-left (chlorine-containing) portion of the triangle was eliminated (Figure 5(b)). For the one-carbon molecules, this left only R-32 (difluoromethane) with a boiling point suitable for typical refrigeration and air-conditioning applications; but R-32 is flammable. The industry turned to the two-carbon HFCs, and settled primarily on R-134a and R-125, plus blends (Figure 5(c)).

R-125 (T_{NBP} = –48 ˚C, GWP = 3450)

Figure 5. Depiction of constraints on CFCs, HCFCs, and HFCs on triangular composition diagrams; (a) one-carbon compounds with no constraints: R-12 and R-22 are widely used; (b) one-carbon compounds with ODP constraint: only R-32 remains; (c) two-carbon compounds with ODP constraint: several HFCs are candidates for A/C systems.

With the additional constraint, imposed by the Kigali Amendment, of reducing the GWP of refrigerants it seems unlikely that even the GWP_{100} = 1360 of R-134a will be an acceptable long-term refrigerant, except perhaps in niche applications. This would leave only R-32 and R-152a remaining among the HFCs. The "A2" rating for R-152a represents a greater degree of flammability than many in the industry are comfortable with. R-32 is less flammable (rating of "A2L"), but it has a moderately high GWP_{100}, which may limit its long-term viability as a candidate. Once again, the search was on. But, even as the HFCs were being commercialized in the 1990s and before GWP was an explicit concern, the search for alternative fluids continued, and a wide variety of chemical classes were considered (see, for example, Bivens and Minor[57]). Concerns over global warming, and, specifically the E.U. F-gas regulations[1], reignited the search, and ultimately, the hydrofluoroolefins (HFOs) were deemed to have the best combination of characteristics.

The presence of a carbon-carbon double bond defines the chemical class of "olefin," and it is the reactivity of the double bond to the atmospheric hydroxyl radical that results in the very low atmospheric lifetimes and GWP values of the HFOs. The reactivity of the olefins, both in the atmosphere and in refrigeration equipment, is discussed by Kujak and Sorenson.[58] The most-common HFC refrigerants (R-134a, R-125, R-32, etc.) are based on one or two carbon atoms. The two-carbon HFOs, on the other hand, have normal boiling point temperatures that are too low for most refrigeration applications, as shown in Figure 6(a). Thus, most of the development efforts are focused on the three-carbon HFOs, and here there are a number of fluids with –40 ˚C < T_{NBP} < –20 ˚C; see Figure 6(b). But a three-carbon HFO is a more complicated molecule than a one- or two-carbon HFC, and this results in a higher vapor molar heat capacity and a vapor dome that is "skewed" to the right, as discussed by McLinden.[10]

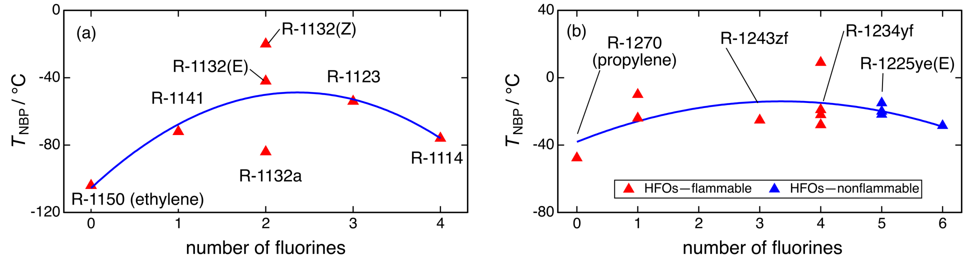

Figure 6. Variation of normal boiling point temperature T_{NBP} with the number of fluorines on the molecule; (a) two-carbon HFOs; (b) three-carbon HFOs. The curves indicate the general trends in T_{NBP}. Flammability is indicated with a color code.

Flammability versus GWP. The best-known HFO is R-1234yf, and this fluid is "marginally flammable" with an ASHRAE Standard 34 flammability classification of "2L". There is often the perception that some degree of flammability is inevitable with the HFOs. Figure 6 indicates flammability and shows that this is not true, but that, compared to the HFCs, additional fluorines are needed with the HFOs to offset the reactivity of the carbon-carbon double bond. For example, the four fluorines of R-134a are sufficient to yield a nonflammable fluid, while the four fluorines on R-1234yf are not; the three-carbon HFOs require five fluorines for nonflammability (*e.g.*, R-1225ye(E)). For the two-carbon HFOs, even the fully fluorinated R-1114 is flammable.

Among the HFCs, on the other hand, a tradeoff between flammability and GWP is somewhat inevitable. The C–F bond in the HFCs absorbs infrared radiation, and this is the root of the radiative forcing (*i.e.*, high GWP) seen with the HFCs. As the number of fluorines on the molecule increases the infrared absorption increases, but also the number of hydrogens must decrease, and it is the reaction of hydrogen with atmospheric hydroxyl that degrades HFCs in the atmosphere. This combined effect results in GWP_{100} values increasing from <1 for R-170 (ethane)[59] to 11 100 for R-116.[12] The HFOs also have C–F bonds and also absorb infrared radiation, but their much, much shorter atmospheric lifetimes result in very low GWP values. Thus, the HFOs can sidestep the flammability versus GWP tradeoff—except that the flammability versus fluorine-number relationship discussed above means that there are a smaller percentage of possible HFOs that are nonflammable.

How Reliable Was the Screening? Did We Miss Promising Fluids? The reliability and completeness of the screening could have been compromised by a number of factors. First, we considered that the PubChem database was a complete listing of the small molecules that we were interested in. While there is no guarantee that this is the case, we note that of the 31 possible three-carbon HFO isomers, 30 were listed in PubChem; it is unlikely that the missing molecule would possess significantly different properties.

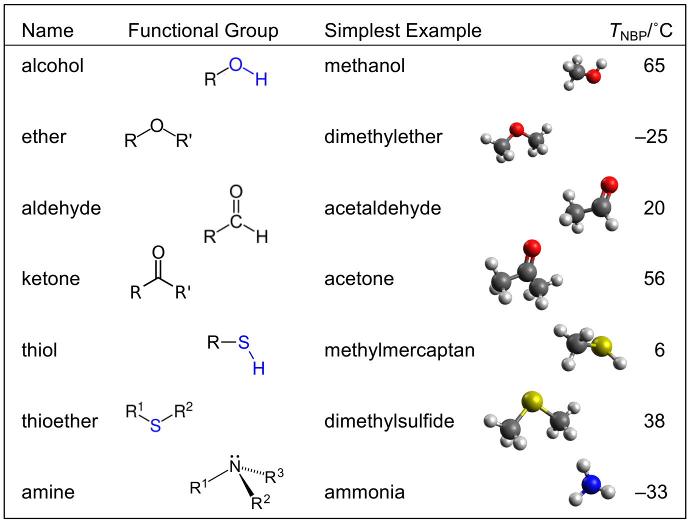
Did the restricted list of eight elements and maximum molecular size of 18 atoms exclude viable candidates? To explore this, we also carried out a search in the DIPPR database[60] of 2000 industrial chemicals based solely on 300 K ≤ T_{crit} ≤ 400 K (see McLinden *et al.*[7] for details). That search revealed 33 fluids not listed in Table 3, but these included the high-GWP CFCs and HCFCs (the DIPPR database does not tabulate GWP values) and highly toxic fluids, such as HCl, HBr, and H_2S. Eight fluids included elements not in our restricted set, but these included included radon (a radioactive gas); arsine (AsH_3), which is highly toxic and pyrophoric (ignites spontaneously on contact with air); phosphine (PF_5), which is toxic; and two silanes—SiH_3Cl and CH_3SiH_3, which are both flammable, with SiH_3Cl also being toxic. None of the molecules identified in the DIPPR search had more than 18 atoms. In other words, none of these fluids brought into question our decision to limit our search to the eight elements (C, H, F, Cl, Br, O, N, and S), although, as noted above, there is renewed interest in CF_3I. In the end, the DIPPR database did not expand the list of candidate fluids obtained from our screenings of the PubChem database.

We searched on specific ranges for the properties, and given that most of the properties were estimated from molecular structure, what was the effect of uncertainties in those estimates? The estimated uncertainty in the critical temperature was 16.5 K, but the range of T_{crit} in the screening was expanded to accommodate this uncertainty. The uncertainty in the estimate of GWP_{100} was a factor of three, and while this might seem large, it was unlikely to exclude any viable candidates—even if a candidate with an estimated GWP_{100} = 10, say, was actually 3 or 30, it would still be considered "very low GWP."

Finally, there is the possibility of incorrect data in the literature. We noted above that R-1132a was originally excluded from the original list of 27 fluids[9] based on an indication of toxicity from a reliable source.[40] Based on newer data, it was later added to the list. There is no way to avoid this situation except to periodically check for updated data.

Other fluids? But why are there so few other fluids? In chemistry, molecules are categorized by the functional group(s) they possess. The HFCs belong to the fluorinated alkane category. The alkanes comprise one or more carbon atoms with hydrogens attached to each carbon as needed to satisfy the requirement that each carbon atom be bonded to four neighbors. In the fluorinated alkanes, some of the hydrogens are simply replaced by fluorine. The alkenes (also known as olefins) are a variation on the alkanes with one or more of the carbon-carbon bonds replaced with a double bond, with each double bond "counting" as two neighbors.

Many other functional groups are well known, and some of these are shown in Figure 7. These are, for the most part, not suitable as refrigerants in moderate-to-high pressure systems because the normal boiling points for even the simplest examples are too high. The simplest alcohol, for example, is methanol with T_{NBP} = 65 ˚C. Acetone is the simplest ketone with T_{NBP} = 56 ˚C. Substitution of hydrogen with other atoms generally increases the boiling point. Functional groups with T_{NBP} low enough to serve as the basis for moderate-to-high-pressure refrigerants include the ethers (C-O-C) and the amines (comprising a central nitrogen with three attached groups). All such compounds were included in the database searches, but apart from dimethyl ether, ammonia, and a very few others, they were rejected because of high GWP_{100}, high T_{crit}, or other factors.



Name	Functional Group	Simplest Example	T_{NBP}/˚C
alcohol		methanol	65
ether		dimethylether	–25
aldehyde		acetaldehyde	20
ketone		acetone	56
thiol		methylmercaptan	6
thioether		dimethylsulfide	38
amine		ammonia	–33

Figure 7. Selected functional groups containing oxygen, sulfur, or nitrogen, with the simplest example of each also shown; R, R', R^1, R^2, R^3 indicate attached hydrogens or alkyl groups.

Conclusions

In this paper we have summarized the results of a thorough and systematic examination of possible low-GWP replacements for the HFC refrigerants currently used in small air-conditioning systems. The significant elements of this effort were (1) an optimization of fundamental thermodynamic parameters for a refrigerant; this approach was not restricted to known fluids, but encompassed all possible fluids allowed by thermodynamics (an approach we dubbed the "exploration of thermodynamic space"); (2) a search in an exhaustive chemical database for fluids having the identified thermodynamic parameters as well as acceptable chemical stability, toxicity, and GWP; and (3) simulation of the candidate fluids and a final screening based on the COP and capacity in the vapor-compression cycle. The identified list of 29 candidate refrigerants includes well-known fluids as well as fluids being actively investigated by industry; several novel fluids were also identified. But none of these are a direct, nonflammable, low-GWP replacement for the R-410A currently used in the majority of small air-conditioning systems.

The present study was focused on the medium-to-high-pressure refrigerants used in most small systems. Different equipment types may yield a different list of candidates. In particular, chillers with centrifugal compressors (which typically employ low-pressure refrigerants) were not considered, nor were high-temperature heat pumps or very-low-temperature systems. Application of the present methodology to such systems would be worthwhile.

Calm[61] introduced the concept of "refrigerant generations," and he characterizes the current, fourth generation of refrigerants as driven by "attention to global warming." Later, Calm[44] posited that, in view of limited options, a fifth generation, which would "re-examine previously discarded candidates", may be forthcoming as the full range of tradeoffs are considered. But the results of McLinden *et al.*[9] indicate (as summarized here) that there are no fundamentally new classes of chemicals available for use in vapor-compression refrigeration systems. While the "re-examination" discussed by Calm[44] may well occur, the situation may be to return (recycle?) to earlier generations, such as the ammonia, CO_2, and hydrocarbons of the first generation of "whatever works." Let us hope that we are not forced back to a "generation zero" of harvesting ice from frozen lakes.

Acknowledgements

Much of the work described in this paper was carried out in a project supported by the U.S. Department of Energy, Office of Energy Efficiency and Renewable Energy under contract no. DE-EE002057. The work on the refrigerant blends was supported by the U.S. Department of Defense, Strategic Environmental Research and Development Program (SERDP), project WP-2740.

Dr. Mark O. McLinden was the 2018 winner of the IOR J&E Hall Gold Medal for innovation. He joined what was then the National Bureau of Standards in 1984, and his current research in the NIST Applied Chemicals and Materials Division focuses on highly accurate measurements of fluid properties over wide ranges of temperature and pressure and the design and fabrication of instruments for such measurements. Throughout his career, Dr. McLinden has researched "new" refrigerants; in the 1990s replacements for the ozone-depleting CFC and HCFC refrigerants were the focus, and more recently, his attention has turned to fluids having low global warming potential (GWP). He is the author or coauthor of more than 100 peer-reviewed publications. Dr. McLinden holds a B.S. from the University of Missouri and M.S. and Ph.D. degrees from the University of Wisconsin, all in chemical engineering.

Automatic Recognition of Advanced Persistent Threat Tactics for Enterprise Security

Anonymous Author(s)

ABSTRACT

Advanced Persistent Threats (APT) has become the concern of many enterprise networks. APT can remain undetected for a long time span and lead to undesirable consequences such as stealing of sensitive data, broken workflow, and so on. To achieve the attack goal, attackers usually leverage specific tactics that utilize a variety of techniques. This paper explores the recognition of APT tactics through synthesized analysis and correlation of data from various sources. We propose a framework for detecting the APT tactics and discuss the application of machine learning techniques in this problem. Our framework can be used by the security analysts for effective detection of APT attacks. The evaluation of our approach shows that it can detect APT tactics with high accuracy and low false positive rate. Therefore, it can be used for tactic-centric APT detection and effective implementation of cyber security response operations.

KEYWORDS

Advanced Persistent Threat, Attack Tactics, Machine learning.

1 INTRODUCTION

Cyber attacks against organizations, including Advanced and Persistent Threats (APT), usually employ certain attack tactics. It is common that some attack tactics are used repeatedly in different APT attacks. Identifying these tactics may help understand attackers' potential intent, objectives and strategies, and even help with identification of specific attacker(s) or attack communities. However, the adversary groups often constantly update their tools and tactics to make detection and analysis more difficult. For instance, the DragonOK group, a well-known adversary group, has been evolving their tactics in targeted APT attacks across Asia Pacific and Japan. They began to use multiple new variants of malware "FormerFirstRAT" along with malware "IsSpace" and "Tidepool" in their 2017 tactics [1].

The emergence of new APT tactics has introduced daunting challenges to APT detection. The attackers can leverage a carefully designed combination of various *APT techniques* (e.g., spear phishing, drive by download, buffer overflow, pass the hash) to strategically achieve a goal. Hence, the detection of individual APT techniques is no longer adequate to identify the attacker's intents, objectives and strategies. That is, individual APT techniques cannot tell the "whole story" of the attacks. This inability has put real-world Cyber Security Operation Centers (CSOCs) into a highly undesired dilemma: (a) on one hand, without knowing the "whole story", CSOCs are more likely to take ineffective intrusion response actions; (b) on the other hand, correlating the detected individual APT techniques to generate the "whole story" requires significant amount of time and manual efforts.

A number of research works have explored the problem of detecting APT attacks from different angles. 1) Since APT may remain stealthy for a long time span, capturing all stages of its life cycle is not an easy task. Hence, some research works propose to detect a specific technique that is used in a stage of APT. For example, [11, 17] detect the network connections during the stage of malware command and control (C&C) communication. [17] applies supervised learning towards the web proxy logs to identify and prioritize the enterprise malicious activities, while [11] proposes unsupervised detection of C&C communications based on the web request graphs. [21] detects the APT malware infection by analyzing malicious DNS and network traffic. 2) Some other works aim to detect APT attack as a whole. For example, [7, 20] use classification models for APT detection; [9, 10, 19] reconstruct the attack by combining past security events. HOLMES [16] also leverages the correlation between suspicious information flows for APT detection. 3) Another angle of detecting APT attacks is through provenance tracking. A provenance tracking system captures the causality relationship between system objects such as processes and files. Security analysts can find the root cause of attacks by tracking system object dependencies generated by the provenance data. Because most existing provenance tracking techniques are at low system level and usually suffer from dependence explosion problem, some research works propose to partition execution to units [12, 14]. [13] further proposes to leverage the annotated application specific high level task structures to partition execution. 4) Mining logs is another technique that is commonly used for APT attack detection, although the purposes and approaches of mining may be different. [18] proposes an automated multi-stage intrusion analysis system that is based on mining various logs. The proposed system discovers the "attack communities" from the weighted graphs that are built from multiple logs. [8] proposes to use a deep neural network model, DeepLog, to detect anomaly log sequences. It models a system log as a natural language sequence, learns the log patterns from normal system execution, and reports anomaly when the log patterns deviate from the trained model.

Although extensive researches have been conducted towards detecting APT, few of them emphasize the detection of commonly used APT tactics. For approaches that focus on specific steps or techniques such as C&C communication, or that focus on log mining, the detected anomaly may or may not be relevant to APT. Other approaches, that focus on provenance tracking, event correlation or clustering, are not tactic-centric.

However, identifying tactics is essential to reveal attackers' potential objectives and strategies, and may even help to identify specific adversary groups. Therefore, this paper seeks to propose a framework that can detect APT tactics with high accuracy and general applicability. If successful, the framework is able to: (a) identify the APT techniques that are not easily detected with traditional approaches; (b) match the APT techniques to the tactics they belong to with the help of system object dependencies; (c) make the APT

(b) A 5-step data exfiltration APT tactic.

Figure 1: Two example APT tactics.

tactic and APT technique identifiers extensible and adaptive to new tactics and techniques.

The significance of this research is three-folds: 1) it is, to the best of our knowledge, the first framework which could simultaneously achieve accuracy and general applicability in detecting multiple APT tactics; 2) implementations of the framework could help CSOCs and analysts identify the attacker's intents, objectives and strategies, and provide a "whole story" of the attacks; 3) the automated APT tactic identifier could significantly reduce the manual efforts involved in detecting APT techniques.

The remaining of this paper is structured as follows. Section 2 will discuss the APT tactic with two examples, and also the differences from attack graph, which is a well-known graphical method in cyber security. Section 3 will discuss our proposed framework. Section 4 will briefly introduce our design and implementation. In Section 5, a simple five-step APT tactic is presented and used to demonstrate how our framework works. Section 6 presents our evaluation experiments results. Section 7 is the conclusion.

2 PRELIMINARY

The MITRE adversarial tactics and techniques knowledge repository [5] provides a comprehensive review of the real-world adversarial tactics and techniques. In this work, we adopt definitions for tactic and technique different from those in [5]. We define:

- *APT technique*: A specific implementation such as a hacking tool, attack script, and/or malware payload.
- *System object dependency*: The relationships among system objects, such as processes, files and user accounts.
- *APT tactic*: A sequence of APT techniques chained by system object dependencies.

Therefore, APT tactics represent attackers' strategies; and APT techniques represent the specific steps that attackers take to implement the strategies.

In this paper, we present an APT tactic as a connected graph showing the chain of techniques in a multi-step cyber attack. APT techniques are basic building blocks of an APT tactic. All the APT tactic presented in this paper are crafted based on our observation on different attack scenarios. Figure 1 presents two example APT tactics as directed graphs that consist of multiple APT techniques.

Each technique in a tactic has its post-conditions and pre-requisites. Post-conditions are the results of the technique, such as malicious processes being created, files being accessed and user account being modified. Pre-requisites describe the requirements for the technique to be matched into tactic.

In Figure 1(a) and Table 1, an APT tactic about data destruction is presented. This tactic starts from drive by download. In this technique, the download is requested by the user, but the downloaded item include functionalities that user does not expect. The user downloads the program and executes it, without knowing that the program has a trojan built in. The trojan allows a remote attacker to connect and execute malicious commands on the victim computer. With the remote access, the attacker can then escalate the privilege to the system level by process injection. Afterwards, the attacker can destruct all documents by deleting or encrypting them.

In Figure 1(b) and Table 2, an APT tactic about data exfiltration is presented. The first three techniques are launched against Windows Domain Controller (DC), whereas the last two are against another user machine in the domain. This tactic starts with supply chain compromise. For privilege escalation, the attacker bypasses the User Account Control (UAC). UAC prompts user for confirmation when a process requests for system-level privileges. By bypassing UAC, the attacker can escalate privileges without being noticed. After that, the attacker dumps users' credentials such as password hashes. These credentials can be used to launch pass the hash attacks to access other machines. In the end, the attacker downloads sensitive files from target machines.

APT tactics are fundamentally different from attack graphs. Some important differences include: (a) attack graphs represent the causality relationship between vulnerabilities and exploits, whereas APT tactics represent the strategies, techniques and procedures used by attackers; (b) attack graphs show all the possible attack routes from the attacker's machine to the target machine, whereas APT tactics focus on the attackers' chosen techniques and procedures, rather than the attack paths; (c) attack graphs are not being used by CSOCs on a daily basis, whereas APT tactics are frequently referred to by security analysts, though in an implicit and informal way according to our observation.

3 PROPOSED FRAMEWORK

To serve the validity of the proposed framework, we assume that:

- Each APT technique used in the APT tactic is identifiable through automated, semi-automated, or manual effort. In the worst case, the CSOC may have to resort to manual effort to identify a particular APT technique, we have no assumption on the maximum time used to identify an APT technique.
- The whole framework is kept safe from the attacker. All the input data is genuine, which means that the attackers cannot modify or delete them; and the attackers have no access to the framework itself in any way.

The framework presented above needs to address the following challenges:

- *Accurate identification of various adversary techniques.* Although we assume every APT technique is identifiable, some APT techniques, such as pass the hash, are hard to accurately identify with traditional methods like pattern matching and

Table 1: Detailed description of a 3-step APT tactic with system object dependency included.

Technique Name	**Post-condition**	**Pre-requisites**	**Description**	**Identification Method**
Drive by download	Process P_1 is created.	(None)	Initial intrusion by drive by download attack, resulting to a malicious process P_1 being created.	The downloaded item has some kind of backdoor built-in. Some backdoors are detectable using signature-based IDS.
Process injection	Process P_2 is created; Process P_3 is affected.	Process P_2 is a child process of or the same as P_1.	Privilege escalation by process injection. Process P_2 is the process which initiates the injection, and P_3 is the victim process. P_3 is usually a process running with system-level privilege.	Detectable by monitoring critical system processes.
Data destruction	Process P_4 is created; File F_1 is accessed.	Process P_4 is a child process of or the same as P_3.	Malicious process P_4 accesses file F_1 and makes it inaccessible to the user.	Detectable by monitoring disk I/O on sensitive files/directories.

Table 2: Detailed description of a 5-step APT tactic with system object dependency included.

Technique Name	**Post-condition**	**Pre-requisites**	**Description**	**Identification Method**
Supply chain compromise	Process P_1 is created.	(None)	Initial intrusion by supply chain compromise, resulting to a malicious process P_1 being created.	Some software distribution or update channels get infected and backdoor gets inserted to the products. Some backdoors are detectable using signature-based IDS.
Bypass User Account Control (UAC)	Process P_2 is created; Process P_3 is created.	Process P_2 is a child process of or the same as P_1.	The attacker bypass the Windows UAC to escalate its privilege to system level.	Many procedures of bypassing UAC needs to modify the Windows registry. Such procedures can be detected by monitoring the registry for specific key creation and modification.
Credential dumping	Process P_4 is created.	Process P_4 is a child process of or the same as P_3.	The attacker leverages escalated privilege to dump user credentials like password hashes.	In a Windows Domain, the DC stores the users' credentials as a database file, and very few processes are allowed to interact with this file. Dumping users' credentials can be detected by monitoring the disk I/O on this file and activities of those special processes.
Pass the hash	Process P_5 is created; User U_1 is impersonated.	(None)	The attacker leverages the password hashes to get into other machines in this domain.	Directly using hashes for authentication relies on certain authentication mechanism, which will leave traces in the network packets. Thus, it is detectable by monitoring the network traffic and inspecting the network packets.
Data exfiltration	Process P_6 is created; File F_1 is read.	Process P_6 is a child process of or the same as P_5.	The attacker, pretending to be user U_1, downloads file F_1 to his/her own machine.	Detectable by monitoring disk I/O on sensitive files/directories.

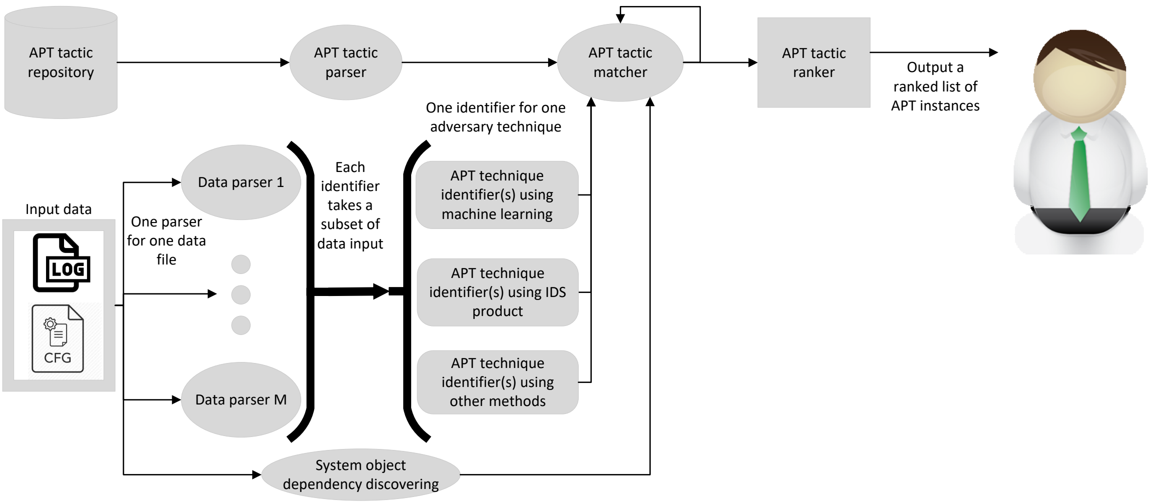
anomaly detection. Pattern matching suffers from low accuracy, and anomaly detection suffers from high false positive rate.

- *Correct match of the adversary techniques to the tactics they belong to.* Assuming that each technique can be accurately identified, the APT tactic matcher needs to match those techniques into tactics. For receiving inputs, the matcher needs to deal with the diversity of technique identifiers, such as different identification delay; for matching, the matcher needs to deal with multiple cases, namely (a) one attacker is using one tactic, (b) multiple attackers are using one same tactic, and (c) multiple attackers are using different tactics. The framework should address those problems.

For the first challenge, we propose to apply machine learning method for those APT techniques that cannot be accurately identified with traditional methods. Pass the hash is one of such techniques. It is difficult to identify with traditional methods because it leverages legitimate authentication mechanism. To apply machine learning method, a huge amount of data is needed to train an accurate neural network. Because we didn't find any open network log data sets for identifying pass the hash, we generate our own data set. Details are described in section 5. The evaluation of our trained neural network is presented in subsection 6.1.

For the second challenge, we design a framework as shown in Figure 2. It comprises three concurrent workflows, the data processing workflow, the tactic knowledge processing workflow, and system object dependency discovering workflow, to address the tactic matching problem.

The data processing workflow is as follows:



APT tactic repository
APT tactic parser
APT tactic matcher
APT tactic ranker
Output a ranked list of APT instances
One identifier for one adversary technique
Input data
LOG
CFG
One parser for one data file
Data parser 1
Data parser M
Each identifier takes a subset of data input
APT technique identifier(s) using machine learning
APT technique identifier(s) using IDS product
APT technique identifier(s) using other methods
System object dependency discovering

Figure 2: Proposed architecture.

(1) **Data Parsing.** The collected data sources are first fed to the corresponding data parsers.
(2) **Technique Identifying.** Based on parsed data, the APT technique identifiers determine whether certain adversary techniques exist or not.

The tactic knowledge processing workflow is as follows:

- **Tactic Parsing.** The previously seen APT tactics, which are stored in the APT tactic repository, are fed to the APT tactic parser.

The system object dependency discovering workflow is as follows:

- **Discovering system object dependencies.** A number of system logs, such as process and file I/O monitoring logs, are used to discover system object dependencies.

Finally, the results from above three workflows are taken as input for the following procedures:

(1) **Tactic Matching.** The APT tactic matcher uses the parsed tactics to match the identified adversary techniques. The matched tactics are stored as tactic instances, no matter it is fully matched or partially matched.
(2) **Tactic Ranking.** All APT tactic instances are ranked based on completeness of tactic matching.

4 DESIGN AND IMPLEMENTATION

The framework is implemented in a Ubuntu 18.04 virtual machine (referred to as detector). To isolate the detector from the IT system being monitored, it is setup as an HTTP server to receive file upload. On receiving files upload, the files are put to specific directories based on its type, such as APT tactic files, network log files or windows event log files. Other daemon programs, which are configured to monitor those directories, will trigger the framework to run once the directories' contents are changed. It is also possible to set the triggering to manual if the contents are changed at a high frequency. In this case, the daemon program monitoring the contents can raise alerts to notify the security analysts about the arrival of new input files. The analysts can then run the program at a preferred time point.

Data parser. On receiving system information, each file (e.g. a log file or configuration file) is assigned to the corresponding data parser for processing. Different data parsers are designed to deal with different types of input system files based on their syntaxes. Therefore, the number of data parser types is the same as the number of input system file types. The data parsers can work in parallel for faster processing speed.

APT technique identifier. The APT technique identifiers receive parsed data from data parsers and determine whether certain APT techniques are used. Each identifier is responsible for checking one technique. Based on different APT techniques, the identifiers may need data from different sources (i.e., different types of system information files). Hence, identifiers may take data from different sets of data parsers. The identifiers can be signature based, anomaly detection based, machine learning based, or other types. The output of the identifiers is data tuples made up of technique name and its post-conditions. Take the "Data exfiltration" technique in Table 2 as an example, the result output can be `("Data exfiltration", 23619, "D:\Documents\customer-list.xlsx")`, in which `23619` is the process ID (PID) on the user machine, and `"D:\Documents\customer-list.xlsx"` is the file. The malicious process with ID `23619` reads the sensitive file `"D:\Documents\customer-list.xlsx"` in this technique.

APT tactic repository. The APT tactic repository is a directory where all APT tactic files are stored. All the previously seen APT tactics are stored in the APT tactic repository in the same syntax. We use the graph description language DOT to describe these APT tactics. In APT tactic graphs, every adversary technique is defined as a box-shaped node, and directed edges denote the attack order.

Zou, Qingtian; Singhal, Anoop; Sun, Xiaoyan; Liu, Peng. "Automatic Recognition of Advanced Persistent Threat Tactics for Enterprise Security." Paper presented at 6th ACM International Workshop on Security and Privacy Analytics 2020, New Orleans, LA, US. March 16, 2020 - March 18, 2020.

Each DOT file can be easily visualized into directed graphs by tools like Graphviz [3]. In cases where other syntax (e.g. STIX [6]) are needed, a new APT tactic parser should be added correspondingly to parse tactic files in the new syntax.

Listing 1 is the DOT description of the APT tactic shown in Figure 1 (a) and Table 1. The example graph contains 3 technique nodes, 5 post-condition nodes, and 3 pre-requisite nodes. Each node definition starts with a *node ID*, and follows by node attributes such as *label* (the text to show in graph), *shape* (the node shape in graph) and *style* (the node style in graph). We use rounded boxes to denote the start and end nodes of the graph, boxes for APT techniques, triangles for post-conditions, and inverted triangles for pre-requisites. Post-conditions are presented as result system objects, and pre-requisites are presented as the relationships between system objects, such as "P1=>P2" stands for process P_2 is a child process of or the same as P_1, "P2->F1" stands for process P_2 writes file F_1, and that "F1->P3" stands for process P_3 reads file F_1.

Listing 1: DOT codes example.

```
digraph example_tactic {
    // nodes
    1[label="start",shape=box,style=rounded];
    2[label="Drive by download",shape=box];
    21[label="P1",shape=triangle];
    3[label="Process injection",shape=box];
    31[label="P2",shape=triangle];
    32[label="P3",shape=triangle];
    33[label="P1=>P2",shape=invtriangle];
    4[label="Data destruction",shape=box];
    41[label="P4",shape=triangle];
    42[label="P5",shape=triangle];
    43[label="P4=>P5",shape=invtriangle];
    44[label="P5->F1",shape=invtriangle];
    5[label="end",shape=box,style=rounded];

    // edges
    1->2->3->4->5;
    21->2;
    31->3;32->3;33->3;
    41->4;42->4;43->4;44->4;
}
```

APT tactic parser. From APT tactic DOT files, the APT tactic parser extracts information including: (a) the number of nodes in the tactics; (b) the types of these nodes; (c) the way that the nodes are connected; (d) the post-conditions and pre-requisites for each technique in this tactic. The information is used to create the initial "template" APT tactics. They are "templates" because no identified techniques have been matched into them at this time. We store the tactic templates in a multi-layer JSON-like data structure, which features pairs of name and values. The first layer presents technique node IDs in the DOT file, and the second layer presents node properties such as node name, post-conditions and pre-requisites. For example, the parsed APT tactic for the tactic in Figure 1(a) and Table 1 is presented below.

Listing 2: Parsed APT tactic example

```
{   '1': {  'name': 'start',
            'post-conditions': 'none',
            'pre-requisites': 'none'},
    '2': {  'name': 'Drive by download',
            'post-conditions': 'P1',
            'pre-requisites': 'none'},
    '3': {  'name': 'Process injection',
            'post-conditions': 'P2; P3',
            'pre-requisites': 'P1=>P2'},
    '4': {  'name': 'Data destruction',
            'post-conditions': 'P4; F1',
            'pre-requisites': 'P3=>P4'},
    '5': {  'name': 'end',
            'post-conditions': 'none',
            'pre-requisites': 'none'}}
```

System object dependency discovering. Some logs, such as process and file I/O monitoring logs, are used to discover system object dependencies, which are used for chaining APT techniques in tactic matching. For example, in Figure 3, there are three edges showing a process forks to create a child process, a process writes a file, and that a process reads a file. We use triple-element tuples to present these dependencies. The first and last element each represents a system object, such as a file or a process; and the middle element represents the operation, such as process forking or file reading/writing. Each system object element is a tuple which starts with a system object indicator that represents its type, followed by other items that vary according to the system object's type. For example, file writing in Figure 3 is presented as `(("P", 5414), "write", ("F", "D:\apt.dll"))`. The first element indicates a process with PID 5414, the second element indicates file writing operation, and the third element indicates the file `"D:\apt.dll"`. Therefore, this whole entry of system object dependency means that a process with PID 5414 writes the file `"D:\apt.dll"`.

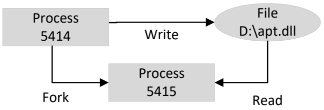


Figure 3: A simple system object dependency graph (SODG).

APT tactic matcher. The matcher takes five inputs: (a) initial "template" APT tactics from APT tactic parser; (b) APT tactic instances; (c) results from APT technique identifiers; (d) a pool of APT techniques that are identified; (e) system object dependencies. Inputs (b) and (d) are from previous run of the matcher.

Once a new APT technique is identified, the matcher will try to match it to an APT tactic if the technique is part of the tactic. Specifically, the technique can be matched to either APT tactic template(s) or partially matched APT tactic instance(s). 1) If there were partially matched APT tactic instances expecting this technique, the matcher will check the pre-requisites of the identified technique to see if they are satisfied. The pre-requisites are checked through system object dependencies. If all pre-requisites are satisfied, the new APT technique is matched into the tactic instance, and the post-conditions are confirmed in the instance. If not, the unmatched new technique is saved to the pool and the post-conditions are discarded. 2) In many times, a given APT technique may not be matched to any partially matched APT tactic instances, but can be matched to a APT template. In this case, a new APT tactic instance is created from the template, the technique is matched into this instance, and system object(s) in the instance regarding this technique is confirmed. Otherwise, the technique is put to the pool.

Whenever an APT technique is matched into an APT tactic template/instance, the matcher goes through all techniques in the pool and start another iteration of the matching process, but this time, the matcher only tries to match the technique into partially matched tactic instances, because those techniques have already been checked against templates before put into the pool. In this way, even if a technique is not matched at the time of identification, it will still be matched once all the conditions are met afterwards.

To illustrate the algorithm, we present two examples of matching based on the tactic presented in Figure 1(a) and Table 1. Firstly, consider the case where no techniques are matched into the tactic. Assuming the identifier first reports that drive by download and the corresponding process are identified. The matcher first assumes that the post-condition P_1 is the process reported, and then checks the pre-requisites. The matcher finds out that this technique has no pre-requisites, so the technique gets matched immediately. An APT tactic instance gets created from this template, the drive by download technique in it is marked as matched, and P_1 is confirmed to be the process reported in this APT tactic instance.

In the second example, consider the case where no techniques are matched into the tactic. However, technique process injection gets identified first. Similarly, the matcher assumes the system objects reported are correct, and then checks the pre-requisites against system object dependencies. The matcher finds out that it needs P_1 and P_2, but P_1 from the previous technique is not matched yet. Therefore, the matcher decides that this technique cannot be matched and put it in the pool of unmatched techniques. After drive by download is matched, during the going through of the pool, this previously unmatched technique, process injection, will be matched if it meets the pre-requisites.

In real world, defense against APT tactics generally needs to tackle three scenarios: one attacker is using one tactic; multiple attackers are using one same tactic; multiple attackers are using different tactics. Our matcher can handle all these scenarios properly. (a) If one attacker is using one tactic, the algorithm shown in Algorithm 1 can detect it by matching every step. (b) If multiple attackers are using one same tactic, they can be differentiated by system object dependencies, such as different process ID, which is presented as pre-requisites (Table 1) used in line 6 of the algorithm. (c) If multiple attackers are using different tactics, they can be differentiated by matching different techniques as shown in line 2 of the algorithm. A more complicated situation is that multiple attackers are using different APT tactics, but these tactics share some techniques in common. At the defender's side, it is unknown which attacker is using which APT tactic, so the best practice is to list all the possible combinations. In light of this, the matcher will create APT tactic instances for all combinations while preserving the system object dependencies.

Algorithm 1 APT tactic matching algorithm

```
1:  **Input**: APT tactic templates; APT tactic instances; one newly identified adversary technique $new\_at$; a pool of identified techniques.
2:  $all\_candidates \leftarrow$ same techniques as $new\_at$ found in APT tactic templates and instances.
3:  if there exists at least one technique in $all\_candidates$ then
4:      for all $candidate \in all\_candidates$ do
5:          Assuming post-conditions are right, examine pre-requisites for each $candidate$.
6:          if All pre-requisites are met for the $candidate$ then
7:              if $candidate$ is in a template then
8:                  Create a new instance from this template, and match $new\_at$ into the position of $candidate$.
9:              else if $candidate$ is in an instance then
10:                 Create a copy of $candidate$.
11:                 Match $new\_at$ into the position of the copy of $candidate$.
12:             end if
13:             In the instance where $new\_at$ is matched into, identify the next adversary technique $next\_at$.
14:             $all\_next\_step\_candidates \leftarrow$ same techniques as $next\_at$ found in the pool of not matched adversary techniques.
15:             for all $next\_step\_candidate \in all\_next\_step\_candidates$ do
16:                 Call APT tactic matching algorithm.
17:             end for
18:         end if
19:         Put $new\_at$ into the pool
20:     end for
21: else
22:     Save $new\_at$ to the pool of not matched adversary techniques.
23: end if
```

APT tactic ranker. The ranker takes the APT tactic instances from matcher as input. The ranking is based on the percentage of APT tactic instances' completeness. The more completely an APT tactic instance is matched, the higher it will appear on the list. Fully matched APT tactic instances are put on top of the list.

The ranker ranks both fully matched and partially matched APT tactic instances. Assuming that the technique identifiers can correctly identify APT techniques, the existence of partially matched APT tactic instances means that either the attacker gives up this campaign, or that the attacker just decides to wait before launching remaining techniques. Therefore, partially matched APT tactics should be kept and ranked but not discarded.

In a word, the framework's workflow can be summarized as input parsing, technique identifying, tactic matching and tactic ranking. Except input parsing phase, the other three phases generate new findings at three time points respectively, and new findings at a previous time point should lead to new findings at the next time point.

- The first time point is when a technique is identified at technique identifying phase. The new findings here are the identified techniques and their post-conditions.
- The second time point is at the end of tactic matching phase. The new findings here are are new and/or updated APT tactic instances.
- The third time point is at the end of tactic ranking phase. The new findings here are updated APT tactic instances' completeness and ranking results.

Thus, at the end of technique identification phase, if new technique(s) is identified, the tactic matcher should be automatically triggered; and at the end of tactic matching phase, if new APT tactic instance(s) is created or previous instance(s) is updated, the tactic ranker should be automatically triggered.

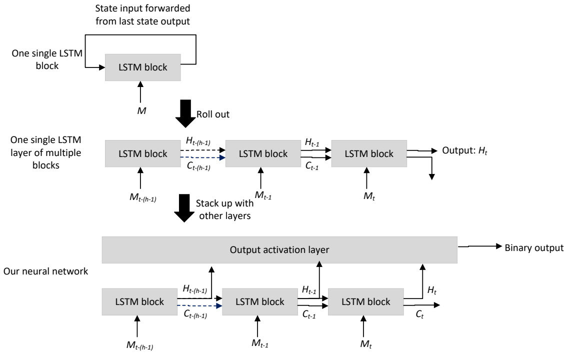

Figure 4: Our LSTM neural network.

5 CASE STUDY

The APT tactic shown in Figure 1(b) and Table 2 contains five different APT techniques. In this section, we use this tactic as a case study and describe how each APT technique can be identified, following the order they appear. We will discuss the identification of Pass the Hash in detail, as it is an example APT technique that we can apply machine learning for its identification.

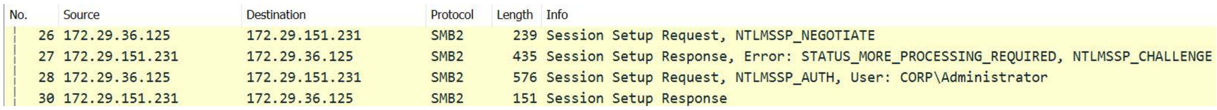
Supply Chain Compromise. This technique can be identified by scanning downloaded item with Anti-Virus (AV) products. Alternatively, network intrusion detection products like Snort [4] can also detect it when the downloaded item tries to establish communication with the attacker's machine. Windows Defender can identify this technique and leave one entry in Windows event logs. The post-condition of this step is a malicious process P_1 is created due to attackers' communication with the victim machine. As an initial intrusion step, it has no pre-requisites.

Bypassing Windows User Account Control (UAC). Bypassing Windows UAC is a common privilege escalation technique towards Windows machines. Many procedures have been discovered to bypass UAC. An extensive list of available procedures can be found in the UACMe project [2]. Some procedures rely on modifying specific, user-accessible Registry entries. Therefore, by monitoring accesses to the Registry with process monitor, especially entry creation and modification, this APT technique can be identified. The post-conditions are that processes P_2 and P_3 are created, with P_3 running at system-level privilege. P_2 may act as a middle stage. In this case, P_2 may be the actual process modifying the Registry. After that, a system service reads the modified Registry and created the process P_3 with system-level privilege. Therefore, P_2 and P_3 may not have direct relation, and the pre-requisite only has requirement on P_2.

Credential Dumping. Credential dumping is the process of obtaining account credentials, normally in the form of account names and password hashes. On a Domain Controller (DC), Active Directory (AD) service maintains all the users' account names and password hashes in the domain. They are stored in a database file locked by AD. Only some specific processes are allowed to access the contents of this file. Local Security Authority Subsystem Service (LSASS) is one of such special processes. It is given the right to read the database file because its role in a DC is to provide an interface for managing local security, domain authentication, and AD processes. With escalated privilege, attackers can craft queries, send them to LSASS, and get domain user account names and corresponding hashes. Therefore, we can monitor the LSASS process to detect this APT technique. We can either match some signatures in malicious queries or detect anomaly behaviors of LSASS. The post-condition is that process P_4 that runs with system-level privilege and interacts with LSASS is created. The pre-requisite is that P_4 is a child process of or the same as P_3, because a process needs system-level privilege to interact with LSASS.

Pass the Hash. Pass the hash is a well-known technique for lateral movement. In remote login, plain-text passwords are usually converted to hashes for authentication. Some authentication mechanisms only check if hashes are matched. Pass-the-hash technique relies on these vulnerable mechanisms to impersonate a normal user with dumped hashes. We assume that a) normal users use benign client programs that are usually authenticated through other mechanisms, and that b) attackers cannot get the plain-text passwords and have to rely on hashes to impersonate a normal user. We can capture the network packets and find out which kind of authentication mechanism is used. The login session that uses those vulnerable authentication mechanisms can then be identified as pass the hash attack. The post-condition is that a malicious process P_5 with user U_1's credential is created. This step has no pre-requisites.

There are three stages during the remote login session. Each stage contains multiple network packets. For example, the second stage, authentication, can be viewed as a sequence made up of client's authentication request, server's challenge, client's challenge response and server's authentication response, as shown in Figure 5. The client first sends a session setup request to the server; then the server responds to the client with a challenge; on receiving the challenge, the client uses the challenge and credentials to do calculations and sends back the result in challenge response packet; finally, the server verifies the result and sends back authentication response indicating whether authentication succeeds or not.



```
No.  Source           Destination      Protocol Length Info
  26 172.29.36.125    172.29.151.231   SMB2        239 Session Setup Request, NTLMSSP_NEGOTIATE
  27 172.29.151.231   172.29.36.125    SMB2        435 Session Setup Response, Error: STATUS_MORE_PROCESSING_REQUIRED, NTLMSSP_CHALLENGE
  28 172.29.36.125    172.29.151.231   SMB2        576 Session Setup Request, NTLMSSP_AUTH, User: CORP\Administrator
  30 172.29.151.231   172.29.36.125    SMB2        151 Session Setup Response
```

Figure 5: A subset of network packets during pass the hash attack.

Pass the Hash Data Generation. The raw data (network packets) are automatically generated by protocol fuzzing. During a pass the hash attack, before a packet is sent to the server, we fuzz certain fields in the application layer (SMB/SMB2 for pass the hash) of the network packets. In this way, (a) the packet structure remains intact, so that the server will not discard the packet; (b) the authentication of pass the hash can be affected; (c) we can get a variety of network packets, and possibly, a variety of network packet sequences so we can get enough diversity in the data for machine learning. The same fuzzing method has also been applied in the generation of benign data from normal network traffic. All the network packets from malicious and benign network traffic are captured using Wireshark. Because of fuzzing, we cannot assure every pass the hash attempt or normal access attempt is successful. For failed pass the hash attempts, we remove them from malicious data. The reason is that, if it fails, the attempt does not generate any impact, so it is not really malicious. For failed normal access, we keep it in benign data, because normal user can also have typos or forget passwords.

Though the raw network logs contain network packets from both malicious and benign network traffic, there are too much redundant data that do not carry useful information for identifying pass the hash, such as timestamp. There are also fields that have fixed values, such as the header length for SMB/SMB2. Values of these two types of fields cannot help identifying pass the hash. Therefore, in the data parser for network logs, such information is removed. Only those that can help identify pass the hash are kept.

Pass the Hash Identification. To identify pass the hash with machine learning, we have two key insights:

- Network communications consist of lots of network packets sent in certain order. What happens at a previous time point can affect what happens afterwards. For example, the first several packets may be a server and a client communicating the protocol to use, and packets afterwards will use the protocol decided;
- Pass the hash relies on certain authentication mechanism to work. Therefore, there must be some differences in certain values in at least one network packet during the network communication.

With these two insights, we decide to build an LSTM neural network that takes a sequence of network packets' types, and outputs the binary label representing whether this sequence is pass the hash network traffic. We have trained a long short-term memory (LSTM) neural network for pass-the-hash identification based on network packets sent between the server (victim) and the client (attacker) during remote logins. Our neural network is presented in Figure 4. M stands for input; H stands for each LSTM block's output; and C stands for each LSTM block's state output. Subscripts stand for the time points, in which h stands for the window size. The network packets' types are defined by the values of fields of interest. If two packets have the same values in all those fields, then the two packets are presented as the same packet type number. Otherwise, different numbers are assigned. In this way, a sequence of network packets can be presented as a sequence of numbers, each standing for a packet of its corresponding packet type.

Now that each network packet is represented as a packet type number, the whole network log can be represented as a whole sequence of packet type numbers. By identifying the start packet for each benign/malicious network communication, we chomp the whole sequence into many variate-length sequences, and the beginning of every sequence is a start packet. Then, we chomp each of those variate-length sequences into one or more fixed-length sequences according to the window size and window shift step size. Depending on whether the sequence comes from a benign traffic or malicious traffic, we assign every fixed-length sequence with the corresponding binary label and get one data sample for our LSTM neural network. If a fixed-length sequence appear in both the benign and malicious data, this sequence is removed from both of them because it cannot help the classification. We then remove duplicate sequences in both the benign data and malicious data. After these two removal processes, all data samples are finally ready to be used.

Data Exfiltration. This technique can be very confidential. It can be encrypted and done through very common protocols like HTTP/HTTPS. As a result, data exfiltration is hard to be identified at the network level. Supposing that attackers are interested in sensitive data, system administrators can enforce disk I/O monitoring with process monitor on sensitive files/folders on a machine. In this way, data exfiltration can be identified at disk level.

6 EVALUATION

At high level, the framework presented can be separated into four phases:

- **Input parsing.** The raw input files are parsed by APT tactic parser, data parsers and system object dependency.
- **APT technique identifying.** APT identifiers use parsed inputs to identify APT techniques.
- **APT tactic matching.** With the help of system object dependencies, the APT tactic matcher matches identified APT techniques into APT tactics.
- **APT tactic ranking.** After tactic matching, the APT tactic ranker ranks all APT tactic instances based on completeness.

We have evaluated each phases and the results show that our framework can correctly detect APT tactics and pick out the one(s) that is fully matched. Specifically, we answer the following questions:

- **RQ1.** How accurately can technique identifiers identify APT techniques?

Zou, Qingtian; Singhal, Anoop; Sun, Xiaoyan; Liu, Peng. "Automatic Recognition of Advanced Persistent Threat Tactics for Enterprise Security." Paper presented at 6th ACM International Workshop on Security and Privacy Analytics 2020, New Orleans, LA, US. March 16, 2020 - March 18, 2020.

Table 3: 384 APT tactics in the repository.

Initial intrusion	Privilege escalation	Credential access	Lateral movement	Impact
Supply chain compromise	Bypass User Account Control	Credential dumping	Pass the hash	Data exfiltration
Exploit public-facing application	DLL search order hijacking	Account manipulation	Logon scripts	Data manipulation
External remote services	New service	Private keys		Data destruction
Spearphishing link	Process injection			Endpoint denial of service

- **RQ2.** Given identified APT techniques, how correctly can the matcher match them into APT tactics and generate instances?
- **RQ3.** Given matched APT tactic instances, can the ranker rank the fully matched APT tactic instances higher than others in the ranked list?
- **RQ4.** How much time and memory does the framework need for each phase?

For evaluation experiments, we first prepared 385 APT tactics in the APT tactic repository. One is a 4-step tactic referred to as tactic001 in Table 4. The other 384 are 5-step tactics presented in Table 3. Each tactic can take any one process belonging to the same technique (column). Therefore, Table 3 provides $4*4*3*2*4 = 384$ APT tactics. Some APT tactics may be very similar at high level. For example, replace one technique in tactic A and get tactic B. The old technique and the new technique are for the same purpose, but done in different ways (e.g. lateral movement by logon scripts or pass the hash). We treat A and B as different APT tactics because different techniques need different technique identifiers to identify them, and those identifiers may use different method and/or system object dependency for identifying.

Out of the 385 APT tactics in the repository, we launched 7 of them in evaluation experiments, presented in Table 4. 3 kinds of logs from those 7 APT tactics are collected, which are network logs (captured by Wireshark), process monitor logs (exported from Prcess Monitor [15]), and windows event logs (exported from Windows Event Viewer). Our test bed, towards which attacks are launched, consists of one Windows AD DC (Windows Server 2012 R2) virtual matching hosting a Windows domain, joined by another Windows 7 virtual machine. The raw input files include 385 APT tactic DOT files, 5.84GB of network logs, 12.6GB of process monitor logs, and 141MB of Windows event logs.

6.1 APT technique identifying

For APT technique identifying, we focus on evaluating one specific technique, which is pass the hash identification. We choose this because other identifiers involve commercial IDS or manually crafted patterns, which have little point in evaluating.

For pass the hash identification, we build an LSTM based neural network. It takes parsed network log files of packets sent between hosts as input, and produce binary results showing whether pass the hash attack is presented in a packet sequence.

With different parameters such as training batch size, LSTM window size and window shift step size, we have trained a total of 144 neural networks. Of all the data fed to the neural network, about 60% are used for training, about 20% are used for validation, and the rest about 20% are used for testing. Every trained neural network is evaluated by false positive rate, false negative rate and F1 score. With different parameters, the number of benign data samples and malicious data samples can also change accordingly. As a result, whether the final dataset is balanced or not is kind of unpredictable, so accuracy is not very helpful. What is more, the true negative samples, which are noises, are not of interest for us, and F1 score does not take true negatives into calculation. Therefore, we choose F1 score as the main criteria.

The best-performing neural network, which has the highest F1 score of 0.9763 on test set, is fed with 2085 benign data samples and 2830 malicious data samples. The false positive rate and false negative rate on the test set of this neural network are 4.437% and 0.252%, respectively. Though the false positive rate is not ideal, we will show that, in tactic matching phase, those false positives cannot produce fully matched APT tactic instance.

Result 1: *The LSTM-based APT technique identifier for pass the hash, which is hard to detect via traditional methods, can identify the technique with low false negative rate, but the false positive rate is not ideal.*

6.2 APT tactic matching

As stated earlier, the number of launched APT tactics in our experiments is small. However, even if there are very few APT tactics happening, the CSOCs need to be aware of all possible APT tactics. With this insight, we evaluated the APT tactic matcher with all the 385 APT tactics in the repository. The goal of evaluating APT tactic matcher is to see whether it can correctly and fully match APT tactic that is actually launched in the following three cases: (a) one attacker is using one APT tactic; (b) multiple attackers are using one same APT tactic; (c) multiple attackers are using multiple different APT tactics. There may be some partially matched APT tactics. This is natural because some APT tactics share the same technique at some point, but the APT tactic matcher just tries its best to match an APT technique into tactic. How much importance should be given to the tactic instance is not evaluated by the APT tactic matcher, but the APT tactic ranker, which will be evaluated in the next subsection.

Case A: One attacker using one APT tactic. In this scenario, tactic001 presented in Table 4 is launched for once in our test bed. The matcher successfully match the target tactic in full. The outputs contains 1 fully matched APT tactic instance of the target tactic and other 123 partially matched instances.

Case B: Multiple attackers using one same APT tactic. In this scenario, tactic001 presented in Table 4 is launched for three times with some different parameters, like PIDs and file names. The

Table 4: A list of APT tactics that were launched.

APT tactic name	1st technique	2nd technique	3rd technique	4th technique	5th technique
tactic001	Supply chain attack	DLL search order hijacking	Logon scripts	Data modification	(None)
tactic002	Supply chain attack	Bypass User Account Control	Credential dumping	Pass the hash	Data exfiltration
tactic003	Supply chain attack	Bypass User Account Control	Credential dumping	Pass the hash	Data modification
tactic004	Supply chain attack	Bypass User Account Control	Credential dumping	Pass the hash	Data destruction
tactic005	Supply chain attack	DLL search order hijacking	Credential dumping	Pass the hash	Data exfiltration
tactic006	Supply chain attack	DLL search order hijacking	Credential dumping	Pass the hash	Data modification
tactic007	Supply chain attack	DLL search order hijacking	Credential dumping	Pass the hash	Data destruction

matcher outputs 9 fully matched APT tactic instances of the target tactic and 375 partially matched instances.

The results show the existence of “duplicates” in fully matched APT tactic instances. The reason behind is that some techniques in the tactic instances can be replaced with others. In Case B, the last two techniques of tactic001 are interchangeable among the 3 attacks. When we launched the 3 attacks, the vulnerable process for DLL search order hijacking remains the same, which made the last two techniques interchangeable. As a result, the final output of fully matched APT tactic instances becomes $3 * 3 = 9$. This is reasonable because at the defender’s side, CSOCs have no idea which attacker is aiming for what in their IT system, so the best practice is to list all possible combinations.

Case C: Multiple attackers using multiple different APT tactics. In this scenario, the APT tactics presented in Table 4 are each launched for once. Note that these APT tactics share some common techniques. The matcher outputs 94 fully matched APT tactic instances and 5468 partially matched instances. The 94 fully matched APT tactic instances include 4 instances of tactic001, 6 of tactic002, 6 of tactic003, 6 of tactic004, 24 of tactic005, 24 of tactic006, and 24 of tactic007.

The similar thing in Case B also happens to Case C. In Case B, the interchangeability results from three attackers using one same tactic; in Case C, the interchangeability results from shared APT techniques among the 7 tactics. For tactic001, its first two techniques (supply chain attack and DLL search order hijacking) are interchangeable among tactic001, tactic005, tactic006, and tactic007, so its fully matched instance number is 4. For tactic002, tactic003 and tactic004, their last two techniques (pass the hash and data exfiltration/modification/destruction) are interchangeable between tactic002 and tactic005, tactic003 and tactic006, and tactic004 and tactic007 respectively. The reason is that pass the hash technique has no prerequisites, so there is no way to chain the first three techniques together with the last two. As a result, the numbers of fully matched instances for tactic002, tactic003 and tactic004 are all $3 * 2 = 6$. For tactic005, tactic006 and tactic007, the first two, the middle one, and the last two techniques are all interchangeable. How the first two and the last two techniques are interchangeable have been discussed earlier; and the middle one technique (credential dumping) is interchangeable among tactic005, tactic006 and tactic007 because they use the same vulnerable process for DLL search order hijacking. Thus, their fully matched instance numbers are all $4 * 3 * 2 = 24$.

One thing worth noting is that after the technique identifying phase, we blindly feed identification results to tactic matching phase. This means that the false positives of pass the hash identification are treated as true positives and used for tactic matching. CSOCs may realize that some of those are false positives, but at the run time, without further inspecting the data, they cannot know that whether the outputs of pass the hash identifier contains false positives or not. In spite of this, the number of fully matched APT tactics is still in consistence with our expectations, which means that, during tactic matching, those false positives cannot be used to produce fully matched APT tactic instances because they do not meet the pre-requisites of system object dependencies.

To further assure the matcher’s resilience to false positives from technique identifying, we carry out an additional experiment. We reproduce Case C, but, this time, we add a filter between the pass the hash identifier and the APT tactic matcher, so that the matcher only gets false positives from pass the hash identifier. Other parts remain the same, and we find out that the matcher only outputs 4 fully matched APT tactic instances of tactic001, and 2126 not fully matched APT tactic instances. Therefore, the APT tactic matcher is resilient to the false positives from technique identifiers.

Result 2: *The APT tactic matcher is resilient to false postives from technique identifiers and can correctly match identified APT techniques into tactics and create APT tactic instances in all three cases.*

6.3 APT tactic ranking

After APT tactic matching, the matcher outputs APT tactic instances, which can be partially of fully matched, to the APT tactic ranker. The APT tactic ranker then ranks these APT tactic instances by completeness. The goal of evaluating APT tactic ranker is to see whether it can correctly pick out fully matched APT tactic instances and put them to the top of the list.

The evaluation results show that, in all of the three Cases A, B and C, the ranker successfully ranks the fully matched instance(s) to the top. In Case B and C, because there are many “duplicate” APT tactic instances with the same 100% completeness, there can be many APT tactic instances, which are the same APT tactics with different system objects, on the top of the ranking list.

Result 3: *The APT tactic ranker can rank the fully matched APT tactic instances on top of the ranked list.*

6.4 Time and memory usage

To evaluate the efficiency of our framework, we have conducted offline measurements of the time and max memory usage for each of the four phases. The machine used for this experiment is a workstation with Intel(R) Xeon(R) E5-2650 v3 processor and 62GB of RAM. The results are presented in Table 5.

Table 5: Max memory and time taken for each phase.

Phase		Max memory taken (MB)	Time taken (s)
Input parsing		38794	1366
APT technique identifying		3812	74
APT tactic matching	Case A	19	1
	Case B	20	1
	Case C	51	13
APT tactic ranking	Case A	16	1
	Case B	17	1
	Case C	49	1

It is shown that, the most resource-consuming phase is the input parsing phase. In this phase, the memory usage can be as high as about twice the size of input files. The memory usage is high because in our Python implementation, we used the data structure of lists a lot. In Python, lists have many redundancies between adjacent elements. To make matters worse, Python does not have any means for memory recycle, which means once some memories are used, they will never be released, until the whole program exits. Therefore, in our Python input parsing implementation, after loading large files into the memories, the program cannot release them after the files' parsing have been finished. If the framework is implemented with other programming languages, like Java, the memory can be better managed.

> ***Result 4:*** *The most resource-consuming phase is input parsing. Other phases consumes acceptable memories and short time. The memory usage and time consumption have the potential to be further reduced.*

7 CONCLUSION AND FUTURE WORK

In this paper, we propose a framework for detecting APT tactics from logs and configuration files. The framework takes previously seen APT tactics, logs and system configuration files as input, and generates a ranked list of APT tactics based on completeness. We also present a detailed case study of a simple 5-step APT tactic, describing how to identify each APT technique in the tactic. Finally, we present the evaluation results of our framework, which clearly shows that the framework can correctly detect APT tactics.

Currently, we implement the framework on one virtual machine. To further improve the efficiency, we plan to implement, validate and evaluate this framework in a cloud environment with multiple virtual machines. Every virtual machine will be dedicated to one task for efficiency. Manual work can be significantly reduced because system administrators only need to care about feeding data into the cloud. The other workloads, including file parsing, technique identifying, and tactic matching will be all completed by the framework automatically.

Our framework matches APT tactics from the repository. However, attackers may update their attack tactics. They may replace old adversary techniques for new ones or add/remove techniques according to their purposes. In the future, we plan to add another component, APT tactic updater, to our framework to automatically handle tactic updating. The updater will take tactic templates from tactic parser, partially matched tactic instances and the pool of unmatched adversary techniques from tactic matcher. Then it can decide when some changes should be made in original tactics, how it should be made, and finally update tactics in the repository.

Another thing worth noticing is that, we simply rank the APT tactics instances based on the completeness. The ranking could be based on more complicated algorithm. For example, CVSS scores can be taken into consideration, and an "impact score" can be calculated for each APT tactic instance. Or another model may be proposed to assess how likely the APT tactic is being used by the attacker. Because this is about APT impact assessment and is out of the scope of our paper, here we do not dig deeper into the ranking problem.

The Impossibility of Efficient Quantum Weak Coin-Flipping

Carl A. Miller

Joint Center for Quantum Information and Computer Science
University of Maryland, College Park, MD 20742, USA

National Institute of Standards and Technology,
100 Bureau Dr., Gaithersburg, MD 20899, USA

Abstract

How can two parties with competing interests carry out a fair coin flip, using only a noiseless quantum channel? This problem (quantum weak coin-flipping) was formalized more than 15 years ago, and, despite some phenomenal theoretical progress, practical quantum coin-flipping protocols with vanishing bias have proved hard to find. In the current work we show that there is a reason that practical weak quantum coin-flipping is difficult: any quantum weak coin-flipping protocol with bias ϵ must use at least $\exp(\Omega(1/\sqrt{\epsilon}))$ rounds of communication. This is a large improvement over the previous best known lower bound of $\Omega(\log\log(1/\epsilon))$ due to Ambainis from 2004. Our proof is based on a theoretical construction (the two-variable profile function) which may find further applications.

1 Introduction

Suppose that Alice and Bob are two cooperating but mutually mistrustful parties, and they must make a unified decision between two choices (X and Y). Alice wants choice X, and Bob wants choice Y. However, neither of them will gain if they do not agree on their decision. How can the decision be made fairly? A natural solution would be for Alice and Bob to have a trusted third party (Charlie) flip a coin and report the result to both Alice and Bob. But, can coin-flipping be done in absence of any trusted third party or common source of randomness?

In this paper we will be concerned with the question of whether coin-flipping can be done if Alice and Bob share a two-way noiseless quantum channel. A standard way to model a protocol in this scenario is like so (see Figure 1). Let n be an even positive integer.

1. Alice possesses a quantum system $\mathcal{A}$, which she controls, and Bob possesses a quantum system $\mathcal{B}$ which he controls.
2. There is an additional quantum system $\mathcal{M}$, initially possessed by Alice, which stores quantum messages exchanged by Alice and Bob during the protocol.
3. If i is odd, then on the ith round of the protocol, Alice performs a prescribed joint quantum operation on $\mathcal{A}$ and $\mathcal{M}$, and then sends $\mathcal{M}$ across the quantum channel to Bob.
4. If i is even, then on the ith round of the protocol, Bob performs a prescribed joint quantum operation on $\mathcal{B}$ and $\mathcal{M}$ and then sends $\mathcal{M}$ across the channel to Alice.
5. After the nth round of communication, Alice performs a binary measurement on $\mathcal{A}$ and reports the result as a bit (a), and Bob performs a binary measurement on $\mathcal{B}$ and reports the result as a bit (b).

We suppose that Alice desires the outcome $a = b = 0$, and that Bob desires the outcome $a = b = 1$. It is presumed that an "honest" party will carry out their operations and measurements exactly as prescribed; however, a dishonest party may perform arbitrary manipulations of the quantum systems that they possess, and may perform any final measurement that they choose at the end of the protocol. (In particular, there is no restriction on the computational power of Alice or Bob.)

We say such a protocol is a **weak coin-flipping protocol with bias** ϵ if the following hold:

Miller, Carl A. "The Impossibility of Efficient Quantum Weak Coin-Flipping." Paper presented at 52nd Annual ACM Symposium on Theory of Computing (STOC 2020), Chicago, IL, US. June 22, 2020 - June 26, 2020.

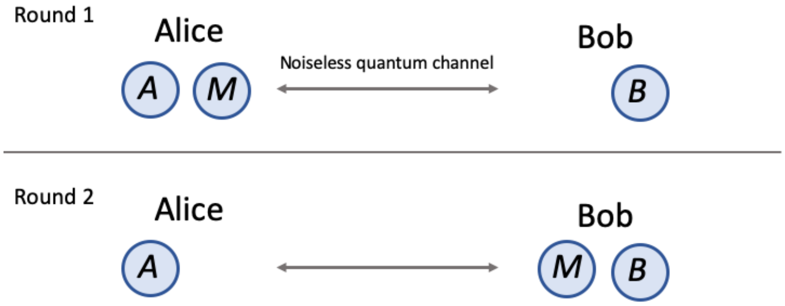

Figure 1: The first two rounds of a weak quantum coin-flipping protocol.

1. If Alice and Bob both perform honestly, then $\mathbb{P}(a = b = 0)$ is exactly $\frac{1}{2}$ and $\mathbb{P}(a = b = 1)$ is exactly $\frac{1}{2}$.
2. If Alice behaves dishonestly and Bob behaves honestly, then $\mathbb{P}(b = 0) \leq \frac{1}{2} + \epsilon$.
3. If Bob behaves dishonestly and Alice behaves honestly, then $\mathbb{P}(a = 1) \leq \frac{1}{2} + \epsilon$.

These conditions assert that Alice cannot bias the outcome by more than ϵ in her favor, and Bob cannot bias the result by more than ϵ in his favor. (A **strong coin-flipping protocol with bias** ϵ is one which guarantees that a dishonest party cannot bias the result of the coin flip by more than ϵ in either direction. Strong coin-flipping with vanishing bias is impossible by an elementary argument attributed to A. Kitaev — see [12].)

We note that in a classical analogue of the setting described above — i.e., where $\mathcal{A}, \mathcal{B}, \mathcal{M}$ are random variables, Alice's and Bob's operations are stochastic maps, and the two parties are computationally unlimited — it is elementary to show that any protocol allows either Alice to force the outcome to always be 0, or Bob to force the outcome to always be 1. (Thus, achieving bias less than $\frac{1}{2}$ is impossible.) This fact can be overcome by putting computational restrictions on Alice and Bob, and classical coin-flipping is itself an elegant and extensively studied topic (see [6, 20]). The main motivation to study quantum coin-flipping is that, in contrast to classical coin-flipping, it allows security proofs based on physical assumptions only.

Quantum coin-flipping was formalized as early as 1998 ([15]), and a series of works proved coin-flipping protocols with progressive improvements in the bias. Aharonov et al. [2] proved bias 0.42. Spekkens and Rudolph, and independently Ambainis, proved successive results [22, 23, 4] which brought the bias down to $\frac{\sqrt{2}-1}{2} \approx 0.207$. These results involved a small constant number of rounds of communication. Mochon [17, 18] then introduced a family of quantum weak coin-flipping protocols which approach bias $1/6 \approx 0.166$, with the number of communication rounds tending to infinity.

Finally, in a landmark work in 2007, Mochon [19] showed the existence of a family of weak coin-flipping protocols with bias tending to zero. Mochon exploited the idea of *point games* (a concept also attributed to A. Kitaev) to achieve this result. Mochon's existence proof was later simplified, re-written and published by Aharonov et al. [1]. Then, in recent work [5], Arora et al. introduced an algorithm which effectively constructs the protocols in the family whose existence was proven by Mochon.

Following this phenomenal progress, at least one major loose end remains. The number of communication rounds used in the protocols in [19, 1] was only shown to be $(1/\epsilon)^{O(1/\epsilon)}$. This asymptotic quantity is hardly efficient or practical. Meanwhile, the best known *lower* bound on the number of communication rounds [4] is $\Omega(\log\log(1/\epsilon))$, leaving a vast range of uncertainty about the optimal resources needed to achieve vanishing bias.

How many rounds of quantum communication are needed to achieve a particular bias ϵ? For example, in a different setting (strong classical coin-flipping with computational hardness assumptions), Cleve [11] showed that the number of communication rounds was $\Omega(1/\epsilon)$, and this bound was shown to be achievable [20]. Could a similar relationship exist for quantum weak coin-flipping?

1.1 Summary of result

In the current paper, we prove the following lower bound on the number of communication rounds for quantum weak coin-flipping (see Theorem 8.2):

Theorem 1.1. *Let* $\mathbf{C}$ *be an* n*-round quantum weak coin-flipping protocol with bias* ϵ*. Then,*

$$n \quad \geq \quad \exp\left(\Omega\left(\frac{1}{\sqrt{\epsilon}}\right)\right). \tag{1}$$

This result shows that, at least in the standard model, practical quantum weak coin-flipping with vanishing bias is not feasible.

The proof of this result builds on previous techniques, including the concept of a *valid time-independent point game* (abbreviated as "valid TIPG"). A valid TIPG is a pair of real-valued functions m_1, m_2 on $\mathbb{R}_{\geq 0} \times \mathbb{R}_{\geq 0}$ that satisfy a certain infinite set of linear constraints (see subsections 3.2–3.3). It is known that any weak coin-flipping protocol determines a valid TIPG, and vice versa. This correspondence was used to prove the family of protocols with vanishing bias in [19]. Here I prove a negative result: any TIPG obtained from a weak coin-flipping protocol with small bias must have very large 1-norm — i.e., $\|m_1\|_1 + \|m_2\|_1$ must be very large as a function of ϵ. Since there is a relationship between the number of communication rounds of a protocol and the 1-norms of its associated time-independent point games, this implies the main result.

Ambainis's original bound [4] of $\Omega(\log\log(1/\epsilon))$ was based on a more direct study of quantum weak coin-flipping protocols: he performed an inductive argument, using the fidelity function, on the intermediate states arising in the protocol. This approach appears to be fairly different from the one in this paper, although it may be possible to relate the two.

Theorem 1.1 is a further step in mapping out the full range of cryptographic possibilities in a two-party quantum setting (see [7, 24] for surveys on this topic). A number of other negative results are known: secure two-party computation (under certain definitions) is impossible [13, 8], and strong coin-flipping [12, 9], bit commitment [14, 16, 9], and oblivious transfer [13, 10] are all impossible except with fixed positive bias. This paper shows that the case of quantum weak coin-flipping is different: it can be achieved with arbitrarily small bias, but it is impossible to do so in polynomial time.

Certainly, this is not the end of the story. The model for quantum weak coin flipping makes a number of assumptions, including that the players exchange information in discrete stages, and that they are completely unconstrained in their ability to manipulate any quantum systems that are not under the control of the other player. This impossibility result gives us additional motivation to study coin-flipping in other settings, including relativistic models.

1.2 Outline

Sections 2–3 of this paper cover preliminaries and known material, and then new contributions appear in sections 4–8. In section 4, I define the *profile* of a time-independent point game, which is a two-variable function associated to a time-independent point game that distills some of its most relevant information. Sections 5–6 prove some mathematical lemmas, including a key result on the behavior of highly concentrated rational functions (Proposition 5.3). Section 7 proves the result about the 1-norm of a time-independent point game using tools from the previous sections. Finally, section 8 proves Theorem 1.1. I conclude by noting some further directions in section 9.

1.3 Acknowledgements

I am grateful to Aarthi Sundaram (my co-author on a companion project) for many interesting discussions about the coin-flipping literature which helped to seed some of the ideas contained here. This paper also owes a large debt to Alexandre Eremenko, who showed me the complex analysis method that I used to prove Proposition 5.3. Thanks to Gorjan Alagic, Jonathan Katz, Yi-Kai Liu, and Scott Wolpert for their help with this project, and to Michael Newman for giving me an introduction to [1] some years ago.

This work is a contribution of the U. S. National Institute of Standards and Technology (NIST), and is not subject to copyright in the United States. Any mention of commercial products is for information purposes only, and does not imply endorsement by NIST.

2 Preliminaries

Let $\mathbb{R}$ denote the set of real numbers, and let $\mathbb{R}_{\geq 0}$ denote the set of nonnegative real numbers. If a, b are real numbers with $a \leq b$, then $[a, b]$ denotes the closed interval $\{x \mid a \leq x \leq b\}$, (a, b) denotes the open interval $\{x \mid a < x < b\}$, and $[a, b)$ and $(a, b]$ are similarly defined. We let ∞ denote infinity, and define intervals such as $[a, \infty] \subseteq \mathbb{R} \cup \{\infty\}$ in the obvious way. If A is a set and $B \subseteq A$ is a subset, then $A \smallsetminus B$ denotes the set of all elements of A that are not in B.

Our notation follows previous work [19, 1, 5] in part. Since we will work extensively with functions on $\mathbb{R}_{\geq 0}$ that have finite support, we make the following definitions.

Definition 2.1. *For any $x \in \mathbb{R}_{\geq 0}$, let $[\![x]\!]$ denote the function from $\mathbb{R}_{\geq 0}$ to $\mathbb{R}$ which maps x to 1 and is zero elsewhere. For any $x, y \in \mathbb{R}_{\geq 0}$, let $[\![x, y]\!]$ denote the function from $\mathbb{R}_{\geq 0} \times \mathbb{R}_{\geq 0}$ to $\mathbb{R}$ which maps (x, y) to 1 and is zero elsewhere.*

If f is a real-valued function on a set S, define $f^+ \colon S \to \mathbb{R}$ and $f^- \colon S \to \mathbb{R}$ by

$$f^+(x) = \max\{0, f(x)\}, \tag{2}$$
$$f^-(x) = \max\{0, -f(x)\}. \tag{3}$$

Note that $f = f_+ - f_-$. Let Supp f denote the support of f (i.e., the set of points in S on which f is nonzero). Let $f^\top$ denote the function $f^\top(x, y) = f(y, x)$. When f is a function with finite support, then (even if the set S is not countable) we will write $\sum_{s \in S} f(s)$ to mean the sum of $f(s)$ over all points in the support of f. The expression $\|f\|_1$ denotes the sum $\sum_{s \in S} |f(s)|$ (that is, the 1-norm of f).

The function $\log \colon \mathbb{R}_{\geq 0} \to \mathbb{R} \cup \{-\infty\}$ denotes the logarithm in base 2.

We use the term **universal function** to mean a function that is not dependent on any variables other than its input variables. Thus, even if we refer to a universal function after some variables have been quantified (e.g., "for all c, ...") it is understood that the function has no implicit dependencies on those variables. We will use boldface Roman letters $(\mathbf{A}, \mathbf{B}, \ldots)$ for universal functions.

When we use asymptotic big-O notation, we may use $O(u)$ as a set (e.g., "there exists $\mathbf{F}(u) \in O(u)$ such that ...") or as a placeholder for a function (e.g., "$x = y + O(z)$"). When a big-O expression is used as a placeholder, it is understood that it also represents a universal function with no implicit dependencies.

If Q is an event, then we write $\mathbb{P}[Q]$ for the probability of Q, and if X is a real-valued random variable, then we write $\mathbb{E}[X]$ for the expectation of X. A **stochastic map** from a set A to a set B is an indexed set of nonnegative real values

$$V = \{v_{ab} \mid a \in A, b \in B\} \tag{4}$$

such that $\sum_b v_{ab} = 1$ for all $a \in A$. For any $a \in A$, the values $\{v_{ab} \mid b \in B\}$ define a random variable on B which we denote by $V(a)$.

If $\mathcal{A}$ and $\mathcal{B}$ are Hilbert spaces, then we may write $\mathcal{AB}$ for the tensor product $\mathcal{A} \otimes \mathcal{B}$.

2.1 Complex analysis

We briefly cover some complex analysis tools that will be important in section 5. The reader can consult [3] for more details.

Let $\mathbb{C}$ denote the set of complex numbers. We will apply addition and multiplication to $\mathbb{C} \cup \{\infty\}$ using natural rules ($c + \infty = \infty, 1/\infty = 0$, etc.). For any $z \in \mathbb{C}$ and $r \geq 0$, let

$$\mathbb{D}(z, r) = \{w \in \mathbb{C} \mid |z - w| < r\} \tag{5}$$
$$\mathbb{S}(z, r) = \{w \in \mathbb{C} \mid |z - w| = r\}. \tag{6}$$

(The set $\mathbb{D}(z, r)$ is the open disc of radius r centered at z, and the set $\mathbb{S}(z, r)$ is the circle of radius r centered at z.) When $z = 0$ and $r = 1$, we may write these sets simply as $\mathbb{D}$ and $\mathbb{S}$. Also let

$$\mathbb{H} = \{w \in \mathbb{C} \mid \text{Im } w > 0\}. \tag{7}$$

If $Y \subseteq \mathbb{C} \cup \{\infty\}$, then $\overline{Y}$ denotes the closure of Y. For ease of notation we will write $\overline{\mathbb{D}}(z, r)$ for the closure of $\mathbb{D}(z, r)$. Let $\overline{\mathbb{H}}$ denote the set $\{z \in \mathbb{C} \mid \text{Im } z \geq 0\} \cup \{\infty\}$.

If $S \subseteq \mathbb{C}$ is an open set, then a function $f \colon S \to \mathbb{C}$ is **analytic** if for any $p \in S$, f can be expressed as a power series on some open neighborhood of p. If f is analytic and $\overline{\mathbb{D}}(z, r)$ is a closed disc within its domain, then the following equation always holds:

$$\frac{1}{2\pi} \int_0^{2\pi} f(z + re^{i\theta}) d\theta \quad = \quad f(z). \tag{8}$$

3 Review of quantum weak coin-flipping

In this section we review the common formal framework for quantum weak coin-flipping, including the mathematical construction of a *point game* (which is attributed to A. Kitaev). Since this framework has already seen thorough treatment in [19, 1, 5], we will mainly provide only definitions and statements of results here. Our terminology and notation are derived most directly from [1].

3.1 Weak coin flipping protocols

The definition of a weak coin flipping protocol (which we will first sketch, and then state formally) is intended to capture a general situation where two parties with competing interests are trying to fairly flip a coin. There are two possible outcomes: 0 (or "heads") which is the desired outcome for Alice, and 1 (or "tails") which is the desired outcome for Bob. There is no trusted third party in the protocol, and thus it consists entirely of communication between Alice and Bob. At the end of the protocol, the parties report bits a and b respectively (representing what they ostensibly believe to be the outcome of the coin flip).

The protocol is accomplished by Alice and Bob passing a quantum system (represented by the finite-dimensional Hilbert space $\mathcal{M}$) back and forth between them, while keeping private systems (represented by $\mathcal{A}$ and $\mathcal{B}$) to themselves. In each odd round i, Alice performs a unitary operator U_i on $\mathcal{AM}$ followed by a binary projective measurement $\{E_i, I_{\mathcal{AM}} - E_i\}$ on $\mathcal{AM}$. If the latter measurement fails — that is, if its postmeasurement state is not in Supp E_i — then Alice aborts the protocol and simply reports her favored outcome 0. (This event is understood to mean that Alice has stopped because she suspects cheating.) On even rounds, Bob does analogous operations with operators U_i, E_i on $\mathcal{MB}$. At the end of the protocol, if neither party has aborted, they each perform a binary projective measurement on their private system and report the result (as a and b, respectively). The definition requires that if Alice and Bob behave honestly in the protocol, then the probability that $a = b = 0$ is 1/2, and the probability that $a = b = 1$ is 1/2.

Definition 3.1. *A **weak coin-flipping protocol** $\mathbf{C}$ consists of the following data:*

- *Finite-dimensional Hilbert spaces $\mathcal{A}, \mathcal{M}, \mathcal{B}$ (Alice's system, the message system, and Bob's system),*
- *An even positive integer n (the number of rounds),*
- *An initial pure state ψ_0 on $\mathcal{AMB}$ of the form*

$$\psi_0 \quad = \quad \psi_{\mathcal{A},0} \otimes \psi_{\mathcal{M},0} \otimes \psi_{\mathcal{B},0}, \tag{9}$$

- *For each odd value i from $\{1, 2, \ldots, n\}$, a unitary operator U_i on $\mathcal{AM}$ and a Hermitian projection operator E_i on $\mathcal{AM}$,*
- *For each even value i from $\{1, 2, \ldots, n\}$, a unitary operator U_i on $\mathcal{MB}$ and a Hermitian projection operator E_i on $\mathcal{MB}$,*
- *Binary projective measurements $\{\Pi^0_{\mathcal{A}}, \Pi^1_{\mathcal{A}}\}$ and $\{\Pi^0_{\mathcal{B}}, \Pi^1_{\mathcal{B}}\}$ on $\mathcal{A}$ and $\mathcal{B}$, respectively,*

where the following condition holds: the state

$$\psi_n \quad := \quad E_n U_n E_{n-1} U_{n-1} \cdots E_1 U_1 \psi_0 \tag{10}$$

*(which is referred to as the **final state** of the protocol) satisfies*

$$\left\| \Pi^0_{\mathcal{A}} \otimes \Pi^0_{\mathcal{B}} \left| \psi_n \right\rangle \right\|^2 = \left\| \Pi^1_{\mathcal{A}} \otimes \Pi^1_{\mathcal{B}} \left| \psi_n \right\rangle \right\|^2 = \tfrac{1}{2}. \tag{11}$$

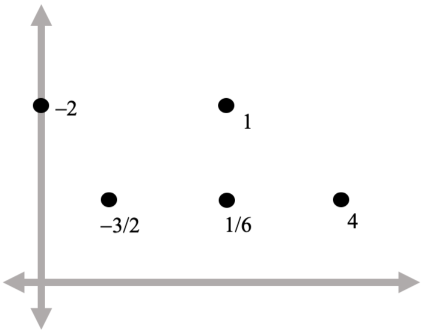

Figure 2: An example of a diagram of a 2-dimensional move w on a Cartesian coordinate system. The marked points are the elements of Supp w, and the labels indicate the values taken by w.

For the definition above, the states

$$\psi_i \quad := \quad E_i U_i E_{i-1} U_{i-1} \cdots E_1 U_1 \psi_0 \tag{12}$$

for $i \in \{1, \ldots, n-1\}$, are referred to as the **intermediate states** of the protocol.

Let us suppose that Bob (whose goal is to force Alice to report $a = 1$) chooses to behave dishonestly in the protocol. In that case, he can apply arbitrary unitary operations $V_2, V_4, V_6, \ldots$ on $\mathcal{MB}$ in place of $E_2U_2, E_4U_4, E_6U_6, \ldots$. (We do not account for any measurements performed by Bob in this case, since his own output is irrelevant.) This motivates the following definition. The **cheating probability** for Bob (in protocol $\mathbf{C}$) is the maximum of

$$\left\| \Pi^1_{\mathcal{A}} V_n (E_{n-1}U_{n-1}) V_{n-2} (E_{n-3}U_{n-3}) V_{n-4} (E_{n-5}U_{n-5}) \ldots V_2 (E_1 U_1) \left| \psi_0 \right\rangle \right\|^2 \tag{13}$$

over all unitary operators $V_2, V_4, \ldots, V_n$ on $\mathcal{MB}$.

Let P_B^* denote the cheating probability for Bob, and let P_A^* denote the cheating probability for Alice (defined analogously). Then, the **bias** of the weak coin-flipping protocol $\mathbf{C}$ is the quantity

$$\max \left\{ P_A^* - \frac{1}{2}, P_B^* - \frac{1}{2} \right\}. \tag{14}$$

3.2 Valid point games

Valid point games are elegant mathematical constructions which, as we will see, are in a near-perfect correspondence with weak coin-flipping protocols. Because they are a lot simpler to define, valid point games provide a convenient method of reduction for questions about weak coin-flipping protocols. We will give the definition of valid point games in this subection, and then explain their relationship to weak coin-flipping protocols in subsection 3.3. We use standard terminology with a few additions.

Definition 3.2. *A **one-dimensional move** is a function $\ell \colon \mathbb{R}_{\geq 0} \to \mathbb{R}$ that has finite support. A one-dimensional move is called a one-dimensional **configuration** if $\ell \geq 0$. A **two-dimensional move** is a function $q \colon \mathbb{R}_{\geq 0} \times \mathbb{R}_{\geq 0} \to \mathbb{R}$ that has finite support. A two-dimensional move is called a two-dimensional **configuration** if $q \geq 0$.*

Remark 3.3. *When we use the words **move** or **configuration** by themselves, we will always mean a two-dimensional move or two-dimensional configuration.*

Given a move q, it can be helpful to visualize q by graphing its support set Supp q and writing out the values $q(x, y)$ associated to each point $(x, y) \in$ Supp q. See Figure 2 for an example of a move whose support is of size 5.

A time-dependent point game is, roughly speaking, a finite sequence of two-dimensional configurations $z_0, \ldots, z_n$. However, for mathematical convenience, we define time-dependent point games in terms of the moves $(z_i - z_{i-1})$ rather than the configurations z_i. Recall that for any real-valued function f, we write f^+ and f^- for the positive and negative parts of f, respectively.

Definition 3.4. *A time-dependent point game M is a sequence of moves $(m_1, \ldots, m_n)$ such that*

$$\left(\sum_{i=1}^{n} m_i \right)^- + \sum_{i=1}^{j} m_i \quad \geq \quad 0 \tag{15}$$

for all $j \in \{1, 2, \ldots, n-1\}$.

In the above definition, we refer to $\left(\sum_{i=1}^n m_i\right)^-$ as the **initial configuration** of M, and we refer to $\left(\sum_{i=1}^n m_i\right)^+$ as the **final configuration** of M. The configurations on the left side of inequality (15) are referred to as the **intermediate configurations** of M. The **support** of a point game M, denoted Supp M, is the union of the supports of the moves in M.

Next we will define valid moves.

Definition 3.5. *A one-dimensional move ℓ is **valid** if the following conditions hold:*

$$\sum_x \ell(x) \quad = \quad 0 \tag{16}$$

$$\sum_x \left(\frac{x}{x+\lambda} \right) \ell(x) \quad \geq \quad 0 \qquad \forall \lambda > 0 \tag{17}$$

$$\sum_x x \cdot \ell(x) \quad \geq \quad 0. \tag{18}$$

(We note that condition (18) is actually redundant, since it can be proved from (17).) Equivalently, a move is valid if and only if its inner product with any operator monotone function is nonnegative (see subsection 3.2 of [1]). We note the following useful fact, which is easily proved from Definition 3.5.

Proposition 3.6. *If ℓ is a valid one-dimensional move, and $c > 0$, then the function $x \mapsto \ell(cx)$ is also a valid one-dimensional move.* $\square$

For any two-dimensional move q, the **rows** of q are the functions of the form $x \mapsto q(x, y)$ (for $y \in \mathbb{R}_{\geq 0}$) and the **columns** of q are the functions of the form $y \mapsto q(x, y)$ (for $x \in \mathbb{R}_{\geq 0}$).

Definition 3.7. *A two-dimensional move is **horizontally valid** if its rows are valid. A two-dimensional move is **vertically valid** if its columns are valid. A point game $(m_1, \ldots, m_n)$ is a **valid point game** if m_i is horizontally valid for all odd i, and m_i is vertically valid for all even i.*

For later use, we define the concept of a time-independent point game, which is simply a sequence of two-dimensional moves with no restrictions on nonnegativity (unlike Definition 3.4). In this paper, as in previous papers on weak coin-flipping, it is only useful to consider time-independent point games that involve 2 moves, and so we confine our definition accordingly.

Definition 3.8. *A **time-independent point game (TIPG)** is a pair of moves (r_1, r_2).*

We apply the term "valid" to time-independent point games in the obvious way: a time-independent point game (m_1, m_2) is valid if m_1 is horizontally valid and m_2 is vertically valid. Note that any time-dependent point game $(m_1, \ldots, m_n)$ yields a time-independent point game

$$(m_1 + m_3 + m_5 + \cdots, m_2 + m_4 + m_6 + \cdots) \tag{19}$$

and the latter game is valid if $(m_1, \ldots, m_n)$ is valid.

Remark 3.9. *When we use the term **point game** by itself, we will always mean a time-dependent point game.*

3.3 The relationship between point games and coin-flipping protocols

Now we will state the known results which motivate our study of valid point games. There is a close correspondence between valid point games and weak coin-flipping protocols, and this correspondence allows us to deduce assertions about coin-flipping protocols (of both existence and impossibility) by studying properties of point games.

Theorem 3.10. *Suppose that* $\mathbf{C}$ *is an* n*-round weak coin-flipping protocol with cheating probabilities* P_A^* *and* P_B^**, and that* $\delta > 0$*. Then, there exists a valid point game* $M = (m_1, \ldots, m_n)$ *with initial configuration* $\frac{1}{2}([\![1,0]\!] + [\![0,1]\!])$ *and final configuration* $[\![P_A^* + \delta, P_B^* + \delta]\!]$*.*

If M is a point game from the configuration $\frac{1}{2}([\![0,1]\!] + [\![1,0]\!])$ to a single point $[\alpha, \beta]$, then we will naturally refer to the quantity $\max\{\alpha, \beta\} - 1/2$ as the **bias** of M. The above theorem can be understood as asserting that if an n-round weak coin-flipping protocol exists with bias ϵ, then there are n-round valid point games with bias arbitrarily close to ϵ. A proof of Theorem 3.10, which is based on semidefinite programming duality, is given in [1].[1] (We note that Theorem 3.10 also has a converse, although we will not need it here. See Theorem 3 and Theorem 4 in [1].)

Next we assert a theorem about the relationship between weak coin-flipping protocols and time-independent point games.

Theorem 3.11. *Suppose that* $\mathbf{C}$ *is an* n*-round weak coin-flipping protocol with cheating probabilities* $\alpha := P_A^*$ *and* $\beta := P_B^*$*, and suppose that* $\delta > 0$*. Then, there exists a valid TIPG* $R = (r_1, r_2)$ *such that*

$$r_1 + r_2 \quad = \quad -\frac{1}{2}[\![0,1]\!] - \frac{1}{2}[\![1,0]\!] + [\![\alpha + \delta, \beta + \delta]\!] \tag{20}$$

and

$$\|r_1\|_1 + \|r_2\|_1 \quad \leq \quad 2n. \tag{21}$$

Proof. By Theorem 3.10, there is a valid time-dependent point game $M = (m_1, \ldots, m_n)$ whose sum is equal to the right-hand side of equation (20). Note that since the initial configuration $\frac{1}{2}[\![0,1]\!] + \frac{1}{2}[\![1,0]\!]$ of this game has 1-norm equal to one, and each move m_i sums to zero, the intermediate configurations all also have 1-norm equal to one, and therefore $\|m_i\|_1 \leq 2$ for all i. Therefore the TIPG $(r_1, r_2) := (m_1 + m_3 + m_5 + \cdots, m_2 + m_4 + m_6 + \cdots)$ satisfies the desired conditions. □

We make one final note about symmetry in valid TIPGs.

Remark 3.12. *Let us say that a move* q *is* ***symmetric*** *if* $q^\top = q$*, and that a TIPG* $Q = (q_1, q_2)$ *is symmetric if* $q_2 = q_1^\top$*. Note that if a valid TIPG* $R = (r_1, r_2)$ *achieves a symmetric move (such as the biased coin-flip move* $[\frac{1}{2} + \epsilon, \frac{1}{2} + \epsilon] - \frac{1}{2}[0,1] - \frac{1}{2}[1,0]$*) then there necessarily exists a symmetric valid TIPG that achieves the same move — specifically,* $R' := ((r_1 + r_2^\top)/2, (r_1^\top + r_2)/2)$*.*

4 The profile of a move

We now begin the contributions of this paper. We start by introducing the idea of a **profile function** of a move. If q is a two-dimensional move, then its profile function, denoted $\widehat{q}$, is a real-valued function on $[1, \infty] \times [1, \infty]$. Profile functions have geometric features that we can use to our advantage when trying to answer questions about point games.

4.1 Definition

We begin with the definition of the profile function in the one-dimensional case. The one-dimensional profile function can be thought of simply as a construction that bundles together the three conditions that define a valid move (Definition 3.5).

Definition 4.1. *For any positive real number* x*, let* $P_x \colon [1, \infty] \to \mathbb{R}$ *be defined by*

$$P_x(\alpha) \quad = \quad \begin{cases} 1 & \text{if } \alpha \in [1,2) \\ (x\alpha - x)/(x + \alpha - 2) & \text{if } \alpha \in [2, \infty) \\ x & \text{if } \alpha = \infty. \end{cases} \tag{22}$$

[1] The authors in [1] define the class of "EBM point games" and effectively prove (in their Proposition 2.5) that our Theorem 3.10 holds with the phrase "valid point game" replaced by "EBM point game." Then, in section 3, they prove that every EBM point game is a valid point game.

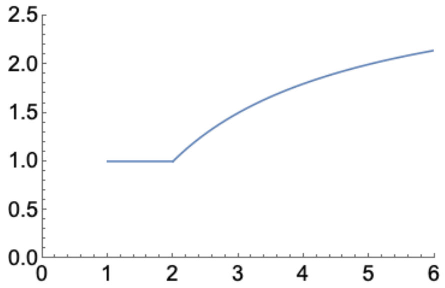

Figure 3: A graph of the function $P_3(\alpha)$. (Mathematica)

If $x = 0$, then let $P_0 \colon [1, \infty] \to \mathbb{R}$ be defined by

$$P_0(\alpha) = \begin{cases} 1 & \text{if } \alpha \in [1, 2) \\ 0 & \text{if } \alpha \in [2, \infty]. \end{cases} \tag{23}$$

*The function P_x is referred to as the **profile of** x.*

*For any one-dimensional move $\ell \colon \mathbb{R}_{\geq 0} \to \mathbb{R}$, the **profile of** ℓ, denoted $\widehat{\ell}$, is the function from $[1, \infty]$ to $\mathbb{R}$ given by*

$$\widehat{\ell} = \sum_x \ell(x) P_x. \tag{24}$$

The profile function $\widehat{\ell}$ collects some useful information about ℓ. One can easily verify from the definition that

$$\begin{aligned} \widehat{\ell}(1) &= \sum_x \ell(x) & (25) \\ \widehat{\ell}(2) &= \sum_{x>0} \ell(x) & (26) \\ \widehat{\ell}(\infty) &= \sum_x x \cdot \ell(x). & (27) \end{aligned}$$

For illustration, we give a graph of the function $P_3(\alpha)$ (that is, the profile of $[\![3]\!]$) in Figure 3.

Proposition 4.2. *A one-dimensional move ℓ is valid if and only if $\widehat{\ell}$ is nonnegative and $\widehat{\ell}(1) = 0$.*

Proof. Given Definition 3.5, this follows from equations (25) and (27) together with the observation that

$$\sum_x \left(\frac{x}{\lambda + x} \right) \ell(x) \geq 0 \qquad \Longleftrightarrow \qquad \widehat{\ell}\,(\lambda + 2) \geq 0. \tag{28}$$

This completes the proof. □

The reader will observe that there are multiple ways that the one-dimensional profile function could have been defined to achieve the property in Proposition 4.2 (e.g., using different ranges for α and different rational expressions). This particular choice of definition will make some of the arguments in section 7 mathematically easier. One of the reasons that this definition is convenient is that the profile of $[\![1]\!]$ is simply the constant function $\alpha \mapsto 1$.

Next we define the profile of a two-dimensional move.

Definition 4.3. *For any two-dimensional move q, the **profile of** q, denoted $\widehat{q}$, is the function from $[1, \infty] \times [1, \infty]$ to $\mathbb{R}$ given by*

$$\widehat{q}(\alpha, \beta) = \sum_{x,y} q(x, y) P_x(\alpha) P_y(\beta). \tag{29}$$

As with the one-dimensional profile, some of the values of a two-dimensional profile $\widehat{q}$ have natural expressions — for example,

$$\widehat{q}(1, \infty) = \sum_{x,y} y \cdot q(x, y) \tag{30}$$

and

$$\widehat{q}(\infty, \infty) = \sum_{x,y} x \cdot y \cdot q(x, y). \tag{31}$$

The basic motivation to study the two-dimensional profile function is the following proposition.

Proposition 4.4. *If q is a move that is either horizontally valid or vertically valid, then $\widehat{q} \geq 0$.*

Proof. Suppose that q is horizontally valid. Then, the single-variable profiles of the rows of q are all nonnegative. Thus for any $\alpha, \beta \in [1, \infty]$,

$$\begin{aligned} \widehat{q}(\alpha, \beta) &= \sum_y \left(\sum_x q(x, y) P_x(\alpha) \right) P_y(\beta) && (32) \\ &\geq 0. && (33) \end{aligned}$$

The vertically valid case is similar. □

As a consequence of the above proposition, if $M = (m_1, \ldots, m_n)$ is a valid time-dependent point game and $z_0, z_1, \ldots, z_{n-1}, z_n$ are its configurations, we must have

$$\widehat{z_0}(\alpha, \beta) \leq \widehat{z_1}(\alpha, \beta) \leq \ldots \leq \widehat{z_n}(\alpha, \beta) \tag{34}$$

for any $\alpha, \beta \in [1, \infty]$. The profile function gives us an infinite family of constraints that must be satisfied by the initial and final configurations of any valid point game.

We make note of some additional elementary facts for later use.

Proposition 4.5. *Let q be a horizontally valid move. If $\alpha \in [1, 2)$, then $\widehat{q}(\alpha, \beta) = 0$.*

Proof. We have

$$\begin{aligned} \widehat{q}(\alpha, \beta) &= \sum_y \left[\left(\sum_x q(x, y) \right) P_y(\beta) \right] && (35) \\ &= 0, && (36) \end{aligned}$$

as desired. □

Proposition 4.6. *Let q be a horizontally valid move. Then, $\widehat{q}(\alpha, 1) \geq \widehat{q}(\alpha, 2)$ for any $\alpha \in [1, \infty]$.*

Proof. By construction, $P_y(1) \geq P_y(2)$ for any y. We have

$$\widehat{q}(\alpha, 1) - \widehat{q}(\alpha, 2) = \sum_y \left[\left(\sum_x q(x, y) P_x(\alpha) \right) (P_y(1) - P_y(2)) \right]. \tag{37}$$

Both factors in the summand enclosed by brackets above are nonnegative, and thus the result follows. □

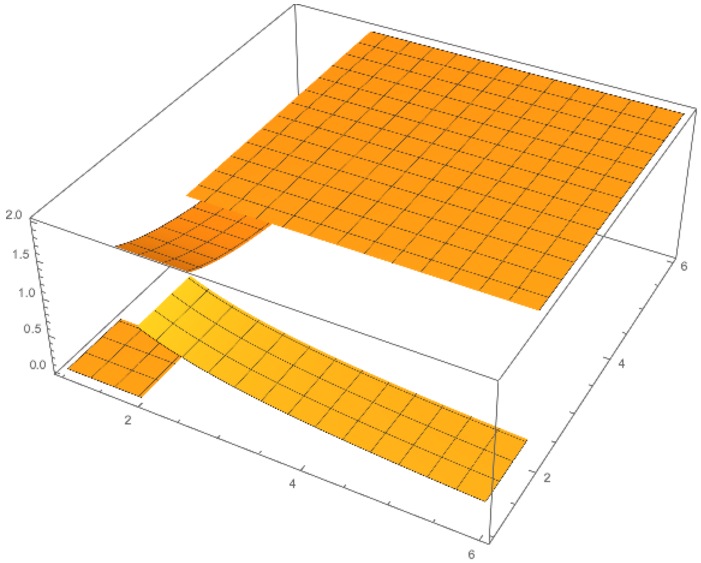

Figure 4: A graph of the function $\widehat{t_{1/10}}$. (Mathematica)

4.2 The target profiles

From subsection 3.3, we know that if there exists a quantum weak coin-flipping protocol whose bias is less than ϵ (with $0 < \epsilon < \frac{1}{2}$), then there must exist a valid TIPG (m_1, m_2) such that $m_1 + m_2$ is equal to

$$v_\epsilon \quad := \quad \left[\!\!\left[\frac{1}{2} + \epsilon, \frac{1}{2} + \epsilon\right]\!\!\right] - \frac{1}{2}[\![1, 0]\!] - \frac{1}{2}[\![0, 1]\!]. \tag{38}$$

We therefore have a crucial interest in the moves v_ϵ. However, it is mathematically simpler to instead study the family of moves

$$t_\tau \quad := \quad 2 \cdot [\![1, 1]\!] - [\![2 - \tau, 0]\!] - [\![0, 2 - \tau]\!] \tag{39}$$

for $0 < \tau < 1$. Note that if $\tau = 4\epsilon/(1 + 2\epsilon)$, then

$$v_\epsilon(x, y) \quad = \quad \frac{1}{2} t_\tau((2 - \tau)x, (2 - \tau)y), \tag{40}$$

and so (using Proposition 3.6), valid TIPGs for v_ϵ correspond exactly to valid TIPGs for t_τ via the same linear transformation.

If $R = (r_1, r_2)$ is a valid TIPG such that $r_1 + r_2 = t_\tau$, then we must have $\widehat{r_1} + \widehat{r_2} = \widehat{t_\tau}$. The profile function $\widehat{t_\tau}$ can be expressed as follows.

$$\widehat{t_\tau}(\alpha, \beta) \quad = \quad \begin{cases} 2 & \text{if } \alpha, \beta \geq 2 \\ 2 - P_{2-\tau}(\alpha) & \text{if } \alpha \geq 2, \beta < 2 \\ 2 - P_{2-\tau}(\beta) & \text{if } \alpha < 2, \beta \geq 2 \\ 0 & \text{if } \alpha, \beta < 2 \end{cases} \tag{41}$$

A graph of an example (with $\tau = 1/10$) is given in Figure 4.

5 Highly concentrated rational functions

This section adapts known complex analysis techniques to prove a result that will be needed in section 7.[2] I am grateful to Alexandre Eremenko for showing me the central method used in this section.

We will be concerned with rational functions on an interval $[a, b]$ that are highly concentrated — that is, rational functions that are significantly large at some interior point $c \in [a, b]$ and are more tightly bounded outside of a small neighborhood of c. Our interest (eventually) will be in studying deductions that we can make when such a function occurs in the profile of a move.

5.1 Preliminaries

We will first reproduce a standard result about the logarithm of the absolute value of an analytic function. We begin with the following observation: if f is an analytic function on a neighborhood of $\overline{\mathbb{D}}$ which has no zeroes in $\overline{\mathbb{D}}$, then there is a well-defined analytic function $\log f$ on a neighborhood of $\overline{\mathbb{D}}$ such that $2^{\log f} = f$. We have (see subsection 2.1):

$$\frac{1}{2\pi} \int_0^{2\pi} \log f(e^{it}) dt \quad = \quad \log f(0). \tag{42}$$

Since the real part of $\log f(z)$ is precisely $\log |f(z)|$, this proves the following.

Proposition 5.1. *Let f be an analytic function on an open neighborhood of $\overline{\mathbb{D}}$ such that f has no zeroes in $\overline{\mathbb{D}}$. Then,*

$$\log |f(0)| \quad = \quad \frac{1}{2\pi} \int_0^{2\pi} \log \left| f(e^{it}) \right| dt. \quad \square \tag{43}$$

For the result that we will prove in subsection 5.2, we will need a similar statement that addresses the case where f is permitted to have zeroes in $\overline{\mathbb{D}}$ and may not be analytic on $\mathbb{S}$. This motivates a somewhat more intricate claim. Let us say that a real-valued function on the unit circle $\mathbb{S}$ is a **step function** if it is locally constant at all but a finite number of points in $\mathbb{S}$. A proof of the following proposition is given in Appendix A.1.

Proposition 5.2. *Let f be a continuous function on $\overline{\mathbb{D}}$ which is analytic on $\mathbb{D}$. Suppose that $b \colon \mathbb{S} \to \mathbb{R}$ is a step function such that $\log |f(z)| \leq b(z)$ for any $z \in \mathbb{S}$. Then,*

$$\log |f(0)| \quad \leq \quad \frac{1}{2\pi} \int_0^{2\pi} b(e^{it}) dt. \quad \square \tag{44}$$

5.2 The complex values of a highly concentrated rational function

We will now prove the main result of this section. This result is concerned with rational functions that have real poles — that is, functions $f \colon \mathbb{C} \cup \{\infty\} \to \mathbb{C} \cup \{\infty\}$ that can be expressed in the form

$$f(z) \quad = \quad \frac{g(z)}{\prod_{i=1}^n (z - c_i)}, \tag{45}$$

where $g(z)$ is a polynomial and $c_i \in \mathbb{R}$. We will show that under certain assumptions, these functions must take on large values on the complex unit circle.

Recall that if A and B are sets and $B \subseteq A$, then we write $A \smallsetminus B$ for the set of all elements in A that are not in B.

Proposition 5.3. *Let $f(z)$ be a rational function whose poles are all real and lie outside of $[-1, 1]$. Suppose that*

$$|f(0)| = 1, \tag{46}$$

and suppose that $\delta, \nu \in (0, 1)$ are such that

$$|f(z)| \leq \nu \qquad \textit{for all } z \in [-1, 1] \smallsetminus (-\delta, \delta). \tag{47}$$

[2] See sections III.1–III.2 in [21] for a more general discussion of some of the techniques used in the current section.

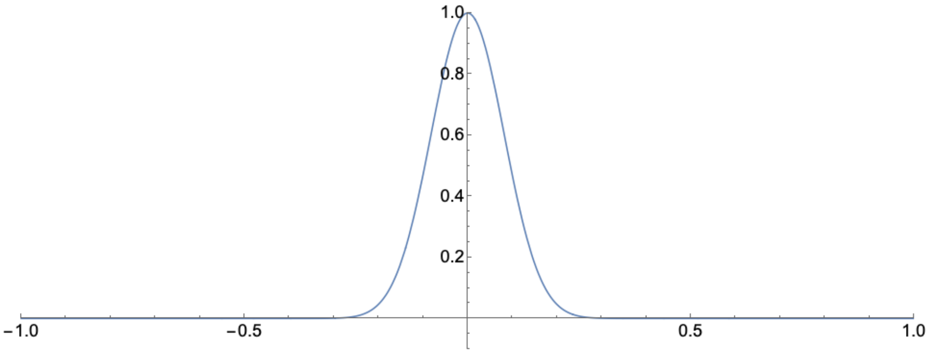

Figure 5: A graph over the interval $[-1, 1]$ of the example function in equation (49).

Then,

$$\max_{|z|=1} |f(z)| \quad \geq \quad \nu^{-\Omega(1/\delta)}. \tag{48}$$

We illustrate the statement above with an example. Let

$$h(z) \quad = \quad \left[\frac{4(z-1)(z+1)}{(z-2)(z+2)} \right]^{100}. \tag{49}$$

This function, which is graphed in Figure 5, satisfies $|h(0)| = 1$ and

$$|h(z)| \leq 0.1 \qquad \text{for all } z \in [-1,1] \smallsetminus (-0.2, 0.2). \tag{50}$$

The quantity $\max_{|z|=1} |h(z)|$ in this case is indeed quite large (on the order of 10^{20}).

Proof of Proposition 5.3. Our approach is to apply an analytic transformation which maps the unit circle $\mathbb{S}$ to the set

$$\mathbb{S} \cup ([-1,1] \smallsetminus (-\delta, \delta)) \tag{51}$$

and to thereby reduce the proof to an application of Proposition 5.2 above.

Let $G \colon \overline{\mathbb{D}} \to \overline{\mathbb{H}}$ be defined by

$$G(z) \quad = \quad i \cdot \frac{1+z}{1-z}. \tag{52}$$

Note that this function is a one-to-one mapping. Its inverse is given by

$$G^{-1}(z) \quad = \quad \frac{z-i}{z+i}. \tag{53}$$

Let $F \colon \overline{\mathbb{H}} \to \overline{\mathbb{H}}$ be the continuous function[3]

$$F(z) \quad = \quad \sqrt{\frac{z^2 |G(\delta)|^2 - 1}{|G(\delta)|^2 - z^2}}. \tag{54}$$

The function F maps ∞ to $G(\delta)$, maps 0 to $G(-\delta) = 1/G(\delta)$, and maps i to i. (Diagrams of F and G are given in Appendix A.2.) The image of $\mathbb{R} \cup \{\infty\}$ under F is the union of $\mathbb{R} \cup \{\infty\}$ together with the line segment from $G(\delta)$ to ∞, and the line segment from $G(-\delta)$ to 0.

[3] The rational function $z \mapsto \left(\frac{z^2 |G(\delta)|^2 - 1}{|G(\delta)|^2 - z^2} \right)$ on $\overline{\mathbb{H}}$ has two continuous square roots. We let F be the square root which maps $\overline{\mathbb{H}}$ into itself.

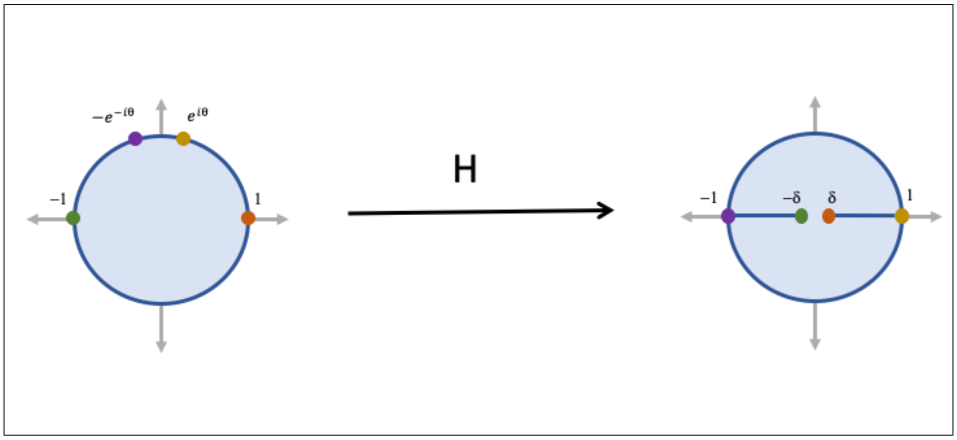

Figure 6: A diagram of the map H.

Now let H be defined by

$$H(z) = G^{-1}(F(G(z))). \tag{55}$$

Then,

$$\begin{aligned} H(0) &= 0 \qquad (56)\\ H(1) &= \delta \qquad (57)\\ H(-1) &= -\delta. \qquad (58)\end{aligned}$$

The image of the unit circle under H consists of the unit circle, the line segment from -1 to $-\delta$, and the line segment from δ to 1. Additionally, if we let $\theta \in [0, \pi/2]$ denote the angle of the unit-length complex number

$$\frac{i+\delta}{1+i\delta}, \tag{59}$$

then the following hold by direct computation:

$$\begin{aligned} H\left(e^{i\theta}\right) = H\left(e^{-i\theta}\right) &= 1 \qquad (60)\\ H\left(-e^{-i\theta}\right) = H\left(-e^{i\theta}\right) &= -1. \qquad (61)\end{aligned}$$

The points on the unit circle which lie clockwise between $e^{-i\theta}$ and $e^{i\theta}$ are mapped into the real interval $[\delta, 1]$, and the points which lie clockwise between $-e^{-i\theta}$ and $-e^{i\theta}$ are mapped into the real interval $[-1, -\delta]$. All other points on the unit circle remain on the unit circle under the application of H. A diagram of H is given in Figure 6.

We now compute upper bounds on the function $z \mapsto |f(H(z))|$. Let $M = \max_{|z|=1} |f(z)|$. Then, by our construction,

$$\begin{aligned} \log \left| f(H(e^{i\chi})) \right| &\leq \log M \qquad \text{if } \chi \in (\theta, \pi-\theta) \cup (\pi+\theta, 2\pi-\theta), \qquad (62)\\ \log \left| f(H(e^{i\chi})) \right| &\leq \log \nu \qquad \text{if } \chi \in [-\theta, \theta] \cup [\pi-\theta, \pi+\theta]. \qquad (63)\end{aligned}$$

Let $T\colon [0, 2\pi] \to \mathbb{R}$ be defined by

$$T(\chi) = \begin{cases} \log M & \text{if } \chi \in (\theta, \pi-\theta) \cup (\pi+\theta, 2\pi-\theta) \\ \log \nu & \text{otherwise.} \end{cases} \tag{64}$$

Then, applying Proposition 5.2,

$$\begin{aligned}\log|f(0)| &= \log|f(H(0))| && (65)\\ &\leq \frac{1}{2\pi}\int_0^{2\pi} T(s)ds && (66)\\ &= \left(1-\frac{2\theta}{\pi}\right)\log M + \left(\frac{2\theta}{\pi}\right)\log\nu. && (67)\end{aligned}$$

To complete the proof, it suffices to note that the quantity (59), which was used to define θ, is within distance $O(\delta)$ from the complex number i. Therefore, θ itself is within distance $O(\delta)$ from $\pi/2$. Thus we obtain

$$\log|f(0)| \leq O(\delta)(\log M) + (1-O(\delta))\log\nu. \qquad (68)$$

Since $\log|f(0)| = 0$ by assumption, we therefore have

$$\frac{-\log\nu}{O(\delta)} \leq \log M, \qquad (69)$$

which yields the desired result. □

We give a brief discussion to show how Proposition 5.3 can be useful for our purposes. Suppose that ℓ is a one-dimensional move such that

$$\widehat{\ell}(4) = 1 \qquad (70)$$

and that $\delta, \nu \in (0,1)$ are such that the inequality $\left|\widehat{\ell}(\alpha)\right| \leq \nu$ is always satisfied when

$$\alpha \in [3,5] \smallsetminus (4-\delta, 4+\delta). \qquad (71)$$

Then, for any $\alpha \in [3,5]$, the rational expression for $\widehat{\ell}(\alpha)$ is given by

$$\widehat{\ell}(\alpha) = \sum_x \ell(x)\cdot\frac{x\alpha - x}{x+\alpha-2}. \qquad (72)$$

By Proposition 5.3, there exists a unit-length complex number ζ such that

$$\left|\sum_x \ell(x)\cdot\left(\frac{x(4+\zeta)-x}{x+(4+\zeta)-2}\right)\right| \geq \nu^{-\Omega(1/\delta)}. \qquad (73)$$

Therefore,

$$\begin{aligned}\nu^{-\Omega(1/\delta)} &\leq \sum_x |\ell(x)|\cdot\frac{|x(4+\zeta)-x|}{|x+(4+\zeta)-2|} && (74)\\ &\leq \sum_x |\ell(x)|\cdot\frac{|x(4+1)-x|}{|x+(4-1)-2|} && (75)\\ &\leq \sum_x |\ell(x)|\cdot 4. && (76)\end{aligned}$$

Thus we conclude that $\|\ell\|_1 \geq v^{-\Omega(1/\delta)}$. Informally, this means that a one-dimensional move ℓ can only achieve a profile that is highly concentrated around $x=4$ if ℓ has exponentially large coefficients. This is similar to reasoning that we will use in section 7.

6 A lemma on random variables with bounded expectation

The following elementary lemma addresses a case where two constraints on the expectation of a random variable approximately determine the value of the random variable. This lemma will be used (in the context of some artificially constructed random variables) in order to carry out an intermediate step in the main proof of section 7.

Lemma 6.1. *There exists a universal function* $\mathbf{A}(u) \in O(\sqrt{u})$ *such that the following holds. If* X *is any positive real-valued random variable satisfying*

$$\begin{aligned} \mathbb{E}[X] &\leq 1, && (77) \\ \mathbb{E}[1/X] &\leq 1 + \delta, && (78) \end{aligned}$$

with $\delta > 0$*, then*

$$\mathbb{P}(|X - 1| < \mathbf{A}(\delta)) \quad \geq \quad \frac{2}{3}. \tag{79}$$

Proof. We have

$$\mathbb{E}[X + 1/X - 2] \quad \leq \quad \delta, \tag{80}$$

and $X + 1/X - 2 \geq 0$. Therefore,

$$\mathbb{P}[X + 1/X - 2 \geq 3\delta] \quad \leq \quad \frac{1}{3}, \tag{81}$$

or equivalently,

$$\mathbb{P}[X^2 - (2 + 3\delta)X + 1 < 0] \quad \geq \quad \frac{2}{3}. \tag{82}$$

By the quadratic formula, the event on the left side of inequality (82) is equivalent to

$$\left| X - (1 + \frac{3}{2}\delta) \right| \quad < \quad \sqrt{3\delta + \frac{9}{4}\delta^2}. \tag{83}$$

Thus with probability at least 2/3, $|X - 1|$ is less than

$$\frac{3}{2}\delta + \sqrt{3\delta + \frac{9}{4}\delta^2}. \tag{84}$$

The function above is in $O(\sqrt{\delta})$, and this completes the proof. □

7 The 1-norm of a time-independent point game

This section will perform most of the remaining technical work necessary to achieve our main result. Throughout this section, suppose that $\tau \in (0, 1)$, and that g is a horizontally valid move such that $g + g^\top = t_\tau$, where t_τ denotes the following move (see subsection 4.2):

$$t_\tau \quad = \quad 2[\![1, 1]\!] - [\![2 - \tau, 0]\!] - [\![0, 2 - \tau]\!]. \tag{85}$$

In this section we will show that the inequality $\|g\|_1 \geq \exp(\Omega(\tau^{-1/2}))$ must always hold. This is the result that will be used in section 8 to conclude that any weak coin-flipping protocol that achieves bias ϵ must involve at least $\exp(\Omega(\epsilon^{-1/2}))$ communication rounds.

For any $b \geq 0$, let $g_b \colon \mathbb{R}_{\geq 0} \times \mathbb{R}_{\geq 0} \to \mathbb{R}$ denote the move defined by

$$g_b(x, y) \quad = \quad \begin{cases} g(x, y) & \text{if } y = b \\ 0 & \text{if } y \neq b. \end{cases} \tag{86}$$

(That is, g_b agrees with g on the horizontal line $y = b$, and is zero elsewhere.) Note that since g is horizontally valid, the profile function $\widehat{g_b}$ of g_b is always a nonnegative function.

7.1 Basic properties of g

By assumption, g is a horizontally valid move and its profile function $\widehat{g}$ satisfies

$$\widehat{g} + \widehat{g}^{\top} = \widehat{t_{\tau}}. \tag{87}$$

The function $\widehat{t_\tau}$ is written out explicitly in equations (41) and (22). The following facts are easily deduced.

Fact 7.1. *If $\alpha \in [2, \infty]$, then $\widehat{g}(\alpha, \alpha) = 1$.*

Fact 7.2. *If $\alpha, \beta \in [2, \infty]$, then $\widehat{g}(\alpha, \beta) \leq 2$.*

By Propositions 4.5 and 4.6, we have the following.

Fact 7.3. *If $\alpha \in [1, 2)$ and $\beta \in [1, \infty]$, then $\widehat{g}(\alpha, \beta) = 0$.*

Fact 7.4. *If $\alpha \in [2, \infty]$, then $\widehat{g}(\alpha, 1) = 2 - P_{2-\tau}(\alpha)$.*

Fact 7.5. *If $\alpha \in [2, \infty]$, then $\widehat{g}(\alpha, 2) \leq 2 - P_{2-\tau}(\alpha)$.*

It is easily seen from Definition 4.1 that for $\alpha \in [2, \infty]$,

$$\begin{aligned} P_{2-\tau}(\alpha) &\geq P_2(\alpha) - \tau \qquad (88)\\ &= \left(2 - \frac{2}{\alpha}\right) - \tau. \qquad (89)\end{aligned}$$

Thus from Fact 7.5 we have

Fact 7.6. *If $\alpha \in [2, \infty]$, then $\widehat{g}(\alpha, 2) \leq \frac{2}{\alpha} + \tau$.*

7.2 The isolating function

For any $a \in (2, \infty)$, we know (Fact 7.1) that

$$\sum_b \widehat{g_b}(a, a) = \widehat{g}(a, a) = 1, \tag{90}$$

and that each term $\widehat{g_b}(a, a)$ in the above summation is nonnegative. Our next goal is to show that the majority of the contribution to $\widehat{g}(a, a)$ comes from the terms $\widehat{g_b}(a, a)$ for which b is close to a. This is formally stated as follows.

Proposition 7.7. *There is a universal function $\mathbf{I}(u) \in O(\sqrt{u})$ such that for any $a \in [3, 5]$,*

$$\sum_{b : |b-a| < \mathbf{I}(\tau)} \widehat{g_b}(a, a) \quad \geq \quad \frac{2}{3}. \tag{91}$$

We note that the choice of the interval $[3, 5]$ in this statement is somewhat arbitrary — the proof method that follows can be used to prove the same statement over any interval $[p, q]$ for which $2 < p < q < \infty$ (with a different choice of function $\mathbf{I}$). The reason for making this type of restriction is that it facilitates calculations involving universal big-O error terms.

Proof of Proposition 7.7. Let Y be the stochastic map from $[3, 5]$ to $\mathbb{R}_{>0}$ defined by

$$\mathbb{P}(Y(a) = b) \quad = \quad \widehat{g_b}(a, a). \tag{92}$$

Note that by construction, for any $a \in [3, 5]$ and any $b > 0$, the function on $[1, \infty]$ defined by

$$\beta \quad \mapsto \quad \widehat{g_b}(a, \beta) \tag{93}$$

is a scalar multiple of the profile function of b (that is, $\beta \mapsto P_b(\beta)$). Therefore,

$$\widehat{g_b}(a, 2) = P_b(2) \cdot \frac{\widehat{g_b}(a, a)}{P_b(a)} = 1 \cdot \frac{\mathbb{P}(Y(a) = b)}{P_b(a)} \tag{94}$$

$$\widehat{g_b}(a, \infty) = P_b(\infty) \cdot \frac{\widehat{g_b}(a, a)}{P_b(a)} = b \cdot \frac{\mathbb{P}(Y(a) = b)}{P_b(a)} \tag{95}$$

which implies

$$\widehat{g}(a,2) = \mathbb{E}\left[\frac{1}{P_{Y(a)}(a)}\right] \tag{96}$$

$$\widehat{g}(a,\infty) = \mathbb{E}\left[\frac{Y(a)}{P_{Y(a)}(a)}\right], \tag{97}$$

where the expectations are taken over the random variable $Y(a)$. Expanding these expressions using the definition of the profile function, we have

$$\widehat{g}(a,2) = \mathbb{E}\left[\frac{Y(a)+a-2}{Y(a)\cdot a - Y(a)}\right] \tag{98}$$

$$= \mathbb{E}\left[\left(\frac{1}{a-1}\right) + \left(\frac{1}{Y(a)}\right)\left(\frac{a-2}{a-1}\right)\right] \tag{99}$$

and

$$\widehat{g}(a,\infty) = \mathbb{E}\left[Y(a)\left(\frac{1}{a-1}\right) + \left(\frac{a-2}{a-1}\right)\right]. \tag{100}$$

By Fact 7.6 and Fact 7.2,

$$\widehat{g}(a,2) \leq \frac{2}{a} + \tau, \tag{101}$$

$$\widehat{g}(a,\infty) \leq 2. \tag{102}$$

Combining the above two inequalities with formulas (99) and (100) above yields

$$\mathbb{E}\left[\left(\frac{1}{Y(a)}\right)\left(\frac{a-2}{a-1}\right)\right] \leq \frac{a-2}{a(a-1)} + \tau \tag{103}$$

$$\mathbb{E}\left[Y(a)\left(\frac{1}{a-1}\right)\right] \leq \frac{a}{a-1}. \tag{104}$$

Multiplying the equations above by $[a(a-1)/(a-2)]$ and $[(a-1)/a]$ respectively, we obtain

$$\mathbb{E}\left[\frac{a}{Y(a)}\right] \leq 1 + 7\tau \tag{105}$$

$$\mathbb{E}\left[\frac{Y(a)}{a}\right] \leq 1, \tag{106}$$

where, in (105), we used the fact that the function $a \mapsto [a(a-1)/(a-2)]$ on the interval $[3,5]$ does not exceed 7.

If we let $\mathbf{A}(u)$ be the function from Lemma 6.1, then

$$\mathbb{P}\left(\left|\frac{Y(a)}{a} - 1\right| < \mathbf{A}(7\tau)\right) \geq \frac{2}{3}. \tag{107}$$

Therefore,

$$\mathbb{P}\left(|Y(a) - a| < a\mathbf{A}(7\tau)\right) \geq \frac{2}{3}. \tag{108}$$

Letting $\mathbf{I}(u) := 5\mathbf{A}(7u)$ therefore yields

$$\mathbb{P}\left(|Y(a) - a| < \mathbf{I}(\tau)\right) \geq \frac{2}{3} \tag{109}$$

for any $a \in [3,5]$. By the definition of the stochastic map Y, this implies the desired result. □

We refer to $\mathbf{I}$ as the **isolating function**.

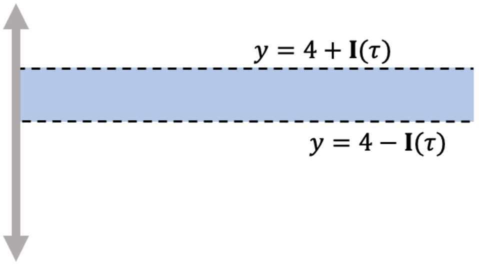

Figure 7: The move $\mathbf{g}$ is supported within the shaded blue region.

7.3 A lower bound on $\|g\|_1$

We are now ready to prove a lower bound on $\|g\|_1$ in terms of τ. We accomplish this by studying the behavior of the part of the move g that is concentrated near the horizontal line $y = 4$. Precisely, we will be concerned with the move

$$\mathbf{g} \quad := \quad \sum_{b : |b-4| < \mathbf{I}(\tau)} g_b, \tag{110}$$

where $\mathbf{I}$ is the isolating function from subsection 7.2. (See Figure 7.)

Proposition 7.8. *For all $a \in [3,5]$ such that $|a-4| \geq 2\mathbf{I}(\tau)$, we must have*

$$\widehat{\mathbf{g}}(a,a) \quad \leq \quad \frac{1}{3}. \tag{111}$$

Proof. For any such a, the move

$$\sum_{b : |b-a| < \mathbf{I}(\tau)} g_b, \tag{112}$$

has disjoint support from that of $\mathbf{g}$. The sum of the profile of (112) and the profile of $\mathbf{g}$ is therefore upper bounded by the profile of g. By Proposition 7.7 and Fact 7.1, we have $\widehat{\mathbf{g}}(a,a) \leq \frac{1}{3}$, as desired. □

Proposition 7.9. *The* 1*-norm $\|g\|_1$ of g satisfies*

$$\|g\|_1 \quad \geq \quad \exp(\Omega(\tau^{-1/2})). \tag{113}$$

Proof. Consider the function on $(2,\infty)$ given by

$$z \quad \mapsto \quad \widehat{\mathbf{g}}(z,z). \tag{114}$$

This function can be written out explicitly as follows:

$$z \quad \mapsto \quad \sum_{x,y} \mathbf{g}(x,y) \cdot \frac{xz - x}{x + z - 2} \cdot \frac{yz - y}{y + z - 2} \tag{115}$$

Let $D \colon \mathbb{C} \cup \{\infty\} \to \mathbb{C} \cup \{\infty\}$ denote the complex-valued rational function given by expression (115). By Propositions 7.7 and 7.8, the function D satisfies $D(4) \geq 2/3$, and $0 \leq D(z) \leq 1/3$ for all z in the set

$$[3,5] \smallsetminus (4 - 2\mathbf{I}(\tau), 4 + 2\mathbf{I}(\tau)). \tag{116}$$

Applying Proposition 5.3 (with appropriate affine transformations), we find that there exists a unit-length complex number ζ such that

$$\begin{aligned} |D(4+\zeta)| \quad &\geq \quad \exp(\Omega(1/\mathbf{I}(\tau)) && (117) \\ &\geq \quad \exp(\Omega(\tau^{-1/2})). && (118) \end{aligned}$$

Next we obtain an upper bound on $|D(4+\zeta)|$ in terms of $\|g\|_1$. We have

$$|D(4+\zeta)| \quad \leq \quad \sum_{x,y} |\mathbf{g}(x,y)| \cdot \left| \frac{x(4+\zeta)-x}{x+(4+\zeta)-2} \right| \cdot \left| \frac{y(4+\zeta)-y}{y+(4+\zeta)-2} \right|. \tag{119}$$

It is easy to see that the second and third factors in the summand above are each no more than 4. Therefore,

$$|D(4+\zeta)| \quad \leq \quad 16\,\|\mathbf{g}\|_1 \tag{120}$$

$$\leq \quad 16\,\|g\|_1\,. \tag{121}$$

Combining the above bound with inequality (118) above yields the desired result. □

8 Main result

We can now tie together the results of section 3 and section 7 to achieve our main result.

Proposition 8.1. *Let $\epsilon \in (0, \frac{1}{2})$, and suppose that $M = (m_1, m_2)$ is a valid time-independent point game such that*

$$m_1 + m_2 \quad = \quad \left[\!\!\left[\frac{1}{2}+\epsilon, \frac{1}{2}+\epsilon \right]\!\!\right] - \frac{1}{2}\cdot [\![1,0]\!] - \frac{1}{2}\cdot [\![0,1]\!]. \tag{122}$$

Then,

$$\|m_1\|_1 + \|m_2\|_1 \quad \geq \quad \exp(\Omega(\epsilon^{-1/2})). \tag{123}$$

Proof. Define moves m_1', m_2' by

$$m_i'(x,y) \quad = \quad 2m_i\left(x\left(\frac{1}{2}+\epsilon\right), y\left(\frac{1}{2}+\epsilon\right)\right). \tag{124}$$

Then, (m_1', m_2') is a valid TIPG which achieves the move $2[\![1,1]\!] - [\![2-\tau, 0]\!] - [\![0, 2-\tau]\!]$, where $\tau = 4\epsilon/(1+2\epsilon)$. Moreover, if we let $m' = [m_1' + (m_2')^\top]/2$, then $(m', (m')^\top)$ is a symmetric valid TIPG that achieves the same move. By Proposition 7.9,

$$\|m'\|_1 \quad \geq \quad \exp(\Omega(\tau^{-1/2})). \tag{125}$$

It is obvious that $\|m_1\|_1 + \|m_2\|_1 \geq \|m'\|_1$ and that $\tau \leq O(\epsilon)$. This completes the proof. □

Theorem 8.2. *Suppose that $\mathbf{C}$ is an n-round weak coin-flipping protocol with cheating probabilities $P_A^* \leq \frac{1}{2}+\epsilon$ and $P_B^* \leq \frac{1}{2}+\epsilon$. Then,*

$$n \quad \geq \quad \exp(\Omega(\epsilon^{-1/2})). \tag{126}$$

Proof. Combining Proposition 8.1 with Theorem 3.11, we find that for any $\delta > 0$,

$$n \quad \geq \quad \exp(\Omega((\epsilon+\delta)^{-1/2})). \tag{127}$$

Since the above inequality is true for any positive real number δ, the desired result follows. □

9 Further directions

A natural next step would be to compute an explicit function which would serve as a lower bound for n in Theorem 8.2. This is a matter of tracing through the steps of the proof, and should not be difficult. Explicit bounds on n will open the door to searching for quantum weak coin-flipping protocols that are optimized for the number of communication rounds (at a particular bias ϵ).

One can also try to lower bound the amount of quantum memory needed to achieve weak coin-flipping for a given bias. As discussed in [1], the quantum memory used by a protocol is related to the size of the support of its point games. Some of the same techniques used in this paper might be applicable to proving lower bounds on quantum memory size.

Can a related impossibility result be proved for strong quantum coin-flipping? A. Kitaev showed that any strong coin-flipping protocol must have bias at least $\frac{\sqrt{2}}{2} - \frac{1}{2} \approx 0.207$. Meanwhile, Chailloux and Kerenidis [9] proved, by building on Mochon's work on quantum weak coin flipping with vanishing bias [19], that strong coin-flipping is possible with bias arbitrarily close to $\frac{\sqrt{2}}{2} - \frac{1}{2}$. One could try to prove that strong coin-flipping with bias approaching $\frac{\sqrt{2}}{2} - \frac{1}{2}$ requires a large amount of communication.

Lastly, I will note that although we have found that the moves (39) that define quantum coin-flipping are exponentially hard to achieve by valid point games, my experience so far suggests this is a uniquely difficult family of moves. It may be worth exploring whether there are other simple classes of moves that can be more easily achieved by valid point games, and exploring whether such classes could have applications to positive results in two-party cryptography.

A Appendices

A.1 Proof of Proposition 5.2

We state some elementary facts.

Fact A.1. *If f is an analytic function on an open neighborhood of a compact set $R \subseteq \mathbb{C}$, and f is not the zero function, then f has only a finite number of zeroes in R.*

Fact A.2. *If $f : \overline{\mathbb{D}} \to \mathbb{C}$ is a continuous function, then the family of functions on $\mathbb{S}$ given by*

$$z \mapsto f(cz), \tag{128}$$

for $c \in [0, 1]$, converges uniformly to $f_{|\mathbb{S}}$ as $c \to 1$.

We next prove modified versions of Proposition 5.1.

Proposition A.3. *Let f be an analytic function on an open neighborhood of $\overline{\mathbb{D}}$ such that f has no zeroes on the unit circle $\mathbb{S}$. Then,*

$$\log |f(0)| \quad \leq \quad \frac{1}{2\pi} \int_0^{2\pi} \log \left| f(e^{it}) \right| dt. \tag{129}$$

Proof. The function $f(z)$ can be written as $f(z) = f_1(z) f_2(z)$, where f_1 is a polynomial with roots in $\mathbb{D}$, and f_2 has no zeroes on $\overline{\mathbb{D}}$. By Proposition 5.1,

$$\log |f_2(0)| \quad = \quad \frac{1}{2\pi} \int_0^{2\pi} \log \left| f_2(e^{it}) \right| dt, \tag{130}$$

while direct computation shows that

$$\log |f_1(0)| \quad \leq \quad \frac{1}{2\pi} \int_0^{2\pi} \log \left| f_1(e^{it}) \right| dt. \tag{131}$$

Summing equation (130) and inequality (131) yields the desired result. □

By affine transformation, we have the following corollary.

Corollary A.4. *Let f be an analytic function on an open neighborhood of a closed disc $\overline{\mathbb{D}}(z, r)$ such that f has no zeroes on $\mathbb{S}(z, r)$. Then,*

$$\log |f(z)| \quad \leq \quad \frac{1}{2\pi} \int_0^{2\pi} \log \left| f(z + re^{it}) \right| dt. \quad \square \tag{132}$$

Now we will prove the desired result.

Proof of Proposition 5.2. If f is the zero function, then Proposition 5.2 is trivial, so we will assume that f is not identically zero. Take any $\delta > 0$. By Fact A.2 above, we can find $\epsilon > 0$ such that the following inequality holds on the annulus $\overline{\mathbb{D}} \smallsetminus \mathbb{D}(0, 1-\epsilon)$:

$$\left| f(z) - f\left(\frac{z}{|z|}\right) \right| \quad \leq \quad \delta. \tag{133}$$

Choose (using Fact A.1) a real number $\zeta \in [\epsilon/2, \epsilon]$ such that f has no zeroes on $\mathbb{S}(0, 1-\zeta)$. Then, applying Corollary A.4,

$$\begin{aligned} \log|f(0)| &\leq \frac{1}{2\pi}\int_0^{2\pi} \log\left| f((1-\zeta)e^{it})\right| dt & (134)\\ &\leq \frac{1}{2\pi}\int_0^{2\pi} \log\left(\left| f(e^{it})\right| + \delta\right) dt & (135)\\ &\leq \frac{1}{2\pi}\int_0^{2\pi} \log\left(2^{b(e^{it})} + \delta\right) dt. & (136)\end{aligned}$$

Since the upper bound (136) holds for any $\delta > 0$, the desired claim follows. □

***Abstract*—Dynamic spectrum access (DSA) to achieve spectrum sharing in unlicensed bands is a promising approach for meeting the growing demands of forthcoming and deployed wireless networks, such as long-term evolution license-assisted access (LTE-LAA) and IEEE 802.11 Wi-Fi systems. In this paper, we consider a coexistence scenario where multiple LAA and Wi-Fi links compete for spectrum sharing subchannel access. We introduce a reinforcement-learning-based subchannel selection technique which allows access points (APs) and eNBs to select best subchannel distributively considering their medium access control (MAC) channel access protocols along with the physical layer parameters. The performance of this scheme is investigated through simulations, including the convergence property and sum throughput. Numerical results show that the proposed reinforcement-learning scheme converges fast and the sum throughput of the LAA and Wi-Fi systems is reasonably close to the result based on exhaustive search.**

***Index Terms*—5G and beyond, artificial intelligence, coexistence, LTE-LAA, MAC layer, PHY layer, Q-learning, WLAN.**

I. Introduction

Wireless communications are tightly integrated into our daily lives and promise to become more so in the future. Cisco Systems forecasts 3.6 mobile-connected devices per person by 2022 and a 7-fold increase in global mobile data traffic between 2017 and 2022 [1]. A promising approach to accommodating this growth is to transition from exclusively-licensed spectrum to a shared one, which offloads into unlicensed spectrum bands. One difficulty in this approach is balancing new network paradigms with incumbent networks, such as Wi-Fi.

Operating long term evolution (LTE) in unlicensed bands, such as with licensed assisted access (LAA), is a proposed solution to improve spectral-usage efficiency [2]. While such wireless coexistence proposals may have an enormous influence in solving spectrum usage issues, there are a number of challenges for both Wi-Fi and LTE networks to constructively share the spectrum. Assigning the spectrum in an intelligent and adaptive way may satisfy the diverse networks' requirements, build up an effective sharing of spectrum, and help to design future radio technologies (e.g., 5G NR-U [3]).

Innovations in artificial intelligence (AI) and machine learning (ML) are transformative in many industries. Wireless networking is also poised to benefit from these advances. For example, future 5G and beyond mobile devices are expected to access optimal spectral bands using highly-developed spectrum learning and inference. However, future networks will be immensely more intricate owing to complex network typologies and coordination schemes facilitating various end-user applications. Hence, it is computationally difficult for these future mobile devices to optimize key performance indicators (KPIs), such as throughput. Even more difficult to determine are strategies for efficient network management taking spectrum sharing into account. Nonetheless, as we demonstrate below, data-driven and adaptive machine learning algorithms are able to combat some of these difficulties to improve network performance.

Reinforcement learning (RL) is an area of ML and optimization which is well-suited to learning about dynamic and unknown environments [4]–[13]. It is especially suited to solving problems related to coexistence of wireless communications devices, as demonstrated by recent research. These works have been done mostly in the context of cognitive radio networks (CRNs). For example, [4] applied RL to estimate optimal channel access strategies for a single secondary user (SU) who dynamically selects one channel out of some number N channels. In [5], the authors assumed there is no primary user (PU) and applied RL to determine channel allocation for each SU without considering any collision with the PU. In [6], it was shown that the sensing capability, and therefore the transmission ability, could be enhanced for SUs with the proposed multi-agent RL (MARL)-based channel allocation. In [7], a MARL-based power control strategy was introduced to speed up the learning process of energy harvesting in communication systems.

A learning approach that accounts for the coexistence of LTE-U to model the resource allocation problem in LTE-U small stations (SBS), has been studied in [8], [9]. Specifically, to determine fair coexistence between LTE and Wi-Fi in the unlicensed spectrum, a Q-learning algorithm is applied in [8]. In [9] an RL algorithm based on long short-term memory (RL-LSTM) learning architecture was proposed to allocate the resources of LTE-U over the unlicensed spectrum. The most similar prior works ([10]–[13]) also used techniques from adaptive and reinforcement learning to study coexistence problems between Wi-Fi and other radio access technologies

Mosleh, Susanna; Ma, Yao; Rezac, Jake; Coder, Jason. "Dynamic Spectrum Access with Reinforcement Learning for Unlicensed Access in 5G and Beyond." Paper presented at 2020 IEEE 91st Vehicular Technology Conference: VTC2020-Spring, Antwerp, BE. May 25, 2020 - May 28, 2020.

(RATs). An adaptive MAC protocol for wireless sensor networks was proposed in [10], while the authors of [11] proposed a channel-selection method among LTE-U networks given only physical layer parameters. A learning method to select the duty cycle of LTE-U networks was presented in [12], [13].

The main contribution of our study is a novel reinforcement learning-based carrier-selection technique designed to ease the concurrent operation of Wi-Fi and LAA networks in unlicensed bands. Specifically, we use a Q-learning algorithm to select the spectrum in which a transmission node will operate based on self-learning experience. These transmission nodes each learn to maximize total network throughput without communicating with each other. Unlike earlier research on this topic [10]–[13], we take into account both MAC and physical layers and study the coexistence of two different types of network (LAA and Wi-Fi) operating simultaneously. To better reflect reality, we assumed there are different types of networks in which each base station serves several users. We consider the effects of collision between transmitting nodes. Moreover, in order to have a fully distributed strategy, there is neither a centralized controller in the network nor any information explicitly exchanged between different operators. The proposed algorithm enables both networks to constructively share the unlicensed spectrum and increase achieved data rates. It is worth noting that the introduced Q-learning algorithm could be applied to many types of communication systems, but LTE here is used as an example.

The remainder of this paper is organized as follows. Section II describes the system model and assumptions required for our analysis. Section III presents the problem formulation and introduces our proposed intelligent dynamic spectrum access. The impacts of the MAC and physical layer parameters in selecting a channel in a coexistence scenario is also explained in Section III. Simulation results are shown and discussed in Section IV. Finally, in Section V, an overview of the results and some concluding remarks are presented.

II. System Model

We consider a downlink coexistence scenario where two mobile network operators (MNOs) share for their operations the same unlicensed industrial, scientific, and medical (ISM) radio band. We are primarily interested in the operation of cellular base stations in an unlicensed band. However, the LTE base stations may have permission to utilize a licensed band as well. We assume each unlicensed band, indexed by $k \in \mathcal{K} \triangleq \{1, 2, \ldots, K\}$, can be shared between the MNOs in a time sharing fashion. The LAA network consists of n_L eNodeBs, while the Wi-Fi network is composed of n_W APs. The eNodeBs and APs are randomly distributed over a particular area, while LAA user equipment (UEs) and Wi-Fi clients/stations (STAs) are distributed around each eNodeB and AP, respectively, independently and uniformly. The transmission node $i \in \{\mathcal{L}, \mathcal{W}\}$, where $\mathcal{L} \triangleq \{n_\ell | \ell = 1, 2, \ldots, L\}$ and $\mathcal{W} \triangleq \{n_w | w = 1, 2, \ldots, W\}$, serves a set of $|\mathcal{U}_i|$ single antenna UEs/STAs on the unlicensed band, where $\mathcal{U}_i \triangleq \{u_{i,1}, u_{i,2}, \ldots, u_{i,|\mathcal{U}_i|}\}$. We assume that the transmission node i transmits with power p_i and the user association is based on the received power. Moreover, in order to meet the diverse network's requirement, we assume that eNodeBs may belong to different LTE operators with different priority classes (PCs) as introduced by the 3GPP standards committee [14]. Similarly, APs may belong to different Wi-Fi operators with four different access categories (ACs) [15]. We also assume *(i)* both Wi-Fi and LAA are in the saturated traffic condition, *(ii)* there is no hidden node problem[1] in the network (*i.e.,* every transmission node i is able to hear one another), and *(iii)*, the channel knowledge is ideal, so, the only source of packet failure (unsuccessful transmission) is collision.

Medium access in Wi-Fi is based on contention with random back-off. This process is known as carrier sense multiple access with collision avoidance (CSMA/CA) [16], [17]. In order to discover whether the channel is idle or busy, the station that accesses the medium should sense the channel by performing clear channel assessment (CCA). The distributed coordination function (DCF) operation progresses if the channel is found out to be idle. Otherwise, the transmitting station refrains from transmitting data until it senses the channel is available. Similarly, LTE-LAA uses a listen before talk (LBT) channel access mechanism to maintain fair coexistence with the Wi-Fi. Among different LAA-LBT schemes, Cat 4 LBT, which is based on the Wi-Fi CSMA/CA scheme, is well-suited to coexistence [2]. Although LTE and Wi-Fi technologies follow the same channel access procedure, they select different carrier sense mechanisms, different channel sensing threshold levels, and different channel contention parameters, leading to different unlicensed channel access probabilities and thus, different throughput.

In this section, we will briefly derive the normalized network throughput of both systems on each unlicensed band, a quantity we aim to optimize below. Conforming with the analytical model in [18], the probability of packet transmission by a transmitting node i in a randomly-chosen time slot on the k-th unlicensed channel can be written as

$$p_{\text{tr},i}^{(k)} = \frac{2(1-2p_{c,i}^{(k)})}{(1-2p_{c,i}^{(k)})(1+\text{CW}_{\min,i}^{(k)})+p_{c,i}^{(k)}\text{CW}_{\min,i}^{(k)}(1-(2p_{c,i}^{(k)})^{m_i^{(k)}})}, \quad (1)$$

where $\text{CW}_{\min,i}^{(k)}$ and $m_i^{(k)}$ are the minimum contention window size and the maximum back-off stage of the transmitting node i on the unlicensed band k, respectively, and $p_{c,i}^{(k)}$ is the probability of collision experienced by the i-th transmitting node on the k-th unlicensed channel. The probability of collision experienced by n_w AP and n_ℓ eNodeB can be expressed as

$$\begin{aligned} p_{c,n_w}^{(k)} &= 1 - \prod\nolimits_{\acute{w} \neq w} (1 - p_{\text{tr},n_{\acute{w}}}^{(k)}) \prod\nolimits_{\ell} (1 - p_{\text{tr},n_\ell}^{(k)}), \\ p_{c,n_\ell}^{(k)} &= 1 - \prod\nolimits_{w} (1 - p_{\text{tr},n_w}^{(k)}) \prod\nolimits_{\acute{\ell} \neq \ell} (1 - p_{\text{tr},n_{\acute{\ell}}}^{(k)}), \qquad (2) \end{aligned}$$

respectively, where $\acute{w} = 1, \ldots, W$ and $\acute{\ell} = 1, \ldots, L$.

[1] Here, we assume perfect spectrum sensing in both systems. Therefore, there are neither hidden nodes nor false alarm/miss detection problems in the network. The impact of imperfect sensing is beyond the scope of this paper and investigating the effect of CCA errors is an important topic for future work.

The probability of collision can be split into three parts: the probability of collision due to the collision between the Wi-Fi transmissions, between the LAA transmissions, and between the Wi-Fi and the LAA transmissions, respectively given by

$$p^{(k)}_{c,\mathcal{W}} = (1 - p^{(k)}_{tr,\mathcal{L}})\big[p^{(k)}_{tr,\mathcal{W}} - \sum\nolimits_{w} p^{(k)}_{\text{tr},n_w} \prod\nolimits_{\acute{w}\neq w}(1 - p^{(k)}_{\text{tr},n_{\acute{w}}})\big],$$
$$p^{(k)}_{c,\mathcal{L}} = (1 - p^{(k)}_{tr,\mathcal{W}})\big[p^{(k)}_{tr,\mathcal{L}} - \sum\nolimits_{\ell} p^{(k)}_{\text{tr},n_\ell} \prod\nolimits_{\acute{\ell}\neq \ell}(1 - p^{(k)}_{\text{tr},n_{\acute{\ell}}})\big],$$

and $p^{(k)}_{c,\mathcal{W},\mathcal{L}} = p^{(k)}_{tr,\mathcal{L}} \cdot p^{(k)}_{tr,\mathcal{W}}$. Here $p^{(k)}_{tr,\mathcal{L}} = 1 - \prod_{\ell=1}^{L}(1 - p^{(k)}_{\text{tr},n_\ell})$ and $p^{(k)}_{tr,\mathcal{W}} = 1 - \prod_{w=1}^{W}(1 - p^{(k)}_{\text{tr},n_w})$ denote the LAA's and Wi-Fi's probability of transmission on the k-th unlicensed channel, respectively. Moreover, the probability of a successful transmission by the i-th transmitter on the k-th unlicensed band can be written as

$$p^{(k)}_{s,n_w} = p^{(k)}_{\text{tr},n_w} \prod\nolimits_{\acute{w}\neq w}(1 - p^{(k)}_{\text{tr},\acute{w}}) \prod\nolimits_{\ell}(1 - p^{(k)}_{\text{tr},n_\ell}),$$
$$p^{(k)}_{s,n_\ell} = p^{(k)}_{\text{tr},n_\ell} \prod\nolimits_{\acute{\ell}\neq \ell}(1 - p^{(k)}_{\text{tr},\acute{\ell}}) \prod\nolimits_{w}(1 - p^{(k)}_{\text{tr},n_w}). \quad (3)$$

Hence, the average length of a time slot in the unlicensed channel k can be calculated as

$$T^{(k)}_{\text{avg}} = (1 - p^{(k)}_{tr})\mathbb{E}\{T^{(k)}_{\text{idle}}\} + p^{(k)}_{s,\mathcal{W}}\mathbb{E}\{T^{(k)}_{s,\mathcal{W}}\} + p^{(k)}_{s,\mathcal{L}}\mathbb{E}\{T^{(k)}_{s,\mathcal{L}}\}$$
$$+ p^{(k)}_{c,\mathcal{W}}\mathbb{E}\{T^{(k)}_{c,\mathcal{W}}\} + p^{(k)}_{c,\mathcal{L}}\mathbb{E}\{T^{(k)}_{c,\mathcal{L}}\} + p^{(k)}_{c,\mathcal{W},\mathcal{L}}\mathbb{E}\{T^{(k)}_{c,\mathcal{W},\mathcal{L}}\},$$

where $p^{(k)}_{tr}$ is the probability of occupation of the k-th unlicensed channel and can be expressed as

$$p^{(k)}_{tr} = 1 - \prod\nolimits_{w=1}^{W}(1 - p^{(k)}_{\text{tr},n_w}) \prod\nolimits_{\ell=1}^{L}(1 - p^{(k)}_{\text{tr},n_\ell}),$$

and $p^{(k)}_{s,\mathcal{W}} = \sum_{w} p^{(k)}_{s,n_w}$ and $p^{(k)}_{s,\mathcal{L}} = \sum_{\ell} p^{(k)}_{s,n_\ell}$ denote the successful transmission probability of the whole Wi-Fi and LAA networks on the k-th unlicensed band, respectively. Moreover, $T^{(k)}_{s,\mathcal{L}}$, $T^{(k)}_{s,\mathcal{W}}$, $T^{(k)}_{c,\mathcal{W}}$, $T^{(k)}_{c,\mathcal{L}}$, and $T^{(k)}_{c,\mathcal{W},\mathcal{L}}$ indicate the time that the k-th channel is occupied by an LAA successful transmission, a Wi-Fi successful transmission, a collision among the Wi-Fi transmissions, a collision among the LAA transmissions, and a collision between the Wi-Fi and the LAA transmissions, respectively. Considering the basic access scheme into account [18], [19], $T^{(k)}_{s,\mathcal{W}} = T_{P,\mathcal{W}} + T_{\text{SIFS}} + T^{(k)}_{\text{idle}} + T_{\text{ACK}} + T_{\text{DIFS}} + T^{(k)}_{\text{idle}} + (\text{PHY}_{\text{header}} + \text{MAC}_{\text{header}})/R^{(k)}_{\mathcal{W}}$, $T^{(k)}_{c,\mathcal{W}} = T_{P,\mathcal{W}} + (\text{PHY}_{\text{header}} + \text{MAC}_{\text{header}})/R^{(k)}_{\mathcal{W}} + T_{\text{DIFS}} + T^{(k)}_{\text{idle}}$, $T^{(k)}_{s,\mathcal{L}} = T_{P,\mathcal{L}} + T_{\text{SIFS}} + T_{\text{ACK}} + T_{\text{DIFS}} + T^{(k)}_{\text{idle}}$, $T^{(k)}_{c,\mathcal{L}} = T^{(k)}_{s,\mathcal{L}}$, and $T^{(k)}_{c,\mathcal{W},\mathcal{L}} = \max(T^{(k)}_{c,\mathcal{L}}, T^{(k)}_{c,\mathcal{W}})$; where $T_{P,\mathcal{W}}$ ($T_{P,\mathcal{L}}$) indicates the Wi-Fi (LAA) payload duration, $\text{PHY}_{\text{header}}+\text{MAC}_{\text{header}}$ presents the packet header, and T_{SIFS}, T_{ACK}, and T_{DIFS} refer to short interframe space (SIFS), acknowledgement signal duration, and distributed interframe space (DIFS), respectively.

Finally, the normalized network throughput of LAA and Wi-Fi systems on the k-th unlicensed band as a function of both MAC and Physical layers parameters and can be expressed as

$$S^{(k)}_{\mathcal{L}} = p^{(k)}_{s,\mathcal{L}} T_{P,\mathcal{L}} R^{(k)}_{\mathcal{L}} / T^{(k)}_{\text{avg},\mathcal{L}}, \quad (4)$$
$$S^{(k)}_{\mathcal{W}} = p^{(k)}_{s,\mathcal{W}} T_{P,\mathcal{W}} R^{(k)}_{\mathcal{W}} / T^{(k)}_{\text{avg},\mathcal{W}},$$

where $T^{(k)}_{\text{avg},\mathcal{W}}$ ($T^{(k)}_{\text{avg},\mathcal{L}}$) denotes the average time duration to achieve a successful transmission in the Wi-Fi (LAA) network and $R^{(k)}_{\mathcal{W}}$ ($R^{(k)}_{\mathcal{L}}$) refers to the Wi-Fi's (LAA's) physical data rate, which can be calculated as follows. Assuming each channel k can be shared between the UEs associated with the eNodeB n_ℓ in a time sharing fashion, the physical data rate of the LAA network on the k-th unlicensed band can be expressed as [20]

$$R^{(k)}_{\mathcal{L}} = \sum\nolimits_{\ell=1}^{L} \sum\nolimits_{i=1}^{|\mathcal{U}_{n_\ell}|} c^{(k)}_{u_{n_\ell},i} B_k \log_2(1 + \chi^{(k)}_{u_{n_\ell},i} \cdot \text{SINR}^{(k)}_{u_{n_\ell},i}),$$

where $0 \leq c^{(k)}_{u_{n_\ell},i} \leq 1$ denotes the time sharing component of the UE $u_{n_\ell,i}$ on the k-th unlicensed band that fulfills $0 \leq \sum_{n_\ell \in \mathcal{N}_L} \sum_{u_{n_\ell},i \in \mathcal{U}_{n_\ell}} c^{(k)}_{u_{n_\ell},i} \leq 1$, B_k is the bandwidth of the k-th channel, and $\chi^{(k)}_{u_{n_\ell},i}$ is the channel access indicator which is 1 if the eNodeB n_ℓ serves the UE $u_{n_\ell,i}$ on the k-th unlicensed channel, and is 0 otherwise. Moreover, $\text{SINR}^{(k)}_{u_{n_\ell},i}$ represents the signal-to-interference-plus-noise ratio (SINR) for serving user $u_{n_\ell,i}$ on the k-th unlicensed band. Following the same notation, the physical data rate of the Wi-Fi's network can be written as [20]

$$R^{(k)}_{\mathcal{W}} = \sum\nolimits_{w=1}^{W} \sum\nolimits_{j=1}^{|\mathcal{U}_{n_w}|} B_k \log_2(1 + \chi^{(k)}_{u_{n_w},j} \cdot \text{SINR}^{(k)}_{u_{n_w},j}).$$

It is worth noting that in the case where an eNodeB/AP aggregates multiple unlicensed bands, the total throughput may be obtained by summation over all unlicensed channels.

III. Intelligent Dynamic Spectrum Access

If both Wi-Fi and LAA on the unlicensed band select channels appropriately, the spectral efficiency of the whole network will improve. Equation (4) reveals the impact of channel selection by each MNO on network's throughput. Specifically, if transmitter i selects channel k and channel k is not occupied by the other transmission nodes, then the probability of successful transmission by the i-th node in the k-th channel increases, leading to higher throughput. Moreover, if each channel is selected such that interference is avoided (or at least minimized) among the transmission nodes, there will be a higher SINR, leading to a higher physical data rate and throughput. In this section, we employ an algorithm for channel selection that learns from previous experience to improve network throughput. The learning algorithm also makes adaptive use of channel usage information.

We introduce a Q-Learning based dynamic channel selection algorithm here for both MNOs. The aim is to enhance the throughput of both Wi-Fi and LAA networks on the unlicensed band. Q-Learning is a value-based reinforcement learning technique that discovers the best action at each state by maximizing a value function, typically denoted by Q, that returns the expected reward of each action-state pair [21]. Here, "actions" are ways to explore the environment, and "states" describe the environment (we give an example for the coexistence problem below). The goal is to learn how to map environmental conditions into actions that maximize a reward. By interacting with the environment and trying different actions over time, the algorithm learns which action (in each state) provides the highest reward. Employing the Q-learning algorithm in a coexistence scenario allows each transmission node to learn to select the channel that yields the best throughput based on its interaction with the environment.

To be specific, we consider a set of $\mathcal{L}$ eNodeBs and $\mathcal{W}$ APs as the transmitters which will take actions. Denote the ith transmitter's set of actions by $\mathcal{A}_i = \{a_{i,1}, \ldots, a_{i,|\mathcal{A}_i|}\}$ and states $\mathcal{S}_i = \{s_{i,1}, \ldots, a_{i,|\mathcal{S}_i|}\}$. There is an associated set of Q-values related to each state-action pair. This is often called a Q-table, and it is unknown a priori. In the proposed algorithm, we consider four states for each channel observed by each transmission node: Idle, Successful transmission, Collision, and Contention. In the intelligent dynamic spectrum access of our interests, a collision is detected if both transmitters select the same channel for their operations, both have at least one user to serve, and the energy that they received from each other is less than predefined energy detectors threshold. The observed state is Contention if the initial clear channel assessment returns busy, either immediately or during the DIFS, or if the transmitter wants to contend after a successful transmission. The actions correspond to picking a different transmission band out of $|\mathcal{K}|$ bands in $\mathcal{K}$ and $|\mathcal{K}| = |\mathcal{A}_i|$.

The Q-table determines the best action at each state as judged by the action-state pair which yields highest reward. Particularly, the Q-value at each action-state pair is initialized with an estimate of the future reward. That results from a transmitter selecting a particular action while it is in a certain state. Then, based on interaction and feedback with the environment (e.g., MAC layer parameters, channel propagation model, topology of the Wi-Fi and LAA networks, sensing threshold), the transmitter learns the outcome of that action-state pair. In the proposed algorithm, each transmission node i measures $Q(s_{i,j}, a_{i,k})$, the expected reward achieved by selecting the k-th channel when the i-th transmission node is in the j-th state. If the k-th channel has never been selected by the transmission node i in the past, then $Q(s_{i,j}, a_{i,k})$ value is fixed to an arbitrary value Q_0 at the initialization step.

We denote by $R(s_{i,j}, a_{i,k}) := S_{\mathcal{L}}^{(k)} + S_{\mathcal{W}}^{(k)}$ the reward resulting from environmental interaction. Since our goal is to select the channel that maximizes the spectral efficiency of the whole network, we define this reward as the average throughput acquired by the i-th transmission node when it is in the j-th state and selects the k-th action (channel). The Q-value is then iteratively updated by

$$Q_{t+1}(s_{i,j}, a_{i,k}) \leftarrow (1-\alpha)Q_t(s_{i,j}, a_{i,k}) + \alpha R_{t+1}(s_{i,j}, a_{i,k})$$

where $0 \leq \alpha \leq 1$ is the learning rate and determines how fast the learning happens [21]. As is typically the case in learning algorithms, selecting α requires some care. Indeed, a small value of α results in a long learning process (which could be detrimental in practice), while a large value of α could cause the algorithm to not converge. As soon as the Q-value of the current state-action is updated according to the above equation, the i-th transmission node selects a channel corresponding to its new state.

Note that in order to find the effect of each selected channel, the transmission node needs to explore the environment. This suggests that the transmission nodes not only select the channels that provide the current highest estimated throughput, but also take on new actions to find better channel selection strategies. There are many methods for choosing action-selection strategies to balance this exploration of the environment with reward maximization. Examples are greedy action-selection, ϵ-greedy action-selection, and softmax action-selection [21]. In the greedy action-selection strategy, the transmission node always picks the channel that provides the highest Q-value and never explores any new channels. Alternatively, in the ϵ-greedy action-selection method, the transmission node uniformly picks a channel with probability ϵ. Although this strategy attempts to balance the exploration of the environment with maximizing reward, the chance of selecting the worst-appearing channel is the same as the chance of picking any other channel, due to the uniform selection probability. The softmax action-selection policy, like the above aforementioned action-selection strategies, gives the highest selection probability to the greedy action. In contrast, however, the rest of the actions are weighted according to their estimated values. Under this policy, the probability of picking the k-th unlicensed channel by the i-th transmission node is

$$Pr(i,k) = \exp\left(\frac{Q(s_{i,j}, a_{i,k})}{\tau(i)}\right) \Big/ \sum_{m=1}^{K} \exp\left(\frac{Q(s_{i,j}, a_{i,m})}{\tau(i)}\right),$$

where $\tau(i) > 0$ is the so-called temperature. With a high value of $\tau(i)$, the softmax policy is nearly identical to the ϵ-greedy action-selection strategy and so, the probability of selecting the different channels is almost the same. In contrast, selecting $\tau(i)$ with a low value makes a big difference in selection probability of an action that varies in Q-value. As a result, the probability of selecting a channel increases when it has a larger Q-value. Then, as $\tau(i)$ goes to zero, the softmax policy becomes the greedy action-selection strategy. Hence, we select the softmax policy to best balance exploration and reward maximization. Moreover, as a means to decrease the amount of exploration by the transmission node i (when the number of channel selection by this node increases), we consider a cooling function [22] that can be expressed as

$$\tau(i) = \tau_0 / \log_2(1 + n(i)),$$

where τ_0 denotes the initial temperature and $n(i)$ represents the number of channels that have been selected by the i-th transmission nodes.

Remark 1. *Compared to existing approaches, Q-learning is at an advantage. Indeed, the Q-learning approach is model-free and becomes adjusted to the new environment changes quickly. Therefore, there is no need to have the full knowledge of state transition in a dynamic environment. In addition, and in terms of computational complexity, Q-learning has much less complexity compared to the tradition optimization approaches such as branch and bound algorithm. To be specific, Q-learning is computationally limited by the size of the action and state spaces. Q-learning is quadratic in the number of st-*

ates and linear in the number of actions, e.g., $\mathcal{O}(|\mathcal{S}|^2|\mathcal{A}|)$.

IV. Simulation Results and Analysis

We evaluate the performance of the proposed algorithm in a coexistence scenario. We simulate a scenario in which 3 eNodeBs compete for the unlicensed channels with 3 APs. All transmitters are randomly distributed over an area of size 120×80 m^2 with minimum distance 40 meters, as shown in Fig. 1. All UEs and Wi-Fi clients are independently and uniformly distributed around each eNodeB and AP, respectively. We consider 5 UEs (Wi-Fi clients) per eNodeB (AP). Each UE (Wi-Fi client) is assigned to the eNodeB (AP) that provides it with the highest received power. The antenna height of the transmission nodes and users are 6 meters and 1.5 meters, respectively. The carrier frequency is 5 GHz and each channel bandwidth is 20 MHz. The path-loss and shadowing between transmission nodes, and between transmission nodes and users are generated following [23] for the indoor scenario. The transmit power at each transmission node is fixed to 23 dBm while the noise figure and the thermal noise level at each user is set to 9 dB and -174 dBm/Hz, respectively. Moreover, we assume the omni-directional antenna pattern with a 0 dBi antenna gain. While Wi-Fi uses the CSMA/CA scheme to access the unlicensed band with CCA-CS and CCA-ED thresholds of -82 dBm and -62 dBm, respectively [15], an LBT with random back-off and variable contention window size with CCA-ED threshold of -72 dBm is considered for the LAA channel access scheme [14]. The MAC layer parameters are given in Table I, and the initial Q-learning parameters are set to $\alpha = 0.1$, $Q_0 = 0.5$, and $\tau_0 = 0.15$.

According to this geometry and propagation model, only some pairs of transmitters can detect each other. We summarize which transmitters can detect each other in matrix $\mathbf{I}_D$ given below, in which the ij-th element of $\mathbf{I}_D$ is nonzero only if transmission node i detects transmission j. In the case of detection, this element is 1. The first three rows (columns) corresponds to AP1 to AP3 while eNodeB1 to eNodeB3 are organized in the last three rows (columns). For the aforementioned scenario the matrix $\mathbf{I}_D$ is given as

$$\mathbf{I}_D = \begin{pmatrix} 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 0 & 0 & 1 & 1 \\ 1 & 0 & 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 & 1 & 0 \\ 1 & 1 & 0 & 0 & 0 & 1 \end{pmatrix} \tag{5}$$

Note that in calculating the reward function and updating the Q-table in the proposed algorithm, we need to determine the throughput. For computing the throughput, we need to determine SINR. The $\mathbf{I}_D$ matrix, which tells us which pairs of transmitters can detect each other, helps us to calculate the interference and hence the SINR, and throughput.

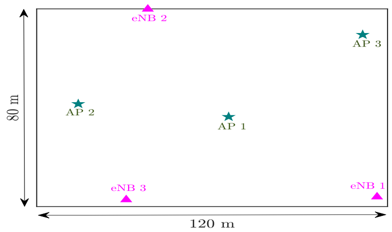

Fig. 1: Simulation layout

TABLE I: MAC Layer Parameters

Parameter	value
LAA's packet payload duration	1 ms
Wi-Fi's packet payload duration	1 ms
MAC header	272 bits
PHY header	128 bits
ACK	112 bits + PHY header
SIFS	16 μs
DIFS	34 μs
Idle slot time	9 μs
Wi-Fi contention window size	16
LAA contention window size	16
Wi-Fi maximum backoff stage	6
LAA maximum backoff stage	3

We consider the case of 6 different available channels in which all active transmission nodes in the area apply the proposed Q-learning method. Neither Wi-Fi nor LAA has knowledge about the other operators' selected channels. Each node *(i)* measures the expected reward achieved by selecting each channel when it is in a specific state, *(ii)* updates its Q-table, and *(iii)* chooses the channel that maximizes the whole network throughput.

The channel selection probability of each transmission node is shown in Fig. 2. At the initialization step, each transmission node interacts with the environment to explore different channels. It is worth mentioning that if the radio conditions change, the transmitters keep interacting with the environment until they determine which channel best improves the whole network throughput. With a change in radio conditions we will see that a learner must re-learn its policies as well. It is expected that any changes in the radio conditions during the initialization step will increase the initialization step duration. When the initialization step is done, according to the feedback from the environment and past experience, each node selects a channel that maximizes the whole network throughput, with a high probability. Since AP1 detects all other transmission nodes, it selects a fully vacant channel. AP2 and AP3 cannot detect each other, and they select the same channel. eNodeB1 only detects AP1. At first eNodeB1 selects the 4-th channel for its transmission, but when AP1 selects this channel, the eNodeB1 learns that this channel is now occupied, and switches to channel 2. The eNodeB2 only detects AP1 and AP2, so learns that the channels occupied by these two nodes do not maximize its throughput, and therefore selects a different channel. However, this channel is using by eNodeB1 that eNodeB2 does not detect. Finally, eNodeB3 selects the first channel which none of the other nodes picks as the means of maximizing the whole network spectral efficiency.

Simulation time is measured with respect to algorithmic time steps. Each time step is equal to the transmission nodes payload duration, i.e., 1 ms. Taking the MAC layer parameters

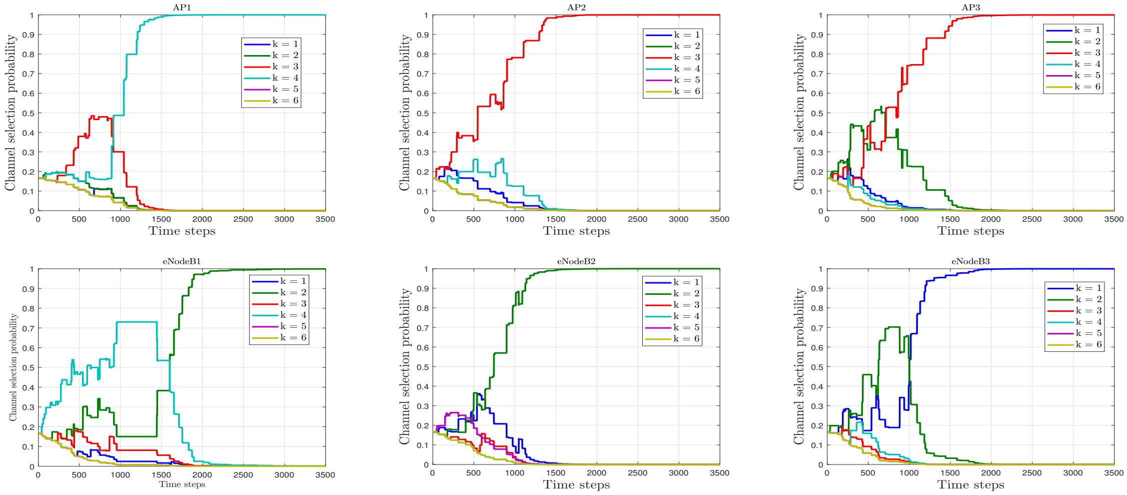

Fig. 2: Channel selection probability of each transmission node versus the time steps.

into account, all the APs and eNodeBs generate activity periods where they transmit data to their users with an average of 69- and 77-time steps. Since, the duration of initial time to learn the best solution is in order of 800-time steps in our simulations, the decisions of selecting a channel for transmitting the data are made after trying 10 initial channel selections.

It is worth mentioning that our simulation did not converge to a simple solution of allocating each transmitter to its own channel, instead favoring a scenario in which the transmitters choose the same channels. The reason for this solution is related to the physical scenario in which we pose the problem, as well as the MAC and physical layer parameters used by the APs and eNodeBs.

In Fig. 3 we consider a challenging case in which there are only 4 channels available. All active transmission nodes apply the proposed Q-learning method. For this scenario, again, we randomly distribute all transmitters and receivers over the area as discussed earlier. According to this geometry and propagation model the new matrix $\mathbf{I}_D$ is given as follows

$$\mathbf{I}_D = \begin{pmatrix} 1 & 1 & 0 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 0 & 1 \\ 0 & 1 & 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 1 & 0 & 1 \\ 1 & 0 & 0 & 0 & 1 & 1 \\ 1 & 1 & 0 & 1 & 1 & 1 \end{pmatrix} \tag{6}$$

Since there are only 4 available channels, sharing the same spectrum bands in the time domain is inescapable. Fig. 3 represents the channel selection probability of each transmission node. As it is shown in Fig. 3 after an initialization step that all channels are evaluated, AP 2 and eNodeB 2 use the same channel. AP 2 and eNodeB 2 are located far from each other and they are not reciprocally detected during the sensing period. Hence, they can utilize the same channel without sharing it in the time domain. Note that if these two transmitters detected each other and decided to select a same channel, they would share the channel in the time domain obeying the LBT requirements. The same discussion is applied to AP3 and eNodeB 1. AP1 and eNodeB 3 learn to use channel 1 and 4, respectively. This is a good choice since both not only detect each other but also detect AP2 and eNodeB 1 and choose different channels (from those selected by these detected nodes) for their transmissions.

In order to evaluate the usefulness of the proposed algorithm, the performance is measured in terms of the cumulative distribution function (CDF) of the normalized throughput. In Fig. 4 the CDF performance of the normalized throughput of the proposed scheme is compared with that of the optimum channel allocation algorithm. The optimum channel allocation assigns the channels to the transmission nodes in such way that the total network throughput maximizes and, it is found by exhaustive search over all possible channel combinations. Fig. 4 shows that the performance of the proposed Q-learning algorithm is close to the optimum one. Specifically, it is shown that under the proposed algorithm users have high probability to achieve the near-optimum normalized throughput with much less computational complexity.

V. Conclusion

In this paper, we have studied machine-learning-based channel selection in a coexistence scenario of LAA and Wi-Fi networks. We have proposed a reinforcement learning-based spectrum selection algorithm that allows the concurrent operating of Wi-Fi and LTE networks in an intelligent and efficient way. This scheme has taken into account the effects of both MAC and physical layers. We evaluated each channel's probability of selection, convergence property, and sum throughput. Simulation results demonstrate that this scheme converges fast and provides a competitive sum throughput reasonably close to that based on exhaustive search.

Influence of Angle Orientation on Firebrand Production from the Combustion of Materials Exposed to Applied Wind Fields

MANZELLO, Samuel L.[1], SUZUKI, Sayaka.[2]

[1] *National Instiute of Standards and Technology (NIST), USA*
[2] *National Research Institute of Fire and Disaster (NRIFD), Japan*

Abstract: A shared feature in the rapid spread of large outdoor fires are the production or generation of new, far smaller combustible fragments from the original fire source referred to as firebrands. A simplified experimental protocol has been developed that allows for the study of firebrand generation processes from various materials exposed to an applied wind field. The influence of angle of orientation on the firebrand production process is presented.

Keywords: Firebrands; Large Outdoor Fires; Ignition

1. Introduction

Across the globe, there exist many recent examples of large outdoor fires. Perhaps the most common are wildland fires that approach urban areas. These are often called Wildland-Urban Interface (WUI) fires. Two recent examples are the 2019 WUI fires that occurred in South Korea and those in 2018 in Northern California in the United States. In countries that are less developed, there have been large fires that have occurred in informal settlements. Some recent examples are those in the Philippines as well as South Africa, both in 2017. There have also been large urban fires in Japan, a country with no large wildland fire problem or informal settlement situation. Such urban fires have been recorded for centuries in Japan's history [**1**].

As communities become involved in large outdoor fires, firebrands are generated from the combustion of various structural fuel types. These include common building materials such as plywood, oriented strand board (OSB), and wood supporting members. At first glance, the liberation of firebrands from these combustion processes appears straight forward but is in fact quite complex. As a result, there is a need develop simplified experimental protocols to be able to investigate these combustion processes in a cost-effective manner. Such experiments have the possibility to aid in the development of computational models to understand these complex firebrand liberation processes from structural fuels. At the same time, such experiments may also lead to new insights into the physics of firebrand generation from various materials to perhaps suggest new methods of material fabrication to lessen firebrand liberation processes from these combustion reactions [**1**].

A simplified experimental protocol has been developed that allows for the study of firebrand generation processes from various materials exposed to an applied wind field. Preliminary results of this methodology was presented at this symposium last year, where it was shown useful insights into complex firebrand production processes was possible from such a simplified method [**2**]. To further understand firebrand liberation processes, mock-ups of actual structural assemblies were ignited and the angle of orientation of the burning assembly with respect to the wind was is studied.

2. Experimental Description

All experiments used mock-ups of structural assemblies and were performed in a wind facility at the National Research Institute of Fire and Disaster (NRIFD). NRIFD's wind facility has a 4 m diameter fan. The flow field was measured to be within ± 10 % over a cross-section of 2.0 m by 2.0 m. Experiments were performed within this cross-section.

Mock-ups used in this study were roofing assemblies, constructed with OSB and wood studs, with the dimensions of 610 mm (W) x 610 mm (H) (**Fig. 1**). Specific roofing treatments, such as roof tiles, were not applied but they are the obvious next step. These assemblies were exposed to applied wind fields and the angle of the assembly with respect to the wind was varied in increments of 25°, 45°, and 65 °. This was adjusted using a series of custom mounting frames fabricated for this study.

Experiments were performed in the following manner. Mock-up assemblies were ignited by a T-shaped burner with heat release rate (HRR) of 32 kW ± 10 % for 10 min. The reason to ignite under no wind was to provide consistent flame contact area for the assembly ignition for all experimental cases, independent of the wind speed. These afforded repeatable ignition conditions.

The total ignition time of 10 min was very important and carefully selected during ignition under no wind. If an ignition time less than 10 min was applied, once the wind field was added, the roofing assembly would self-extinguish, and little or no firebrand collection was possible due to lack of combustion. If an ignition time longer than 10 min was applied, the roofing assembly was observed to be consumed a great deal before the application of wind, thus rendering it unstable for firebrand collection (i.e. large holes were formed due to long ignition combustion process compromising the structural integrity).

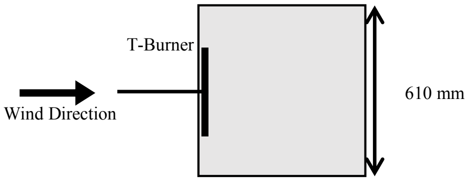

Figure 1 Schematic of roofing assemblies used for the experiments. Top view is shown (top view). OSB was used as base sheathing.

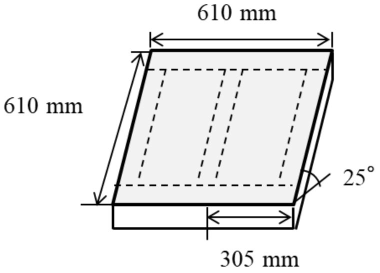

Figure 2 Schematic of mock-up assemblies used for the experiments (front view). The angle was varied from 25° to 65°. For illustration purposes, an angle of 25° is shown.

After the burner was turned off, a desired wind speed (6 m/s or 8 m/s) was applied. Experiments were stopped when the combustion of the assemblies was completed or the assemblies were not able to support themselves anymore.

A series of pans filled with water, placed downwind from the assemblies, were used to collect firebrands generated from the mock-ups. Water was needed to quench combustion otherwise only ash remained when experiments were finished. After the experiments, pans were collected, and firebrands were filtered and dried at 104 °C for 24 h. Dried firebrands were measured with a scale and pictures were taken for image analysis.

Manzello, Samuel; Suzuki, Sayaka. "Influence of Angle Orientation on Firebrand Production from the Combustion of Materials Exposed to Applied Wind Fields." Paper presented at 57 Japanese Combustion Symposium, Hokkaido, JP. November 20, 2019 - November 22, 2019.

3. Results and Discussion

Experiments were conducted for wind speeds of 6 m/s and 8 m/s. Commercially available image analysis software was used to determine the projected area of a firebrand by converting the pixel area using an appropriate scale factor. The projected areas with the maximum dimension of three dimensions were measured. The easiest method to visualize this is to imagine a sheet paper, as firebrands are often of very thin thickness, so the largest projected area is of interest. Images of specific shapes that have known areas (e.g. circles) were used to determine the ability of the image analysis method to calculate the projected area [2]. The standard uncertainty in determining the projected area was ± 10 %. Repeat measurements of known calibration masses were measured by the balance which was used for the firebrand mass analysis. The standard uncertainty in the firebrand mass was approximately ± 1 %.

Figs. 3-4 display a comparison of the collected firebrand size and mass distribution collected from these experiments. To more clearly show the results, linear curve fits are applied to the data. As may be seen, the angle of orientation had very little influence on the size and mass of liberated firebrands for an applied wind speeds of 6 m/s. As the wind speed was increased, for a given projected area, the mass of firebrands generated was quite sensitive to the angle of orientation.

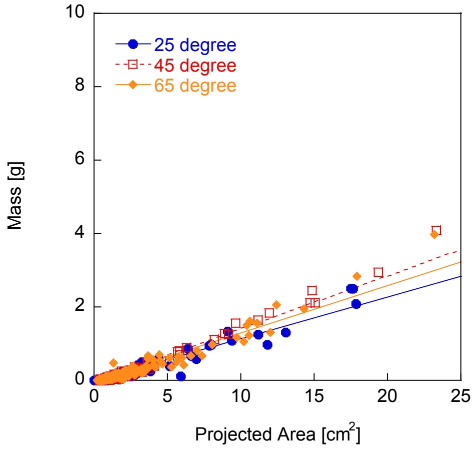

Figure 3 The mass and the projected Area of firebrands collected under 6 m/s. Data is shown for structural assemblies oriented at three different angles with respect to the applied wind speeds.

It is known that the wind force plays an important role in liberating firebrands from structural fuels. In its most simplistic representation, the wind force is proportional to the square the applied wind speed. As the projected area of liberated firebrands has a linear relationship, the values of slopes presented in **Figs. 3-4** are summarized in **Fig. 5**. The mass of a given firebrand may be expressed as follows:

$$m_F = \rho_F d A_{proj} \qquad (1)$$

where m_F is the firebrand mass, ρ_F is the firebrand density, d is the firebrand thickness, and A_{proj} is the projected area. As all the firebrands are liberated from the same materials in these experiments, it is reasonable to assume the firebrand densities are similar. Therefore, the largest slope indicates firebrands with the largest thickness, suggesting that the thickest firebrands were produced at angles of 45° for applied wind speeds of 8 m/s.

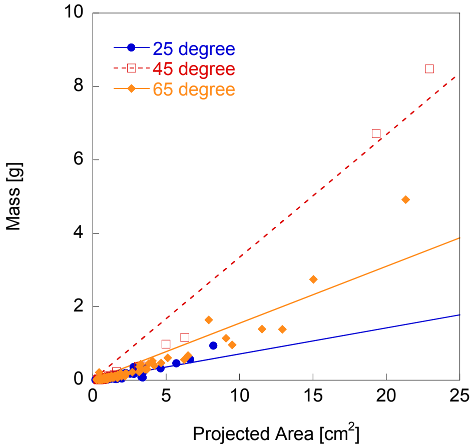

Figure 4 The Mass and the projected Area of firebrands collected under 8 m/s. Data is shown for structural assemblies oriented at three different angles with respect to the applied wind speeds.

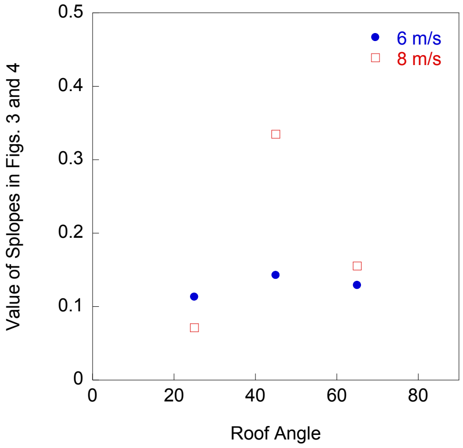

Figure 5 Effect of wind speeds on characteristics of firebrands generated from structural assemblies (mock-up roofing).

4. Conclusions

A simplified experimental protocol has been developed that allows for the study of firebrand generation processes from various materials exposed to an applied wind field. At wind speeds of 8 m/s, the angle of orientation greatly influenced the characteristics of the liberated firebrands.

5. Acknowledgments

Mr. Marco Fernandez of NIST's Engineering Laboratory is appreciated for sending experimental supplies that made this work possible.

Investigating coupled effect of radiative heat flux and firebrand showers on ignition of fuel beds

SUZUKI, S. [1], MANZELLO, Samuel L.[2]

[1] *National Research Institute of Fire and Dissaster (NRIFD), Japan*
[2] *National Institute of Standards and Technology (NIST), USA*

Abstract: Fire spread occurs via radiation, flame contact, and firebrands. While firebrand showers are known to be a cause of spot fires which ignite fuels far from the main fire front, in the case of short distance spot fires, radiation from the main fire may play a role for firebrand induced ignition processes. Many past investigations have focused on singular effects on fire spread, and little is known about coupled effects. The coupled effect of radiative heat flux and firebrand showers on ignition processes of fuel beds is studied by using a newly developed experimental protocol. Experiments were performed under the an applied wind field, as the wind is a key parameter in large outdoor fire spread processes

Keywords: Firebrands; Radiation, Large Outdoor Fires; Ignition

1. Introduction

Large outdoor fires pose problems for societies across the world. Perhaps the most often in the news are wildland fires that approach urban areas. These are more simply referred to as Wildland-Urban Interface (WUI) fires. In Asia and North America, some recent examples are the 2019 WUI fires that occurred in South Korea and those in 2018 in Northern California in the United States. In Africa, in less developed countries, there have been large fires that have occurred in informal settlements. For centuries there have also been large urban fires in Japan, a country with no large wildland fire problem or informal settlement situation [**1**].

In all of these large outdoor fires, firebrands are produced and lead to enhanced fire spread processes. Often referred to as spotting processes, firebrands are liberated from the combustion of various fuel types and then induce ignition of fuel sources away from the initial fire source. A potentially important aspect of the physics of ignition induced by firebrand are the coupled influence of firebrand showers and radiant heat.

Here, the coupled effect of radiation and firebrand showers on ignition processes of fuel beds is studied by using a newly developed experimental protocol. Experiments were performed under an applied wind field, as the wind is a key parameter in large outdoor fire spread processes

2. Experimental Description

All experiments were conducted at the National Research Institute of Fire and Disaster (NRIFD). To generate firebrand showers, the reduced-scale continuous-feed firebrand generator was used and installed inside NRIFD's wind facility. The device consisted of two parts; the main body and continuous feeding component.

A conveyer was used to feed wood pieces continuously into the device. The conveyer belt was operated at 1.0 cm/s, and wood pieces were put on the conveyer belt at 12.5 cm intervals. Douglas-fir wood pieces machined with dimensions of 7.9 mm (H) by 7.9 mm (W) by 12.7 mm (L) were used to produce firebrands. These same size wood pieces were used in past studies and have been shown to be within projected area/mass of firebrands measured from full-scale burning trees as projected areas obtained from actual WUI fires [**2**]. The wood feed rate used here was 80 g/min, which is near the upper limit for this reduced-scale firebrand generator [**2**].

As the base of the fan used to generate the wind in the NRIFD facility is located 1. 6 m from the floor, the conveyer was placed under a custom stage designed for experiments when using NRIFD's wind facility. The wind field exits from a 4.0 m diameter fan, and it is possible to generate wind speeds up to 10 m/s. The flow field was measured to be within ± 10 % over a cross-section of 2.0 m by 2.0 m.

When the blower was set to provide an average velocity below 5.0 m/s measured at the exit of the firebrand generator when no wood pieces were loaded, insufficient air was supplied for combustion and this resulted in a great deal of smoke being generated in addition to firebrands. Above 5.0 m/s, smoke production was mitigated but then many firebrands produced were in a state of flaming combustion as opposed to glowing combustion. In these experiments, glowing firebrands were desired.

The fuel beds used for ignition were 300 mm by 300 mm in size and consisted of the same Douglas-fir wood pieces used to generate firebrands (**Fig. 1**). These were installed inside a mock-up corner assembly lined with calcium silicate board, since the ignition of the corner assembly itself was not the goal here; only ignition induced in the wood pieces was of interest.

To provide uniform radiant heat flux to fuel beds, an electrically operated quartz radiant panel was used. Dimensions of the radiant panel were also 300 mm by 300 mm (**Fig. 1**). It was mounted at a height of 440 mm from the fuel bed surface. A custom calibration rig was designed and fabricated to quantify the radiant heat flux that the radiant panel provided at the fuel bed surface. Pre-heating time was determined as the duration from the time when the radiant panel was turned on to the time to start the firebrand generator. Selected pre-heating time was 0 min, 10 min, and 20 min. Baseline experiments were also performed to examine the ignitions by firebrands without applied radiant heat flux. The two wind speeds were selected, namely 6 m/s and 8 m/s.

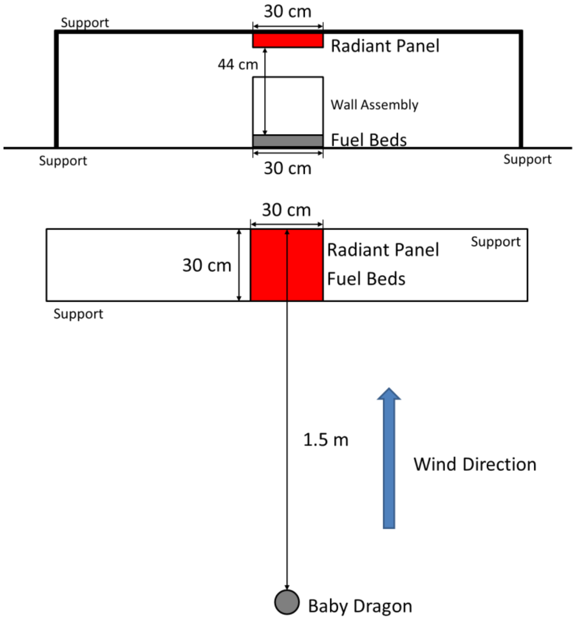

Figure 1 Schematic of the experimental settings. Front view (top) and Top view (bottom) are shown. Firebrand showers were produced using the reduced-scale firebrand generator installed in NIRFD's wind facility. Fuel beds consisted of Douglas-fir pieces of uniform size.

Manzello, Samuel; Suzuki, Sayaka. "Investigating coupled effect of radiative heat flux and firebrand showers on ignition of fuel beds." Paper presented at 57 Japanese Combustion Symposium, Sapporo (Hokkaido), JP. November 20, 2019 - November 22, 2019.

3. Results and Discussion

Fig. 2 displays a picture of a typical experiment. In this picture, the applied wind speed was 8 m/s and radiant panel was switched on at the same time as firebrand generator, that is there was no pre-heating time.

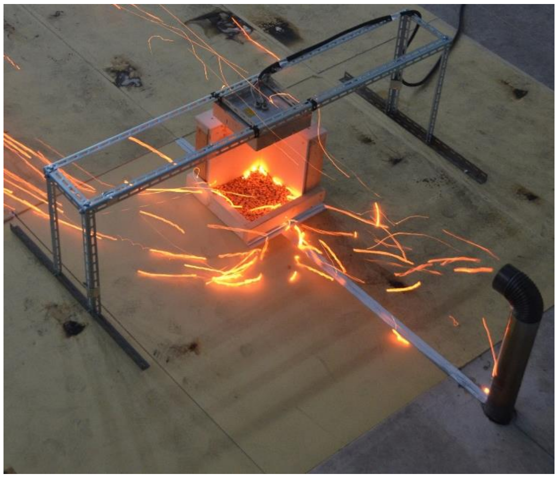

Figure 2 A typical experiment conducted at 8 m/s. Multiple glowing firebrands are seen depositing in the fuel bed.

Fig. 3 displays the time to smoldering ignition in the fuel beds a function of pre-heating time and wind speed. Here, sustained smoldering ignition (SI) was defined as the start of intense smoke generation in the fuel be due to the coupled effects of accumulated firebrands and radiant heat flux. To aid in understanding, in **Fig 3**, no radiant panel conditions imply that the radian panel was not switched on. For other cases, the applied radiant heat flux to fuel beds was 10 kW/m^2.

An interesting result from these findings is that for wind speed of 6 m/s, the pre-heating due to the applied radiant heat flux to the fuel bed influenced the time to SI significantly. Yet, as the wind speed was increased to 8 m/s, the applied radiant heat flux had very little effect.

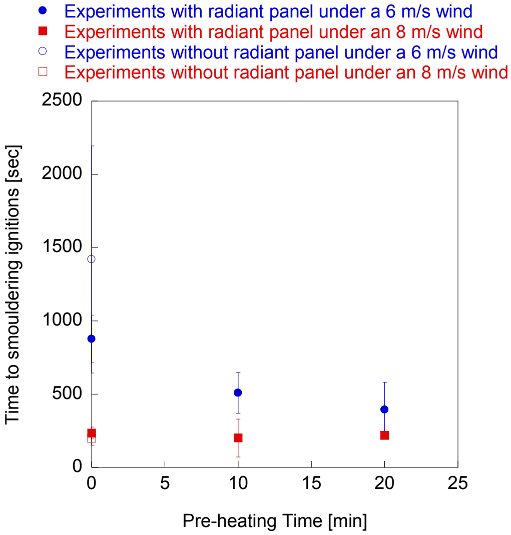

Figure 3 Coupled effects of radiation and firebrands on ignition under different wind speeds and pre-heating time.

The ignition time for thermally thick materials is known to be proportional to the room-temperature density, ρ, of the material and inversely proportional to the square of the net heat flux to the fuel bed [**3**]. As a result, at 6 m/s, the applied radiant heat flux acts to reduce the time to SI ignition greatly with increased pre-heating time. As wind speed is increased, convection cooling to the fuel beds is increased but the time to ignition was not influenced by the additional assistance from the applied radiant heat flux. It is believed that the increased wind speed rather changes the combustion dynamics of the firebrands and therefore alters their temperatures, resulting in larger applied heat fluxes from the firebrands themselves.

Manzello *et al.* [**3**] quantitatively showed that glowing firebrand surface temperature increased as the wind speed was increased. In that work, the surface temperature of charred area on the glowing firebrand was simultaneously measured using both the thermocouple and the infrared camera [**3**]. The glowing, charred, area close to the thermocouple bead was imaged using the infrared camera and the emissivity was then adjusted until the temperature readings on the infrared camera converged to those registered by the thermocouple measurements. Temperatures measured by the infrared camera approached those measured by the thermocouple as the emissivity set on the camera was reduced from 0.7 to 0.6. The firebrand temperatures were quite sensitive to airflow (**Fig. 4**). Therefore, larger firebrand temperatures were expected as the wind speed was increased from 6 m/s to 8 m/s.

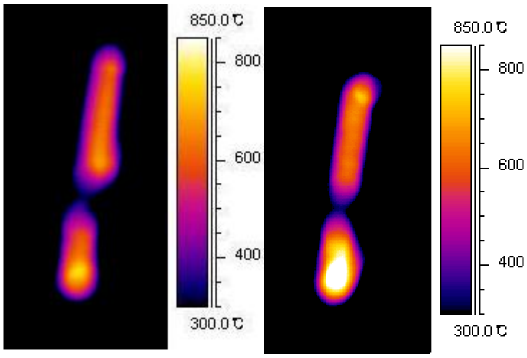

Figure 4 IR images of the glowing firebrand exposed to two different air flows (1.3 m/s, left and 2.4 m/s, right) [**3**].

4. Conclusions

The coupled effect of radiative heat flux and firebrand showers on ignition processes of fuel beds was studied by using a newly developed experimental protocol. An interesting result from this preliminary study is that for wind speed of 6 m/s, the pre-heating time due to the applied radiant heat flux to the fuel bed influenced the time to SI significantly. Yet, as the wind speed was increased 8 m/s, the applied radiant heat flux had very little effect. It was postulated that differences in firebrand temperatures may explain these differences. More work is required to quantify firebrand temperatures at higher wind speeds.

Abstract: Due to the increasing cyber-activities and the use of diverse devices offered on cloud environments, cloud forensic investigations must deal with data in diverse formats and large quantities from different devices. The process of forensic investigation in a cloud environment involves filtering away noisy data and using expert knowledge to make up the missing attack steps from advanced persistent threats (APT) attacks that have a long time span. Under such circumstance, obtaining timely and convincing forensic results is a challenge.

We show how MITRE's ATT&CK framework and Lockheed Martin's cyber kill chain can be used to identify forensically valuable data, aggregate and correlate them to construct attack steps. ATT&CK is a globally accessible knowledge base of adversary tactics and techniques that is based on real-world observations. APT attacks on cloud systems consist of a successful reconnaissance, command and control communication, privilege escalation, lateral movement through the network, exfiltration of confidential information that are also the key phases of a cyber kill chain. In this paper we investigate using cyber kill chains to organize the evidence and construct the attack steps. By using an experimental network, we show how our methodology can be used to identify evidence, aggregate them and feed them to a Prolog-based tool to re-construct attack steps for the purpose of performing forensic analysis.

Keywords: Cloud attacks, forensic analysis, ATT&CK, cyber kill chain, attack steps

1. Introduction

Liu, Changwei; Singhal, Anoop; Wijesekera, Duminda. "Forensic Analysis of Advanced Persistent Threat Attacks in Cloud Environments." Paper presented at Sixteenth IFIP 11.9 International Conference on Digital Forensics, New Delhi, IN. January 06, 2020 - January 08, 2020.

Cyber forensics is the application of science to the identification, collection, examination, and analysis, of data while preserving the integrity of the information and maintaining a strict chain of custody [21]. Due to a continued increase in cyber-activities and the diversity of devices that use services provided in cloud environments, the scope of post attack forensic investigations, especially the ones involving attacks on cloud environments have expanded in two dimensions: (1) Expansion of the attack surfaces created by cloud devices that may not have undergone rigorous security check; (2) The need to analyze data that comes in diverse formats and quantities from new attackable interfaces. Of special concern is that instances of servers running on virtual machines in the cloud are monitored by hypervisors that lack warnings, procedures and tools for forensic investigations. Because existing forensic techniques have not been designed for cloud environments, it is challenging to use existing tools to perform forensic analysis in a cloud environment, especially for those advanced persistent threat attacks (APTs) that could last for so long(such as a year) that the timestamps of evidence are not the indicators of the same attack. The process of investigating such cloud attacks involves filtering away noisy data and using expert knowledge or experience to speculate the attacker strategy. This situation creates increasing obstacles in their abilities to obtaining pertinent forensic results.

Researchers have proposed methodologies to collect evidence and correlate them for forensic analysis of cloud attacks, which include developing tools to collect data from hypervisors or virtual machines (VM)s [5,6], leveraging graphical framework to reconstruct the attack scenarios [2, 7] etc. However, cited research is based on strong assumptions that the forensic data was manually aggregated and preprocessed to evidence representing pre-attack conditions and post-conditions, and uses forensic investigators' expertise to build an attack step when the corresponding evidence is incomplete or compromised.

Recently, ATT&CK-like frameworks have been used in understanding and fighting cyber-attacks. Lockheed Martin's intrusion kill chain (also called *cyber kill chain*) describes seven phases including reconnaissance, weaponization, delivery, exploitation, installation, command and control, actions on objectives. Because most APT attacks consist of a successful reconnaissance, command and control communication, privilege escalation, lateral movement through the network, exfiltration of confidential information etc., the cyber kill chain has been used to analyze security logs, develop attack detection and defense systems, and aggregate evidence for APT attack forensic analysis [1,3]. MITRE ATT&CK is a globally accessible knowledge base of adversary tactics and techniques based on real-world observations [11] to emulate cyber-attacks. It has been used in recent years to create a taxonomy of possible attacks in the enterprise IT environment to allow defenders to understand what attacks are being used in the wild and provide methods to detect attacks including certain APTs. Inspired by these works, we propose to leverage MITRE's Adversarial Tactics and Common Knowledge (ATT&CK) and Lockheed Martin's cyber kill chain to identify the evidence of cloud APT attacks, aggregate it and correlate it to construct the attack steps, as the enhancement to our previous work [2,7] of performing forensics in a cloud environment, which had to depend on the investigator's experience and knowledge to identify evidence and building the attack step when the corresponding evidence is incomplete or compromised. Though existing research uses the two tools to detect cyber-attacks or aggregate/correlate evidence [1,3, 19, 20], to the best of our knowledge, there is no published research work that combines both for attack evidence identification and correlation. That is the main contribution in this paper. We use sample attacks to show how both frameworks can be used to identify forensic data in a cloud environment, covert it to pre-attack and after-attack evidence, and feed it to a logic-based forensic tool to construct attack steps.

The rest of the paper is organized as follows. Section 2 describes the background knowledge and related work. Section 3 shows the experimental attacks and the collected evidence. Section 4 describes how we use the two frameworks to identify, correlate evidence, and implement an existing Prolog based forensic tool to construct attack steps. Finally, we conclude the paper in Section 5.

2. Background Knowledge and Related Work

We describe Lockheed Martin's cyber-kill chain model, MITRE ATT&CK framework and related work in this section.

2.1 The Cyber-Kill Chain Model

As shown as the bottom part in Figure 1, there are seven attacking phases in Lockheed Martin's kill-chain model, representing the steps composed of a successful network attack. In "reconnaissance" phase, the adversaries identify the targets by researching what targets can meet their attacking objectives, and correspondingly collect information that could enable them to launch attacks; in "weaponization" phase, the adversaries prepare their operations by coupling malware and exploits into a deliverable payload, selecting backdoors/implants and appropriate command and control infrastructures for operations; in "delivery" phase, the adversaries convey the malware to the target to launch the attack operations; in "exploitation" phase, the adversaries trigger exploits to gain access to the targeted victim; in "installation" phase, the adversaries install a persistent backdoor or an implant in the victim to maintain the access for an extended period; in "command and control(C2)" period, the adversaries remotely control the backdoor or implant to open a command channel so that the adversaries could control the victim; in the last phase, "actions on objectives", the adversaries achieve their attacking objectives that include collecting user credentials, escalating their privileges, destroying the system, overwriting or corrupting data or modifying data [8]. According to Milajerdi at el.[1], most APT attacks are accomplished through steps conforming to the cyber kill chain, and aim to obtain and exfiltrate highly confidential information.

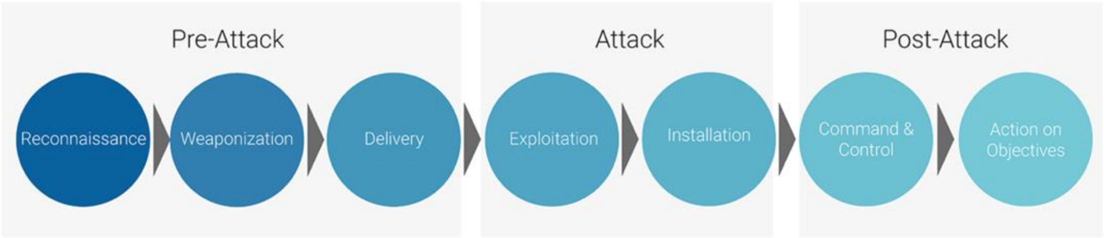

Figure 1. The cyber intrusion kill chain from Lockheed Martin

Cyber Reboot (an American company) reexamined the seven phases and argued that there are three fundamental phases to most network attacks. They are pre-attack, attack and post-attack phases as shown at the top of Figure 1. In the pre-attack phase, the attacker is tasked with attacking objectives and starts to perform reconnaissance of the target; in the attack phase, the attack is executed, enabling the attacker to break through the target's defense and set up communication between the attacked target and the attacker; in the post-attack phase, a further exploitation or access of the targeted victim occurs, which allows the attacker to escalate privilege, destroy the victim system, steal confidential information and etc.

2.2 The Adversarial Tactics and Common Knowledge (ATT&CK) Framework

The ATT&CK framework proposed by MITRE [19] is a behavioral model based on real-world observations. As shown in Figure 2, it uses the cyber kill chain to emulate cyber-attacks by emulating the tactics and techniques the attackers could use to achieve their goals. Figure 3 is a snippet of MITRE ATT&CK matrix of enterprise networks, from which we can see that, unlike other threat models that were built by analyzing available threat/vulnerability reports, ATT&CK describes behaviors commonly employed by real adversaries. All attacking techniques are real-world examples of malware or from threats used by red teams. Besides, this framework has public descriptions of attack techniques and how they are leveraged and why the network defenders should pay attention. Therefore, it is useful for network defenders and forensic investigators to decide what they should monitor and how to specifically investigate to reconstruct the attack steps and mitigate the attack risks.

2.3 Related Work

Techniques, including remote data acquisition, management plane acquisition, live forensics and snapshot analysis, have been proposed to collect evidence from cloud environments [12]. Dykstra and Sherman retrieved volatile and non-volatile data from the Amazon EC2 cloud active user instance platform using traditional forensic tools such as EnCase and FTK [13]. In order to validate the integrity of the collected data, they subsequently developed the FROST toolkit that can be integrated within OpenStack to collect logs from an operating system that runs the virtual machines [14]. While this technique assumes that the cloud provider is trustworthy, Zawoad et al. resolved this issue by designing a forensics-enabled cloud [15]. Hay and Nance [16] have conducted live digital forensic analyses on clouds with virtual introspection, a process that enables the hypervisor or any other virtual machine to observe the state of a chosen virtual machine. Dolan-Gavitt et al. bridged the semantic gap between the high-level state information and low-level sources such as physical memory and CPU registers and developed a suite of virtual introspection tools for Xen and KVM [17]. Several hypervisors, including Xen, VMWare, ESX and Hyper-V, support snapshot features that can be used to obtain information about the running state of the virtual machine.

Meanwhile, in order to reduce the time and effort involved in forensic investigations, researchers have proposed automating evidence correlation and attack reconstruction by leveraging rule-based tools and business process diagrams [2]. However, this work depends on forensic experts when the evidence is missing, disjointed or compromised. To execute security investigators in a methodical manner and help to detect real-time APT attacks, intrusion kill-chain has been modified to facilitate data aggregation within a relational database [1, 3].

3. Experimental Attacks in a Cloud Environment

In this section, we show an experimental network attacked by both conventional and cloud cyber-attacks to show how the two frameworks of ATT&CK and cyber-kill chain are used to assist cloud forensic analysis.

3.1 Our Experimental Cloud and Sample Attacks

Based on the location of an vulnerability and the source of an attacker, the attacks in the cloud can be categorized to two groups [5, 7]: (1) an attacker from the Internet uses conventional network vulnerabilities to attack a virtual machine connected to the Internet; (2) an attacker from a virtual machine uses the vulnerabilities from the shared cloud management resources to launch attacks to other virtual machines on the same hypervisor. The attacks from both kinds of attacks range from Denial of Service, information leakage to privilege escalation, arbitrary code execution etc.

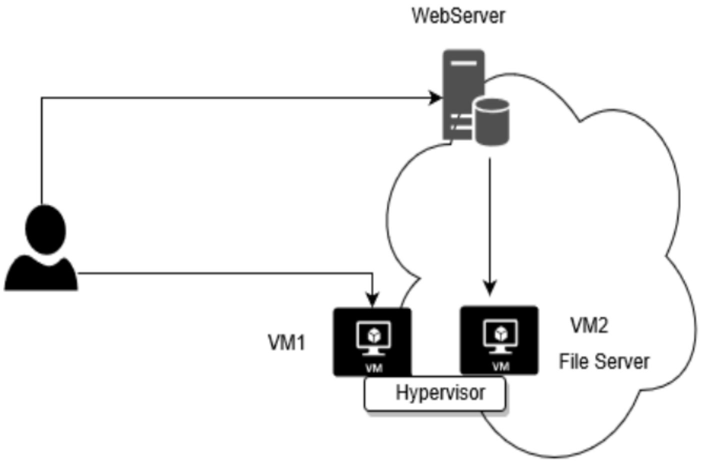

Figure 4. Our experimental cloud and sample attacks toward

Figure 4 illustrates our experimental set up in a lab environment. In this small cloud environment, VM1 and VM2 are two Linux (Ubuntu 14.04) virtual machines that are configured on the same hypervisor (Xen 4.6). We also configured a Windows machine as a webserver, in which a web application can use SQL queries to retrieve the database information stored on VM2--the file server that hosts databases and other files. Toward VM2, we launched two attacks. One is a conventional SQL injection attack exploited by using the vulnerability from the web application that does not sanitize the users' input. The other one is a VM escape attack that could be a kind of APT attacks. The VM escape attack takes advantages of the vulnerability CVE-2017-7228 from VM1, which allows VM1 to control Xen privileged domain, domain 0, and then VM2 so that it can perform local operations, such as deleting a file, in VM2.

3.2 Forensic Data Obtained by Using Forensic Tools

To obtain data for forensic analysis, during the attack processes, we logged the accesses toward the webserver, deployed Snort as an IDS to monitor network traffics to the webserver and file server, and installed a VM introspection tool, LibVMI, on Xen Dom0 to capture events and running processes in the guest VMs(VM1 and VM2). LibVMI is a C library that can be used to monitor the low-level details of a running VM of Xen by viewing its memory, trapping on hardware events, and accessing the vCPU registers. Below are the machine IP addresses and forensic data captured by using the methods/tools mentioned here.

Table 1. The IP address for each machine or VM in Figure 4

Machine/VM	IP Address

Figure 8. The Processes, injected Linux modules, and CPU register values of VM2

Table 1 shows the corresponding IP addresses of each machine/VM. According to Table 1, we can see the Snort alert in Figure 5 shows the attacker from 129.174.124.122 attempted to launch a SQL injection attack by using the web application deployed in the webserver with IP address 129.174.125.35 at port number 8080. Figure 6 is the web access history on the webserver, which shows that the attacker machine accessed the web application right before the time when the Snort sent out the alert listed in Figure 5. Figure 7 is the SQL access logging that includes the SQL injection query (the line of “40 Queryselect * from profiles where name='Alice' AND password='alice' or '1'='1'”) that resulted in information leakage. Figure 8 are the results obtained by running LibVMI on the attacker VM. These results are forensic data without timestamps. They are composed of the running processes, injected Linux modules and CR3 register values representing the running processes (the process identifier (PID) is used to find the process name).

4. Leveraging the ATT&CK Matrix and Cyber Kill Chain for Forensic Investigation

In this section, we show how we used ATT&CK and the cyber kill chain to assist the investigation process.

4.1 Use ATT&CK to Identify the Forensic Data

MITRE ATT&CK includes a knowledge base of 11 tactics and hundreds of techniques an attacker would leverage when compromising an enterprise network. In this framework, while a tactic is a high-level description of a certain type of attack's behaviors, a technique provides a more detailed description of every specific type of behavior within a certain tactic class. The tactics from ATT&CK aren't followed in any linear order as Lockheed's cyber kill chain as shown in Figure 1, and an attacker could bounce between tactics in order to achieve his final goal.

We map forensic data to ATT&CK matrix in order to assist identifying evidence for cloud forensic investigation. As shown in Figure 3, the matrix model's various phases of an attack's lifecycle include "initial access", "execution", "persistence", "privilege escalation", "defense evasion", "credential access", "discovery", "lateral movement", "collection", "command and control", "exfiltration", and "impact". Each of these phases is consisted of different techniques as listed in the matrix table, and the general description is provided below.

- Initial Access consists of techniques that use various entry vectors to gain their initial foothold within a network, which may allow for the attacker's continued access to external remote services.
- Execution consists of techniques resulting in adversary-controlled code running on a local or remote system, which can achieve broader goals such as exploring a network or stealing data by paring with other technologies. Notice that this step does not leave any evidence.

- Persistence consists of techniques that the attacker uses to maintain their foothold on systems even if any interruptions from the system cut off their access.
- Privilege Escalation consists of techniques that an attacker uses to gain higher-level permissions on a system or network. The common approaches include taking advantage of system weaknesses, misconfigurations, and vulnerabilities.
- Defense Evasion consists of techniques such as uninstalling/disabling security software or obfuscating/encrypting data and scripts that an attacker uses to avoid detection throughout their compromise.
- Credential Access consists of techniques that an attack uses to steal credentials to gain access to systems, which provides the opportunity for the attacker to achieve his goals by creating more accounts.
- Discovery consists of techniques an attacker may use to gain knowledge about the system and internal network, which allows the attacker to explore what he can control and discover how the knowledge could benefit his post-compromise information-gathering objective.
- Lateral Movement consists of techniques that an attacker uses to enter and control remote systems on a network. An attacker might install his own remote access tools to accomplish lateral movement or use legitimate credentials with native network and operating system tools.
- Collection consists of techniques an attacker uses to gather information. Frequently, the next goal after collecting data is to steal the data.
- Command and Control consists of techniques that an attacker may use to communicate with systems under his control within a victim network.
- Exfiltration consists of techniques that an attacker may use to steal data from the victim network. The attacker often compresses or encrypt the data to avoid detection, and the channels used to get

data out of a victim network typically include the attacker's command and control channel or an alternate channel with limited size.

- Impact consists of techniques that an attacker uses to disrupt availability or compromise integrity by manipulating business and operational processes, which include destroying or tampering with data.

In our experimental network, we can identify the evidence of the SQL injection attack, because the Snort alert (Figure 5) and SQL query (Figure 7) of this attack clearly show it was a SQL injection attack. For the VM escape attack of using the vulnerability CVE-2017-7228, thought the attack could be observed (the file in VM2 has been deleted), it is hard to construct the attack from the data obtained by using LibVMI (Figure 8), because there was no obvious logging that can identify this attack. Clearly, this is a step that does not leave any evidence. Under this situation, using ATT&CK could narrow down the search scope, helping to find the evidence. According to ATT&CK, the initial access techniques include "drive-by compromise, exploit public facing application, external remote services, hardware additions, replication through removable media, spear phishing attachment, …, trusted relationship". In our experimental cloud, except for the facts that the database in VM2 can be queried by using the web application in the webserver and VM2 shares the same hypervisor (therefore, the hardware) with VM1, it does not have any other connected media, remote services or running applications. Thus, the initial accesses could be narrowed down to the tactics including "exploit public-facing application" from the webserver, and "hardware additions" from the hypervisor. Because the observed attack activities on VM2 include SQL injection alerts and a file deletion, according to ATT&CK, the execution techniques of the attacks could fall into two categories, "exploitation for client execution"(corresponding to application from the webserver) and "command-line interface"(corresponding to the hardware addition). And, the techniques for "privilege escalation" would be narrowed down to "exploitation for privilege escalation", since the attackers obviously escalated their privileges from the Internet or other VM remotely and other techniques including "access token manipulation", "accessibility features", … etc. are not suitable for the system configuration.

The SQL injection attack has obvious evidence as listed in Figure 5, 6 and 7. However, for the VM escape attack that resulted in the file deletion, the data provided in Figure 8 could only show all running process (including the normal Linux processes and the suspicious user process named as "attack") and injected modules (including normal Linux modules and the suspicious injected user module named as "test"), which does not show the process of exploiting the vulnerability that uses the shared hardware. Therefore, using the potential attack tactics obtained from ATT&CK, the forensic investigators should continue to investigate more forensic data related to exploitations that takes advantage of tactics including "hardware additions", "command-line interface" to launch attacks that allowed the attacker to escalate privileges to the hypervisor level and then delete the file in VM2. According to our previous work [5, 7], system calls constitute good forensic evidence, so a snapshot of VM2 captured during the attacking time was used to retrieve the system calls and kernel messages of the process "attack" and module "test". The system calls we obtained from the process of "attack" are shown in Figure 9, where the arguments following "execve" command in Line 1 clearly shows the attacker from VM1 used command line to execute an attack program named "attack", trying to delete the "samplefile.txt" located at the home folder of VM2(VM2 in named as "victim" in our experiment), and Line 25 clearly shows that the Linux module "test.ko" was injected to the Linux kernel of VM1 to do some work. The kernel activities of VM2 are illustrated in Figure 10, where the kernel messages between Line 1 and Line 6 show that the attacker from VM1 wrote some bytes to the memory after the address "ffff88007c723008", and the messages between Line 8 and Line 19 show that the attacker controlled the page table in Xen to execute the attacker's shellcode by linking the physical memory address where the shellcode is held to the virtual memory address in the page-table. This clearly shows the attacker used the shared memory to launch the attack.

Figure 10. The kernel message from the injected module

Identifying an attack component is not a trivial task due to the nature of APTs. It requires a lot of detailed analysis such as looking at all processes and process threads that would have altered the state of an object, even under enhanced super-user privileges. As shown in our example, some of these missing steps may need to use system call logs. ATT&CK has techniques and tactics based on real-world observations, which makes it very helpful in identifying the corresponding processes or system calls that are related to a sub-attack phase of an APT attack.

4.2 Mapping Log Entries to Attack Steps

Once we identify the evidence by leveraging ATT&CK, we use cyber kill chain to map the corresponding evidence to different attack phases in order to construct the attack steps.

The evidence in Figure 5, Figure 6 and Figure 7 belong to the SQL injection attack, since the timestamps and alerts of these date are consistent. As our analysis in Section 4.1, the data in Figure 5 and 6 show that the attacker from 129.174.124.122 accessed the webserver (129.174.124.35) with SQL injection attempt("—1=1"), which is considered as "initial access" in ATT&CK, that can be easily mapped to the "weaponization" in pre-attack phase. The data in Figure 7 shows, at the same time the database had been queried by using the statement "select * from profiles where name='Alice' AND password='alice' or '1'='1'", which is clearly a SQL injection attack on the database. Since the database itself did not have any security mechanism, this implies the attack succeeded. Therefore, the attack had been delivered, and we can map the data in Figure 7 to "attack" phase in the cyber kill chain.

Likewise, we group the forensic data in Figure 8, Figure 9 and Figure 10 to the same attack by matching the process name "attack" and injected module name "test.ko". Because the data in Figure 8 and 9 only shows the attacker from VM1 ran the process "attack" and module "test" to do some work that did not show details, we map it to the "weaponization" phase that belongs to pre-attack stage. In addition, as we described in Section 4.1, the data in Figure 9 and 10 shows that the attacker manipulated the shared memory in the same hypervisor to execute shellcode on the victim VM, which can be mapped to "exploitation" phase that belongs to attack stage. Because we observed that the "samplefile.txt" file in the victim VM had been deleted, we knew the attack succeeded, which can be mapped to "action on objectives" in the cyber kill chain that belongs to the post-attack stage.

4.3 Co-relate Attack Steps to APTs (Cyber Kill Chains)

Our previous work [18] used a prolog-based tool to generate attack steps by using evidence in the form of Prolog predicates to instantiate rules composed of these predicates representing pre-conditions and post-conditions of an attack. These rules simulate generic attack techniques, which are written in the form of p :- p_1 , p_2 , $p_{n,}$ where predicate p represents the post-conditions of an attack, and predicates $p_{1,}$ p_2 ···, p_n represent the pre-conditions of the attack. The post-conditions refer to the privileges the attacker obtained after an attack, and the pre-conditions include the attacker's initial privilege, location, system configuration and the vulnerability used to launch the attack.

While this prolog-based tool can be used to generate attack steps, it requires users to categorize evidence to post-attack conditions and pre-attack conditions. The tool does not have predicates mapping to the seven cyber kill chain phases. Neither does it have corresponding rules that correlate the evidence corresponding to the seven phases of the cyber kill chain to pre-attack conditions and post-conditions. In this work, we propose to add the missing link by making changes as follows.

(1) We use predicate Pr_r, Pr_w, Pr_d, A_e, A_i, Po_c, Po_a to represent the pre-attack "reconnaissance", "weaponization", "delivery" phases, the attack "exploitation", "installation" phases, and the post-attack "command and control(C2)", "actions on objectives" phases respectively.

(2) We convert techniques in the ATT&CK matrix to corresponding predicates, and map them to the cyber kill chain phases as follows: (a) Predicates of “initial access” are mapped to Pr_r, (b) Predicates of “execution”, “persistence”, “privilege escalation”, “defense evasion”, “credential access” are mapped to Pr_w, (c) Predicates of “discovery” are mapped to A_i, (d) Predicates of “lateral movement” are mapped to A_i, (e) Predicates of “command and control” are mapped to Po_c, and (f) Predicates of “collection”, “exfiltration”, “impact” are mapped to $Po_{a.}$ Notice that these steps can be modeled as pre-conditions and post-conditions as given in Figure 11.

All predicates are composed of names and variables that depict the system configuration, attacker’s privilege, the network topology, software vulnerability and etc. For example, technique “exploit public-facing application” in “initial access” of the ATT&CK matrix is written to Predicate “Pr_r (attackerAccess(_host, _program))”, and technique “account manipulation” in “credential access” of the ATT&CK matrix is written to Predicate “Pr $_w$(hasAccount(_principal, _host, _account))”, where the variables (such as _host, _program …) following the predicate names(publicApp and hasAccount) in the predicates will be instantiated by concrete information during the run time of using this Prolog tool.

(3) We add rules to use cyber kill chain to correlate the corresponding predicates in different phases to an attack step. The rules are in the in the form of Po_c :- $(Pr_r\ ; Pr_w\ ; Pr_d)$, $(A_e\ ; A_i)$. *and* Po_a :- $(Pr_r\ ; Pr_w\ ; Pr_d)$, $(A_e\ ; A_i)$, where “;” represents logical OR, and “,” presents logical AND. These rules mean that, if there is evidence in pre-attack, attack and attack phases, an attack step is constructed.

1	ExecCode(VM2,read)	6	networkServiceInfo(dbServer, httpd, tcp, 3660, user)
2	ExecCode(VM2,modify)	7	vulExists(webServer, 'CWE89', httpd)
3	THROUGH 3 (remote exploit of a server program)	8	hasAccount(attacker,VM1,root)
4	Through 8 (Access a host through executing code on the machine)	9	vulExists(sharedMemory,'CVE-2017-7228', hardware)
5	attackerAccess(publicWebApp)	10	vulProperty('CVE-2017-7228', remoteExploit, privEscalation)

Figure 11. The constructed attack steps of the experimental network

With these changes in our Prolog based tool, we constructed our attack steps as shown in Figure 11, which shows intuitive graphical attack steps for the two attacks constructed by using cyber kill chain to correlate evidence found in the attacked system. The left path shows that the attacker used a publicly available web application to launch SQL injection to the database in VM2, and the right path shows the attacker used the vulnerability in the shared hardware to attack VM2 and deleted a file in VM2.

We notice that our miniature example provides an initial example of the ATT&CK rule model. Although some rules (for example lateral movement by the attacker or pass the hash attacks) are missing. We postulate that these missing rules can be learned by using machine learning algorithms and incorporated into the steps of the ATT&CK process.

5. Conclusion

Justifying pre-attack, attack, and attack phases, requires having evidence of activities related to these phases. In APT attack analysis, there are many difficulties in constructing attack steps because (1) they do not lend themselves to traditional precondition, post-condition analysis (2) recognizing the pre-attack post-attack phases may require statistical correlation techniques that uses data from multiple sources. Thus, creating valid arguments for such attacks becomes more challenging. In particular assigning a "timestamp" for such an attack in a cloud environment becomes a challenge. We showed that we can leverage ATT&CK to identify the evidence and build the attack steps by mapping the evidence to different phases in the cyber kill chain. We used a case study to validate our framework. We plan to extend the relationship between the kill chain, evidence gathering and attack-attribution in the future work.

***Abstract*— Many industries, including manufacturing, are adopting data analytics (DA) in making decisions to improve quality, cost, and on-time delivery. In recent years, more research and development efforts have applied DA to additive manufacturing (AM) decision-making problems such as part design and process planning. Though there are many AM decision-making problems, not all benefit greatly from DA. This may be due to insufficient AM data, unreliable data quality, or the fact that DA is not cost effective when it is applied to some AM problems. This paper proposes a framework to investigate DA opportunities in a manufacturing operation, specifically AM. The proposed framework identifies and prioritizes AM potential opportunities where DA can make impact. The proposed framework is presented in a five-tier architecture, including value, decision-making, data analytics, data, and data source tiers. A case study is developed to illustrate how the proposed framework identifies DA opportunities in AM.**

Keywords—Data analytics, opportunity identification and prioritization, architecture, additive manufacturing

I. Introduction

Additive Manufacturing (AM) is a set of manufacturing technologies that join materials to produce three-dimensional (3D) objects from 3D solid models in layer-upon-layer ways opposed to the traditional subtractive manufacturing [1]. The tool-less and layer-upon-layer nature of AM provides unique capabilities of shape complexity, material complexity, hierarchical complexity, and functional complexity [2]. Such AM-enabled capabilities have largely lessened manufacturing constraints and significantly broadened design freedom, which offers new opportunities for developing functionally enhanced customized products [3]. AM is expected to lead the next generation of the manufacturing industry, the 1-batch customization era. To reach this expectation, it is important to improve performance in AM processes that eventually contributes to achieving the objectives of AM on first-part-correct and lead-time reduction.

Data analytics (DA) tools are expected to analyze data and produce actionable intelligence for the decision-makers. In recent years, the technology of DA has rapidly advanced [4]. Many researchers have demonstrated DA can help solve various manufacturing problems [5]. In this context, AM has been generating increasingly available data in the sense of volume, variety, and velocity [6]. The AM big data is providing great opportunities to use DA technologies and leverage DA capabilities to improve AM decision-making. Indeed, DA has been attracting attention in AM for data-driven decision-making [7].

DA studies in AM are still in the early stage. The majority of the existing DA studies in AM focuses on data analysis supporting only a few typical decision-making phases such as melt pool analysis for in-situ process signature monitoring [8]–[10]. This is because it is difficult to systemically map the decision-making and value chains to available DA capabilities and data, especially in AM where well-structured guidelines lack compared to other traditional manufacturing processes. It is necessary to systemically identify and prioritize DA opportunities in a complete view of AM decision-making that improves AM in general.

This paper proposes a novel framework for identifying and prioritizing DA opportunities in AM. The proposed framework has a five-tier architecture that consists of value, decision-making, data analytics, data, and data source tiers. Based on the architecture, the framework enables (1) identifying DA opportunities in AM and (2) prioritizing the identified DA opportunities. At the former phase, DA opportunities are identified with a top-down approach. The latter phase evaluates importance and feasibility (data readiness) of each identified DA opportunity.

The remainder of the paper is organized as follows. The second section describes background of AM data and DA opportunities. The third section introduces a five-tier architecture for AM data analytics that forms the foundation of the proposed framework. The fourth section presents the proposed framework for identifying and prioritizing DA opportunities in AM using the five-tier architecture. A case study in the fifth section implements the proposed framework. The paper is concluded with a brief conclusion and future work.

II. Background

A. AM Data

Advancements in sensor technologies have led to an unprecedented increase in AM data, encompassing many of

Funding agency: National Institute of Standards and Technology

Park, Hyunseop; Ko, Hyunwoong; Lee, Yung-Tsun; Cho, Hyunbo; Witherell, Paul. ”A Framework for Identifying and Prioritizing Data Analytics Opportunities in Additive Manufacturing.” Paper presented at 5th International Workshop on Methodologies to Improve Managing Big Data projects in IEEE big data 2019, Los Angeles, CA, US. December 09, 2019 - December 12, 2019.

the aspects of big data. From the volume perspective, AM generates terabyte (TB) size of in-situ monitoring data per build and TBs of computed tomography (CT) scan data [7]. From the variety perspective, AM generates data types including numerical data (e.g., machine logs), 2D images (e.g., thermal, optical), 3D (e.g., CAD models, CT scans), Audio (e.g., acoustic signals), and videos (e.g., thermal, optical) [7]. From the velocity perspective, up to 600 variables may be logged per second during the build [7]. The examples of each AM data are categorized and listed in Section III.

To capture, store, and properly manage for AM data, [11] proposes an additive manufacturing integrated data model (AMIDM) based on a product lifecycle management data modeling methods. Reference [12] presents a collaborative AM data management system, which is set to evolve through sharing of both the AM schema and AM development data among the stakeholders in the AM community. Reference [13] presents a digital thread and data package for AM to address not only data manageability but also traceability and accountability. As noted with the above studies, AM data management is studied actively but there are only few cases of DA using AM data.

B. *DA Opportunity Identification and Prioritization*

A DA opportunity can be defined as “a set of circumstances that makes DA possible to support and make impact on a decision-making issue”. Due to the lack of existing cases to refer, it is difficult to identify and prioritize DA opportunities in AM. Besides, there is no systematic method available to discover a DA opportunity. To address this issue, this paper proposes a two-phase approach: (1) identifying opportunities, and (2) prioritizing the identified opportunities. The methods for each phase used currently are reviewed as follows.

For opportunity identification, DA architectures that help describe each DA opportunity can be leveraged. Two popular architectures are used to describe DA. The Data, Information, Knowledge, Wisdom (DIKW) hierarchy uses four main components such as data, information, knowledge, and wisdom to describe DA [14]. However, the DIKW hierarchy has been criticized for its hard-to-consent definition of each tier [15]. The Analytics Canvas uses four-layer model including analytics use cases, data analysis, data pool, and data sources to describe DA use cases and the necessary data infrastructure [16]. However, the Analytics Canvas does not have a component that describes the value that each DA opportunity pursue. The DA opportunities may differ depending on the values pursued even in the same use case. For example, in the use case of predictive maintenance, the DA opportunity solves different problems depending on whether the value pursued is quality (good parts), performance (as fast as possible), or availability (no stop time).

For opportunity prioritization, multi-criteria decision-making methods, such as Fuzzy analytic hierarchy process (AHP), Fuzzy technique for order of preference by similarity to ideal solution (TOPSIS), and Fuzzy quality function deployment (QFD), can be used. Reference [17] uses Fuzzy AHP and Fuzzy TOPSIS to prioritize newly identified business model alternatives. Reference [18] uses Fuzzy QFD and Data Envelopment Analysis (DEA) to prioritize project portfolio. Reference [19] uses Fuzzy AHP and Fuzzy TOPSIS to prioritize solutions for reverse logistics barriers. Reference [20] uses Fuzzy AHP to select sustainable energy conversion technologies for agricultural residues.

III. Five-Tier Architecture for AM Data Analytics

A five-tier architecture for AM data analytics is presented in Fig. 1. The architecture is composed of the following tiers: (1) ‘Value Tier’ where values pursued in AM lifecycle are defined, (2) ‘Decision-Making Tier’ where AM decision-making activities are defined, (3) ‘Data-Analytics Tier’ where DA problems are defined, (4) ‘Data Tier’ where AM data and information are defined, and (5) ‘Data-Source Tier’ where AM data sources are defined. DA opportunity can be represented as a package composed of these five tiers.

There are relationships that drive the interactions between each tier. ‘Value Tier’ gives motivation to ‘Decision-Making

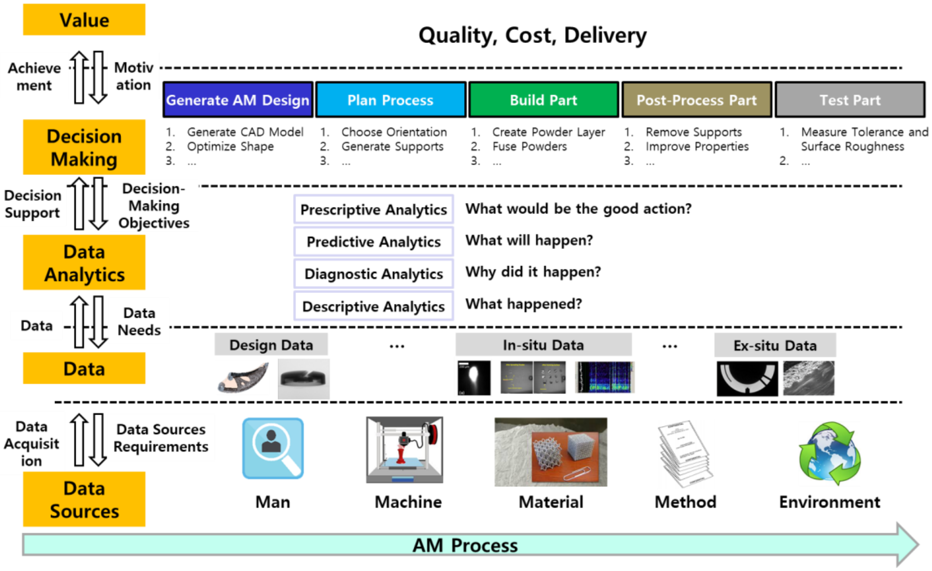

Fig. 1. 5-tier architecture for AM data analytics

Tier', 'Decision-Making Tier' achieves 'Value Tier'. 'Decision-Making Tier' gives decision making objectives to 'Data-Analytics Tier', 'Data-Analytics Tier' supports 'Decision-Making Tier'. 'Data-Analytics Tier' gives data requirements to 'Data Tier', 'Data Tier' provides data to 'Data-Analytics Tier'. Finally, 'Data Tier' gives data source requirements to 'Data-Source Tier' and 'Data-Source Tier' provides data sources to 'Data Tier'. Each tier is explained in more detail as follows.

A. Value Tier

At the Value Tier, values pursued in AM lifecycle are defined in terms of Quality, Cost, and Delivery (QCD) [21]. QCD is about value dimensions used to assess production process. Quality in AM can be performance, conformance, durability, and aesthetics. Cost in AM can be labor costs, material costs, energy costs, and maintenance costs. Delivery in AM can be on-time delivery, right amount delivery, and right location delivery. Examples of related research works in AM are in improving quality [22], reducing cost [23], and realizing on-time delivery [24].

B. Decision-Making Tier

At the Decision-Making Tier, decision-making activities for AM are defined. These activities follow the design-to-product transformation of the part, beginning at early design stages and ending with a finished part. The predefined activity model for Laser Powder Bed Fusion (LPBF) process [13], [25], which is represented using the IDEF0 [26], is used as an example. The top three levels of the decision-making activities listed in that model are shown in Table I. It includes six of Level-1 activities: 'Generate AM Design', 'Plan Process (Machine Independent)', 'Plan Process (Machine Dependent)', 'Build Part', 'Post-process Part', and 'Test Part'. These six activities are decomposed to twenty-two (22) Level-2 and thirty-four (34) Level-3 sub-activities. Decision-making objectives for each decision-making activity are also defined at this tier.

Using IDEF0, the decision-making activities can be defined by functions and related components such as input (I), control (C), output (O), and mechanism (M), or ICOM [26]. A function describes what an activity should accomplish. An input can be data, objects, or materials that are transformed by the activity. A control can be one or more conditions necessary for the activity to create correct outputs. An output is a set of results generated by the activity. A mechanism is the means that support the execution of the activity such as software, equipment, and personnel. An example is shown in Fig.2 [25]. The activity 'A11: Generate CAD Model' itself is a function. The input of the activity is a design, which refers to the conceptual design of a part and related design requirements. The control of the activity is guidelines, which refers to the design guidance that may be provided from feedback opportunities or part of governing design or process or material requirements. It is at the controller where many of the decision-making opportunities can be identified, as the configuration of the controller will impact the output of the activity. Here, the output of the activity is a CAD model, which refers to the computer-generated geometry that was developed using a CAD software. The mechanism of the activity is software, which is used to transform the design into a CAD model.

C. Data-Analytics Tier

At the Data-Analytics Tier, each decision-making objective may be translated in DA perspectives with the following four types of analytics: prescriptive analytics, predictive analytics, diagnostic analytics, and descriptive analytics [16]. Each type of analytics is described as follows. Prescriptive analytics is to answer the question of what action should be done. Prescribing optimized powder fusion parameters is an example of prescriptive analytics in AM. Predictive analytics is to answer when and what will happen. Predicting porosity is an example of predictive analytics in AM. Diagnostic analytics is to answer the question of why it happened. Identifying the relationship between design parameters and surface roughness is an example of diagnostic analytics in AM. Descriptive analytics is to answer the question of what happened. Characterizing melt pool behavior is an example of descriptive analytics.

As the type of DA is defined, it is often easier to choose suitable algorithms in a practical use. For prescriptive analytics, reinforcement learning algorithms, such as Deep Q-Learning, and recommender system algorithms, such as associate rule mining, can be used to find best action or optimize problems [27]. For predictive analytics, supervised learning algorithms, such as neural networks and support vector machine, can be used to develop predictive model [27]. For diagnostic analytics, unsupervised learning algorithms, such as K-means clustering, can be used for grouping a set of objects; and supervised learning, such as linear regression, can be used to identify causal relationships [28]–[30]. For descriptive analytics, general statistics, like mean, min, and max; and signal processing algorithms, like Wavelet Transform and Fast Fourier Transform, can be used to obtain meaningful descriptive information from raw data [31].

D. Data Tier

At the Data Tier, AM data types are defined. AM generates a variety of data. Examples are listed as follows [7].

- Material properties: material chemistry, material microstructure, powder size distribution, etc.
- Design parameters: wall thickness, orientation, overhang angle, etc.
- Process parameters: laser power, scan speed, hatch spacing, machine logs, etc.
- Process signatures: thermal data (e.g., melt pool width, temperature), optical images and videos, acoustic signals, etc.
- Part property: tensile toughness, hardness, etc.
- Product performance: fatigue life, corrosion, meets design criteria, etc.

AM data can be stored in database systems. The Additive Manufacturing Materials Database (AMMD) [32] built by National Institute of Standards and Technology (NIST) is an example.

E. Data-Sources Tier

An AM lifecycle is composed of five stages: (1) Design, (2) Process Plan, (3) Build, (4) Post Process, and (5) Test and Validation [11]. Each stage produces data from its data sources. In this tier, the data sources can be categorized into Man, Machine, Material, Method, and Environment (4M1E) [33].

4M1E are the foundation resources managed for QCD in production systems. To achieve QCD, data from 4M1E needs to be analyzed. Among 4M1E, Man means participants in the AM lifecycle such as part designers and process planners. Machine can be every machine used in the AM lifecycle including coordinate measuring machine and AM machine, also known as 3D printer. Material can be any material used in the AM lifecycle such as plastic, metal powder, or ceramic. Method in the AM lifecycle can be AM standards, part measurement methods, test specifications, etc. Finally, Environment in the AM lifecycle can be software, workplace, temperature, energy usage, etc.

IV. Proposed Framework

The proposed framework uses a five-tier architecture with sequential steps. By applying the proposed framework to set an overall DA -direction in AM, we use a two-phase approach. First, the proposed framework helps to identify DA opportunities through a top-down approach. Second, the proposed framework helps prioritize the identified DA opportunities in terms of importance and feasibility. Here, the feasibility refers to data readiness. The detail processes are described as follows.

A. Phase 1 - Identifying DA Opportunities

DA opportunities are identified with a top-down approach, as shown in Fig. 3. First, AM-lifecycle values are determined using QCD at the Value Tier. The value(s) can be one or more of the following: 'Quality', 'Cost', and 'Delivery', or their extensions, such as "Aesthetics" and "labor costs efficiency".

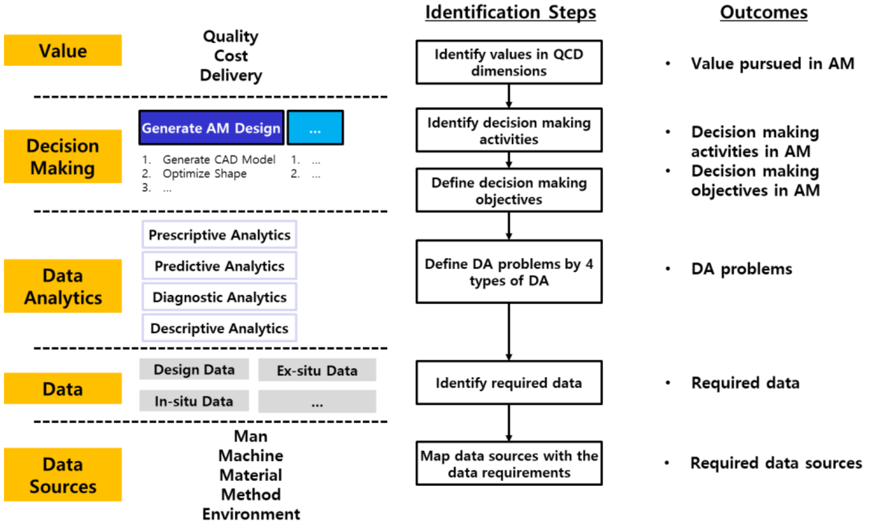

Fig. 3. Identification of DA Opportunities

Decision-making activities and decision-making objectives are identified in the 'Decision-Making Tier'. Decision-making activities are related to a pre-defined value from the Value Tier, here identified from the existing activity models, e.g., Table I. As mentioned in Section III, the decision-making activities can be broken into a set of functions and ICOMs. Once the value and decision-making activities are defined, a decision-making objective can be stated as "**Improving + [value] + when + [decision-making activity]**", where "Improving" and "when" provide syntax. For example, if the target value and decision-making activity are defined as "Material cost efficiency" and "A11: Generate CAD Model", then the corresponding decision-making objective can be stated as "Improving material cost efficiency when Generate CAD Model".

Once a decision-making objective is defined, potential types of DA problems are defined for each decision-making objective at the 'Data-Analytics Tier'. The syntax of each DA problem is summarized as follows. Note that these syntaxes are examples and are for the illustration purpose. A more complete syntax is currently under development.

- Prescriptive analytics: **"Prescribing + [C] + to maximize + [V]"**
- Predictive analytics: **"Predicting + [V] + based on given + [ICOM]"**
- Diagnostic analytics: **"Identifying relationship between + [ICOM] + and + [V] + based on their characteristics"**
- Descriptive analytics: **"Characterizing + [I] + [C] + [O] + [M] + [V]"**

Where V represents a predefined value from the Value Tier, and I is a input, C is a control, O is an output, M is a mechanism defined in the ICOM.

The goal of the prescriptive analytics is to directly support the achievement of the objectives of the corresponding decision-making activity in the IDEF0. Therefore, the prescriptive analytics tier in the framework identifies prescriptive analytics problems that consider DA objectives based on V, which aims to construct data-driven prescriptive guidelines. Based on the structured syntax of prescriptive analytics problems, following prescriptive analytics supports the development of a condition in C that can maximize V. The syntax is intended to lead associated prescriptive analytics to specifically support a transformation of an input I to a desired O with a consideration of M identified from the IDEF0 representation. Based on the syntax, prescriptive analytics can be then designed under possible situations or scenarios, to suggest courses of actions or strategies.

The predictive analytics tier aims to identify analytics problems to predict the target V. V is intended to be maximized in the prescriptive analytics. Therefore, V is used as criteria for suggesting courses of actions or strategies in the prescriptive analytics. To support this, the predictive analytics tier sets problems to predict information about possible situations or scenarios influencing V. Leveraging V and ICOM, the proposed syntax of predictive analytics problems helps to design data analytics that provides predictive criteria for associated prescriptive analytics.

The diagnostic analytics tier sets analytics problems for identifying the corelationships between ICOM and V in the past, or identifying which ICOM relationships influenced V in the past. The proposed syntax of diagnostic analytics problems helps to set data analytics approaches that provide bases the associated predictive analytics selects/extracts predictive parameters based upon. An example of the diagnostic analytics that can be considered is data analysis of ICOM relationships as root causes of the target V. Such analysis can be pursued leveraging the proposed syntax to support the V prediction of which analytics is designed in the upper-level predictive analytics tier.

The descriptive analytics tier identifies analytics problems to characterize ICOM and V to support the identification of relationships in the diagnostic analytics. It generates descriptive parameters representing data requirements that describe the required characteristics or behaviors of ICOM- and V-specific data. The ICOM- and V-specific data are then adaptively requested in the data tier to support the identification of DA opportunities.

The following examples illustrate the four DA problem types by using the same decision-making objective discussed previously, i.e., “Improving material cost efficiency when Generate CAD Model”. Note that the ICOM of A11 are I: Design, C: Design Guidelines, O: CAD Model, and M: CAD Software. To achieve that objective, a prescriptive analytics problem can be defined as “Prescribing Design Guidelines to maximize Material cost efficiency”. A predictive analytics problem can be “Predicting Material cost efficiency based on given Design, Design Guidelines, CAD Model, CAD Software”. A diagnostic analytics problem can be “Identifying relationship between Design, Design Guidelines, CAD Model, CAD Software and Material cost efficiency based on their characteristics”. Finally, a descriptive analytics problem can be “Characterizing each Design, Design Guidelines, CAD Model, CAD Software, and Material cost efficiency”.

Each defined DA problem, presented using the proposed syntax, with some grammar modifications when necessary, is treated as the title of a DA opportunity. Note that descriptive analytics can be sometimes substituted by the outputs of other decision-making activities. For example, when “Characterizing aesthetic”, other quality indicators such as surface roughness of ‘A613: Measure Surface Roughness’ can be used.

To realize the objectives of the DA problems data requirement for each DA problem should be defined at the ‘Data Tier’. For the above example, the descriptive analytics for “Characterizing each Design, Design Guidelines, CAD Model, CAD Software, and Material cost efficiency” requires data related to the Design, Design Guidelines, CAD Model, and Material cost efficiency. The prescriptive analytics for “Prescribing Design Guidelines to maximize Material cost efficiency” requires not only to have data related to the Design, Design Guidelines, and CAD Model, and Material cost efficiency but also the results of other analytics including the predicted Material cost efficiency as well. The data requirements of the DA problem will influence the feasibility of each DA opportunity. This is because the feasibility is mainly measured based on the data readiness level.

Finally, data sources are defined in the ‘Data-Source Tier’. For instance, to satisfy the data requirements for the “Characterizing Design, Design Guidelines, CAD Model, CAD Software, Material cost efficiency,” it requires data from these data sources: part designer, design guideline documents, CAD software, and cost measurement method.

Often, we identify many DA opportunities through the phase 1 process. In reality, it is difficult and also not necessary to research and develop all the identified DA opportunities, due to the constraints of time, cost, and importance. Therefore, prioritizing the DA opportunities is an important task.

B. Phase 2 - Prioritizing DA Opportunities

As shown in Fig. 4., the prioritization phase is broken into two parts: evaluating the importance of each DA opportunity and evaluating the feasibility of each DA opportunity. Decision makers (DMs) are the key persons to participate in the evaluation.

To evaluate the importance of each DA opportunity, the evaluation is performed by the DMs, starting from the ‘Value Tier’ to the ‘Decision-Making Tier’, and then to the ‘Data-Analytics Tier’. First, the importance of each identified value is assessed. Then, the importance of improving each identified value for the corresponding decision-making activity is evaluated and rated. At last, the importance of each DA problem for the decision-making activity is evaluated and rated. Finally, using a hierarchical multi-criteria decision-making method, the importance of each DA opportunity can be calculated.

To evaluate the feasibility of each DA opportunity, the evaluation is performed through ‘Data Source Tier’ to ‘Data Tier’ and ‘Data Tier’ to ‘Data-Analytics Tier’. First, the feasibility of data satisfying the requirements for each DA opportunity is investigated. Then, the importance of each data for each DA problem is evaluated. Finally, the data readiness

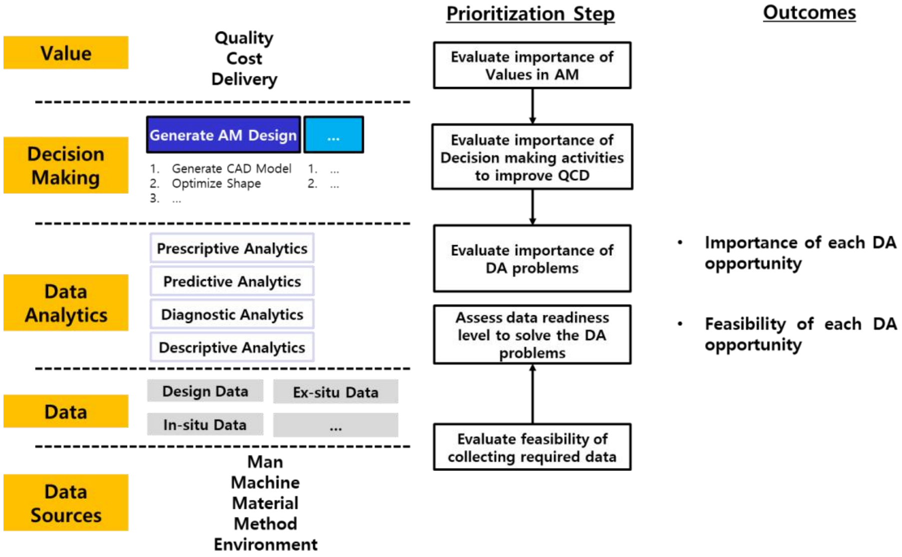

Fig. 4. Prioritization of DA opportunities

level for each DA opportunity is assessed by performing a gap analysis between the feasibility and the importance of the required data.

A sample output of the prioritization, i.e., Phase 2, using the proposed framework is shown in Fig. 4. The identified DA opportunities from Phase 1 are mapped into the prioritization matrix, where x-axis represents feasibility and y-axis represents importance. Based on the prioritization matrix, the identified DA opportunities can be classified into four groups, as shown in Fig. 5.

When mapping DA opportunities, the DA opportunities in the high importance and high feasibility groups are critical to work on. On the other hand, the DA opportunities in the low importance and low feasibility group are considered the lowest priority. The DA opportunities in the high importance and low feasibility group are potentially critical projects, where new solutions may be needed to improve the data readiness level and hence upgrade the prioritization group of the opportunity. The DA opportunities in the low importance and high feasibility group may be easy to develop but most likely the effort is not beneficial, however, sometimes such opportunities might be useful for proof of DA concept in emerging areas.

V. Case study

Phase 1 of the proposed framework is illustrated in this case study on LPBF processes. Table II shows the outputs of the proposed framework in the overall cases. Three cases, Case 1, Case 2, and Case 3 are identified by the proposed top-down approach.

The case study begins by taking the input Vs: surface texture quality, part porosity reducibility, and time efficiency. The Vs are mapped to associated decision-making activities of 'Design', 'Build Part', and 'Test Part' in Case 1, Case 2, and Case 3, respectively, in the Decision-making Tier. Then, the target levels of decision-making abstraction are systematically identified through the decomposition of the functional relationships in the IDEF0 that represents the Decision-making Tier. The AM activities identified at the target abstraction levels are "Generate Detailed Design Model for LPBF", "Monitoring In-situ Process Signatures of LPBF Behaviors", and "3D Scan Part". Once the target AM activity is determined, its corresponding ICOMs and decision-making objectives are also identified for the DA.

At the Data Analytics Tier, the target Vs, ICOMs, and decision-making objectives are leveraged to define DA objectives utilizing the proposed DA objective structures. For example, in Case 1, the Prescriptive Analytics has an objective of "Prescribing design rule to maximize surface texture quality". This objective is identified to prescriptively guide what specific design actions the activity A12-n should pursue to maximize surface texture quality for LPBF. The required information for this prescriptive analytics is the predicted surface texture quality (V for Case 1) based on based on given overhang design model, design rule, process plan, material properties, redesigned part. Based on this requirement, the Predictive Analytic formulates "Predicting surface texture quality based on given overhang design model, design rule, process plan, material properties, redesigned part".

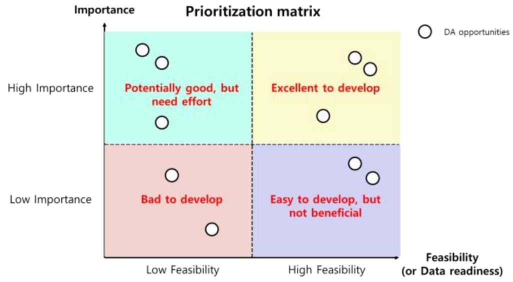

Fig. 5. Prioritization matrix

The Dignostic Analytics in Case 1 aims to solve an associated problem to support the predictive analytics. Case 1's predictive analytics requires identified relationships between the overhang design model (I for Case 1), design rule for overhang features, process plan, material properties (C for Case 1), and surface texture quality (V for Case 1). Based on this requirement, a diagnostic analytics objective is set as "Identifying relationship between overhang design model, design rule, process plan, material properties, and surface texture quality based on their characteristics". Such objectives help group data features and set necessary hypotheses in predictive analytics. Finally, the Descriptive Analytics has an objective of "Characterizing each overhang design model, design rule, process plan, material properties" to generate descriptive parameters that describe the characteristics and behaviors of Case 1-specific data.

In the proposed top-down approach, the DA objective structures enable selecting or requesting AM data sets suitable for each type of data analytics. At the same time, the DA objective structures become a bridge that links values and decision-making objectives to data requirements. Therefore, the top-down approach adaptively generates data requirements that are goal-oriented as well as DA type-specific. Such advantage provides varying DA opportunities even for the same data sources that bottom-up approaches may not be able to capture. The data of material type are good examples while they are commonly required in the 3 cases for different values, decision-making objectives, and DA types. When required data sets are not available, the top-down approach can generate a request for new AM data to incorporate data requirements into plans for further data obtainments [34]. Examples of the further data obtainment can be fusions of available data, field tests and simulations, and installations of sensor environments guided by the top-down approach.

The case study identified twelve DA opportunities from the three cases in the AM lifecycle. It is meaningful that the DA opportunities are identified without heavily referring to existing opportunities identified from other existing DA studies. This study is expected to serve as a structured guideline for researchers and practitioners who seek new DA opportunities in AM. However, the case study did not prioritize the identified DA opportunities yet. More opportunities remained to be identified so we will prioritize them in the future work.

TABLE II. AN OVERVIEW OF CASE STUDIES: OUTPUT OF EACH TIER

Tier	**Sub-items**	**Case Studies**		
		Case 1	***Case 2***	***Case 3***
Value	Quality	Surface texture quality	Part porosity reducibility	-
	Cost	-	-	-
	Delivery	-	-	Time efficiency
Decision Making	Decision Making Activity	A1: Design A12: Optimize shape A12-n: Generate Detailed Design Model for LPBF - I: Overhang design model - C: Design rule for overhang features, Process plan, Material properties - O: Redesigned part - M: CAD Software	A4: Build Part A43: Monitoring fusion A43-n: Monitoring in-situ process signatures of LPBF behaviors - I: In-situ process signatures - C: In-situ defect evaluation rule/guideline, Process plan, material properties - O: Evaluation results - M: In-situ monitoring cameras and software	A6: Test Part A61: Measure Tolerance and Surface Roughness A611: Measure External Tolerances A611-n: 3D Scan part - I: Target part - C: 3D Scan path, material properties - O: Reconstructed 3D model - M: Robotic 3D scanning system
	Decision Making Objective	Improving surface texture quality when generating detailed design model for LPBF	Improving part porosity reducibility when monitoring in-situ process signatures of LPBF behaviors	Improving time efficiency when 3D Scan part
Data Analytics	Prescriptive Analytics	Prescribing design rule to maximize surface texture quality	Prescribing in-situ defect evaluation rule/guideline to maximize part porosity reducibility	Prescribing 3D scan path to maximize time efficiency
	Predictive Analytics	Predicting surface texture quality based on given overhang design model, process plan, material properties	Predicting part porosity reducibility based on given in-situ process signatures, process plan, material properties	Predicting time efficiency based on given target part, 3D scan path, and material properties
	Diagnostic Analytics	Identifying relationship between overhang design model, process plan, material properties, and surface texture quality based on their characteristics	Identifying relationship between in-situ process signatures, process plan, material properties, and part porosity reducibility	Identifying relationship between target part, 3D scan path, material properties and time efficiency based on their characteristics
	Descriptive Analytics	Characterizing overhang design model, design rule, process plan, material properties	Characterizing in-situ process signatures, process plan, material properties, part porosity reducibility	Characterizing target part, 3D scan path, material properties, time efficiency
Data	For Prescriptive Analytics	Data of predictive surface roughness with given overhang geometry, process plan, and material properties changes	Data of predictive porosity density, shape, location with given in-situ process signatures, process plan, and material properties	Data of predictive scan time with given target part, scan path, reconstructed 3D model, material properties, scanning environment
	For Predictive Analytics	Historical data on the surface roughness as response variable Selected/extracted features from overhang geometry, process plan, and material properties as input variables	Historical data on the porosity density, shape, location as response variable Selected/extracted features from in-situ process signatures, process plan, and material properties as input variables	Historical data on the scan time as response variable Selected/extracted features from target part, scan path, reconstructed 3D model, material properties, and scanning environment as input variables
	For Diagnostic Analytics	Historical data on the surface roughness as response variable Historical data on overhang geometry, process plan, and material properties as input variable	Historical data on the porosity density, shape, location as response variable Historical data on in-situ process signatures, process plan, and material properties as input variable	Historical data on the scan time as response variable Historical data on target part, scan path, reconstructed 3D model, material properties, and scanning environment as input variables
	For Descriptive Analytics	Surface roughness data, Overhang geometry data (e.g. overhang type, downskin, surface angle, overhang dimension), Process plan data (e.g. tool path, energy source, power, speed, hatching distance, layer thickness, part position and orientation), and Material properties (e.g. density, powder distribution, material type), Design rule data	Porosity data (e.g. density, shape, location), In-situ process signatures (e.g. melt pool size, shape), Process plan data (e.g. tool path, energy source, power, speed, hatching distance, layer thickness, part position and orientation), and Material properties (e.g. density, powder distribution, material type), Design rule data	Scan time data, Target part data (e.g. CAD data), Scan path data, Reconstructed 3D model (e.g. point cloud), Material properties (e.g. material type), and Scanning environment data (e.g. light condition)
Data Source	Man	-	-	-
	Machine	LPBF machine, Ex-situ part measurement machine (e.g., XCT scanner)	LPBF machine, in-situ monitoring camera (e.g., optical camera), ex-situ part measurement machine (e.g., XCT scanner)	3D scanning robot
	Material	Process planning model, LPBFed part model	In-situ process signature model, process planning model, LPBFed part model	Target part
	Method	CAD development, LPBF machine control method, surface and volume measurement system (e. g., XCT scanner)	LPBF machine control method, in-situ monitoring method, surface and volume measurement system (e. g., XCT scanner)	3D reconstruction method
	Environment	-	-	Scanning environment, CAD software

VI. Conclusion

Although AM generates big data that provides opportunities to use DA, the AM community does not have many successful stories of the DA applications. The lack of DA cases makes it difficult for researchers and practitioners in AM to define the AM problems where DA can have an impact. To address this issue, this paper proposes a framework in a five-tier architecture, including value, decision-making, data analytics, data, and data sources, to help (1) identify and (2) prioritize DA opportunities in AM. For the former phase, a top-down approach in the five-tier architecture is formulated with a set of suggested syntaxes for describing potential DA opportunities. For the latter phase, there are two dimensions to be evaluated for prioritization: importance and feasibility. By using the proposed framework, a case study identified twelve DA opportunities in LPBF processes. These DA opportunities were identified from different values, decision-making activities, and DA types, where values are the targets the improvement aims at, decision-making activities are the AM activities that could potentially be improved in terms of quality, cost and delivery, and DA types include prescriptive, predictive, diagnostic, and descriptive analytics. The case study demonstrates the proposed framework could systematically identify potential DA opportunities in a complete view of the AM lifecycle, without heavily relying on the existing DA studies in AM. Since this framework does not stick to a certain domain so it is expected to contribute to not only AM but also other domain where DA is pre-mature.

The future work will focus on formalizations of the proposed framework that will enable the identification and prioritization of DA opportunities in a consistent way. We will continue to develop novel sets of syntax structures where the proposed formulations of DA objectives are expanded. The range of the syntax structure formulation will be expanded for the other tiers in the proposed architecture as well. The future work will then transform the prioritization phase into a formal method. The formal method will be equipped with the prioritization techniques mentioned in Section II. Furthermore, the formalized framework will be implemented in software environments with AM data and knowledge bases to automatically support identifying and prioritizing DA opportunities. The continuation of this study will eventually provide a set of DA opportunities with higher data readiness level and higher impact to the AM community.

***Abstract*—We have fabricated 129 kΩ and 1 MΩ quantum Hall array devices using GaAs/AlGaAs heterostructures and their quantized Hall resistance plateaus were precisely evaluated with an accuracy of better than 5×10^{-8} based on NIST's quantized Hall resistance standard via stable standard resistors. These higher quantized values have been attracting industrial interests for applications such as precise small electric power (small current) measurements, leakage current, and electrical insulation measurements. Given these quantum Hall array devices, an accuracy of better than 1×10^{-7} for 10 MΩ resistance standard measurements will be achieved, through a simple cryogenic quantum Wheatstone bridge technique. These devices could also be utilized for a quantum voltage divider.**

***Index Terms*—quantum Hall effect, quantum Hall array resistance standard (QHARS), high resistance measurement, low current measurement, GaAs/AlGaAs heterostructure, quantum Wheatstone bridge.**

I. Introduction

Precise measurement of DC high resistance is important for the evaluation of insulation materials, measurements of small leakage currents for the development of low power consumption devices, current-based measurements of ionizing radiation, etc. High resistance values have been measured precisely using a two-terminal cryogenic current comparator (CCC) bridge [1], [2], a four-terminal CCC [3], or an active arm bridge [4], [5] in primary metrology laboratories. A quantized Wheatstone bridge, consisting of quantum Hall array devices, could provide another way to measure 10 MΩ resistance values precisely and to confirm the reliability of these other existing measurement methods. Quantum Wheatstone bridges have been used for universality comparisons of the quantum Hall effect [6] and have been proposed for precise four-terminal measurements [7] but these treated only 1 : 1 ratios and there have been no reports regarding a 10 : 1 quantum Wheatstone bridge to date. In this paper, we propose a 10 : 1 quantum Wheatstone bridge for the precise measurement of 10 MΩ with relative uncertainty better than 1×10^{-7}. The bridge consists of a 12.9 kΩ single Hall device, a 129 kΩ device which contains ten Hall bar elements connected in series, and a 1 MΩ quantum Hall array device, and we report the precise measurement results of the 129 kΩ and the 1 MΩ devices.

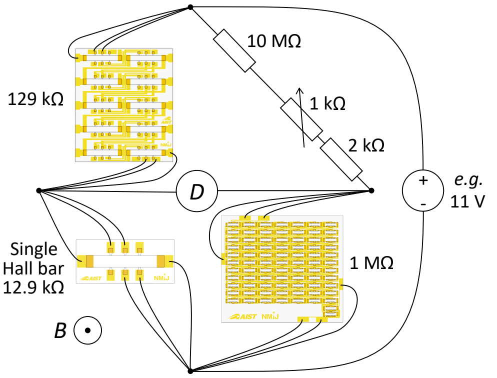

Fig. 1. Conceptual diagram of the quantum Wheatstone bridge. The left side realizes a precise and almost exact 10 : 1 ratio using the 10 series quantum Hall array device and the single Hall device. All quantum Hall array devices are connected to each other using the triple series connection technique to minimize the influence of the wiring and contact resistance.

II. Quantum Wheatstone bridge and the precise evaluation of array devices

Figure 1 shows the conceptual diagram of the quantum Wheatstone bridge. The bridge consists of a 12.9 kΩ single Hall device, a 129 kΩ device which contains ten Hall bar elements connected in series to realize a precise and almost exact 10 : 1 ratio in the left arm, and has a 1 MΩ quantum Hall array device in the right arm. A 10 MΩ standard resistor is connected in the upper right with a serially connected 2 kΩ standard resistor and a 1 kΩ precise variable decade resistor box with the minimal step of 100 mΩ to balance the bridge and to realize 10^{-8} resolution. The 10 MΩ resistance value can be determined precisely by adjusting the resistance value of the variable resistor and measuring the residual voltage or current between the neutral points. In the diagram, all array devices are connected to each other using the triple series connection technique to minimize the influence of wiring and contact resistances.

Figure 2 shows the photographs of 129 kΩ and 1 MΩ array devices mounted on TO-8 chip carriers. The 129 kΩ array device consists of ten series-connected Hall bars. The 1 MΩ array device consists of 79 Hall bars, with 77 Hall bars connected in series and two Hall bars connected in parallel

Oe, Takehiko; Panna, Alireza; Elmquist, Randolph; Jarrett, Dean G.; Fukuyama, Yasuhiro; Kaneko, Nobu-Hisa. "Precise evaluation of the 129 kΩ and 1 MΩ quantum Hall array devices for a quantum Wheatstone bridge." Paper presented at Conference on Precision Electromagnetic Measurements (CPEM), Denver, CO, US. August 24, 2020 - August 28, 2020.

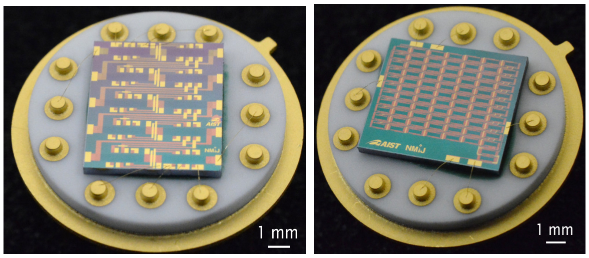

Fig. 2. Photograph of the (a) 129 kΩ and (b) 1 MΩ quantum Hall array devices mounted on a TO-8 chip carriers. 10 and 79 Hall bars are integrated on the chips, respectively.

to realize the ratio of 77.5 times $R_K/2$ and its quantized resistance value is $h/2e^2 \times 77.5 \simeq 1000\ 246.289\ \Omega$.

The current dependence curves of the Hall and the longitudinal resistance against the magnetic flux density and the precise measurement results using a four terminal cryogenic current comparator (CCC) bridge of the 129 kΩ and 1 MΩ quantum Hall array device were obtained. The results for the 1 MΩ device are shown in Figures 3 and 4. The devices were cooled down using a ^{3}He refrigerator and the device temperature was determined from the vapor pressure of ^{3}He gas to be less than 0.5 K. Both devices show flat and wide $\nu = 2$ plateaus and their longitudinal resistance shows no noticeable change for applied source-drain voltages from 1 V to 10 V. From these results, it is expected that the 10 : 1 quantum Wheatstone bridge shown in Fig. 1 can operate with an applied voltage of 11 V (77.5 μA for the left side). Both devices were fabricated on the same 20 mm square chip so that they have similar carrier density, and these devices showed no noticeable magnetic dependence from 9.3 T to 10.3 T for the 129 kΩ and from 8.4 T to 9.9 T for the 1 MΩ device. The results show that these devices can be used at the same magnetic flux density in the same refrigerator.

Since the 129 kΩ and the 1 MΩ array devices were quantized to well within 10 nΩ/Ω of their designed values, it is expected that a 10 MΩ standard resistor can be evaluated or measured precisely with relative uncertainty less than 1×10^{-7} by using the quantum Wheatstone bridge. If the applied voltage to the bridge is 11 V and the input impedance of the current detector is 10^4 Ω with a transimpedance gain of 10^{11} V/A, a resolution of 1×10^{-8} can be achieved by detecting 0.09 V (0.9 pA) at the output of the detector. The insulation resistance of the wiring should be over 10^{15} Ω for the precise measurement of 10 MΩ standards. To ensure this insulation resistance, an active guard might be needed.

III. Conclusion

The 129 kΩ and 1 MΩ GaAs/AlGaAs quantum Hall array devices were fabricated and evaluated precisely using the cryogenic current comparator bridge. These devices were well quantized to within 10 nΩ/Ω of their designed value for an overlapping range of magnetic field from 9.3 T to 9.9 T. The quantum Wheatstone bridge measurement with these devices will be performed.

***Abstract*—Over the past two decades, MEMS resonators have received considerable attention for physical, chemical and biological sensing applications. Typically, the operation of MEMS resonant sensors relies on the tracking of a resonance frequency using a feedback oscillator. The sensitivity of these sensors is limited by physical parametric variations, as in the Young's modulus, and noise in the oscillator circuit, such that improvement in the sensitivity can require significant effort in the design, fabrication, ovenization, and control of the resonator. In this paper, we experimentally demonstrate an alternative sensing approach based on a newly documented physical phenomenon, 'phononic frequency combs', where the sensitivity can be actively tuned by the drive conditions. In addition, the spectral response of frequency combs enables an 'N+1' fold enhancement in the sensitivity, with '2N+1' being the number of spectral lines associated with a frequency comb.**

Keywords—MEMS resonator; mechanical resonator; sensor; temperature sensor; nonlinear dynamics; phononic frequency comb.

I. Introduction

MEMS resonators have been actively explored for sensing applications by many research groups around the world [1-8]. Resonant sensing is traditionally made possible by tracking the resonance frequency of one of the modes of the MEMS structure with the help of an electronic feedback circuit. Parametric variations due to temperature fluctuations and noise in the oscillator circuit can limit the performance of these sensors. Solutions for mitigating these limits, including the use of material combinations that minimize parametric variations, ovenization, and improved circuit and control design are possible but require significant research effort to optimize their performance. In this paper, we present an alternative sensing approach that fundamentally relies on the nonlinear dynamics of MEMS resonators leading to the generation of phononic frequency combs. Phononic frequency combs correspond to a series of equidistant and phase-coherent frequencies [9-18]. These frequency combs can be generated when a resonant

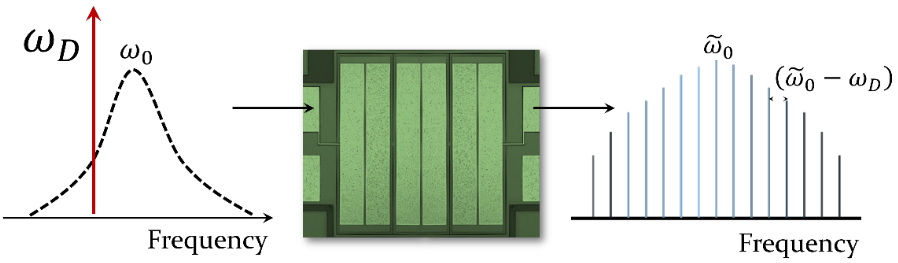

Figure 1: A strong off-resonance drive of the mechanical mode leads to an array of equidistant frequencies, referred to as a 'phononic frequency comb'. The equidistant frequency spacing of the frequency comb is set by the difference between drive frequency (ω_D) and the renormalized resonant frequency ($\widetilde{\omega}_0$) of the MEMS resonator.

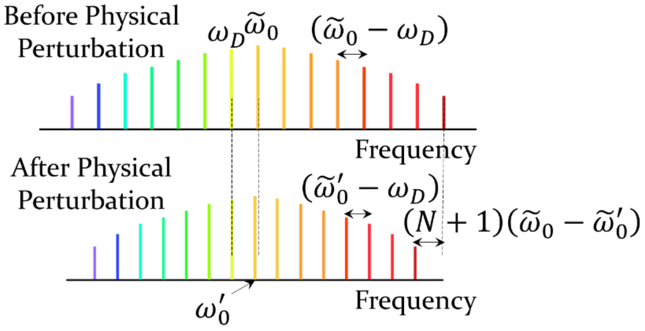

Before Physical Perturbation
$\omega_D \widetilde{\omega}_0$
$(\widetilde{\omega}_0 - \omega_D)$
Frequency
After Physical Perturbation
$(\widetilde{\omega}'_0 - \omega_D)$
$(N+1)(\widetilde{\omega}_0 - \widetilde{\omega}'_0)$
ω'_0
Frequency

Figure 2: The shift of the frequency comb line $[\widetilde{\omega}_0 + N(\widetilde{\omega}_0 - \omega_D)]$ is 'N+1' times more sensitive than the fundamental comb line $[\widetilde{\omega}_0]$.

Ganesan, Adarsh; Seshia, Ashwin; Gorman, Jason J. "Phononic Frequency Combs For Engineering MEMS/NEMS Devices With Tunable Sensitivity." Paper presented at IEEE SENSORS 2019, Montreal, CA. October 27, 2019 - October 30, 2019.

mode of a MEMS resonator is strongly driven off-resonance (Figure 1). The frequency spacing of such combs is governed by the difference between the drive frequency (ω_D) and the renormalized resonance frequency ($\widetilde{\omega}_0$) of the MEMS resonator (Figure 1). Unlike the resonance frequency of MEMS resonators (ω_0), the renormalized resonance frequency can heavily depend on the drive conditions. We want to leverage this dependence for sensing applications. Also, since the shift of the renormalized resonance frequency is cumulatively accrued in the highest order frequency comb lines, an 'N+1' fold enhancement in the sensitivity can be obtained: $[\widetilde{\omega}_0 + \mathrm{N}(\widetilde{\omega}_0 - \omega_D)] - [\widetilde{\omega}'_0 + \mathrm{N}(\widetilde{\omega}'_0 - \omega_D)] = \left[\underbrace{(\mathrm{N}+1)} * (\widetilde{\omega}_0 - \widetilde{\omega}'_0)\right]$, as pictorially demonstrated in Figure 2.

II. Experimental Setup

For the demonstration of the phononic frequency comb-based sensing approach, a MEMS system containing three coupled free-free beam structures of dimensions $1100\ \mu\mathrm{m} \times 350\ \mu\mathrm{m} \times 11\ \mu\mathrm{m}$ is considered (Figure 1). The mechanical coupler connecting the three beams has the dimensions $20\ \mu\mathrm{m} \times 2\ \mu\mathrm{m} \times 11\ \mu\mathrm{m}$. The device consists of three material layers: $10\ \mu\mathrm{m}$ thick Si, $0.5\ \mu\mathrm{m}$ thick AlN and $1\ \mu\mathrm{m}$ thick Al. The Al pad electrodes that are connected to Al patterns on the MEMS device allow for electrical interfacing, and the AlN film provides piezoelectric actuation in response to the electrical signal inputs. The synthesized electrical signal from an arbitrary waveform generator with the frequency set close to the resonance frequency is applied and the resulting response of the device is characterized using a spectrum analyzer. Additionally, a vector network analyzer is used to characterize the linear response of MEMS resonator. All frequency measurements have an uncertainty of +/- 8 Hz. The entire set of measurements presented here was conducted in a temperature-controlled oven.

III. Temperature Sensitivity of the Linear Dynamics for the MEMS Resonator

The open-loop response of the MEMS resonator is obtained at 0 dBm (Figure 3A). The peak frequency of ≈ 3.853 MHz is tracked using a manual peak detection algorithm at varying oven temperature and the scatter in the data is due to measurement repeatability and fit errors (Figure 3B). The temperature range of 70 ℃ to 90 ℃ was chosen arbitrarily. The temperature coefficient of frequency (TCF) for this specific device under test is calculated to be ≈ -4.67 Hz/MHz/℃ (ppm/℃).

IV. Temperature Sensitivity of Phononic Frequency Combs

For the excitation of phononic frequency combs, a single tone is fed into the MEMS resonator. The device is set at a temperature of 70 ℃ and the drive conditions corresponding to the existence of phononic combs is charted out in Figure 4. A representative spectral response of the phononic frequency comb is presented in Figure 5, with frequencies at $\widetilde{\omega}_0 + \mathrm{N}(\widetilde{\omega}_0 - \omega_D)$.

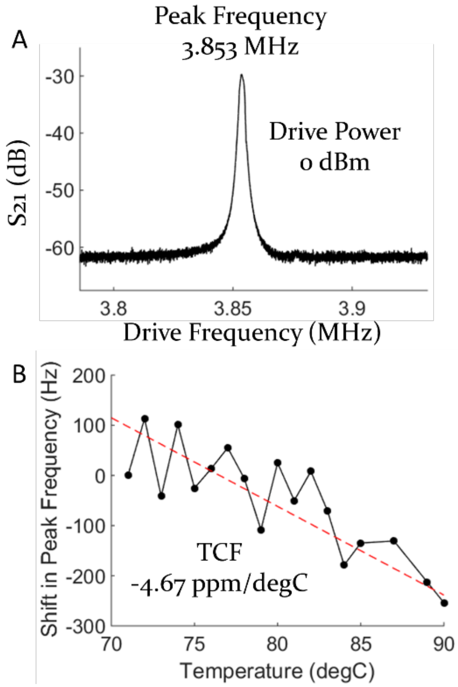

Figure 3: A: Linear response of the MEMS resonator, as recorded using the network analyzer; B: The shift in the peak frequency as the temperature is varied from 70 ℃ to 90 ℃. A linear fit to the experimental data is used to calculate the temperature coefficient of frequency (TCF).

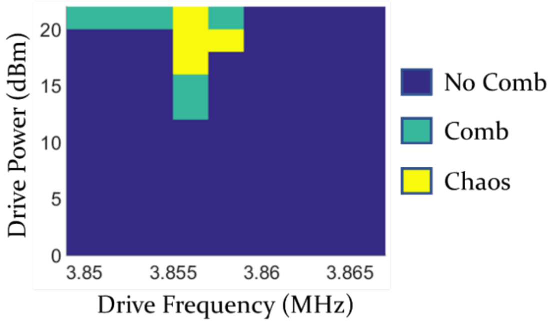

Figure 4: The drive parameter map indicating the existence of phononic frequency combs - 'green' colored region.

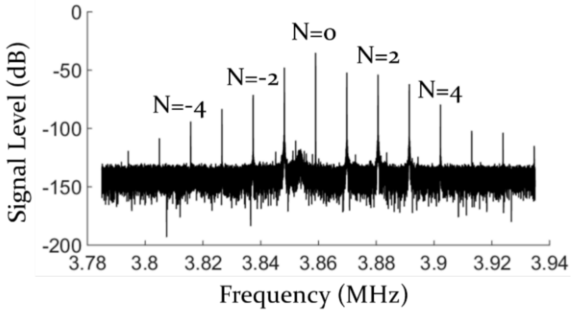

Figure 5: The spectrum of phononic frequency combs at the drive frequency 3.859 MHz and drive power 22 dBm.

Ganesan, Adarsh; Seshia, Ashwin; Gorman, Jason J. "Phononic Frequency Combs For Engineering MEMS/NEMS Devices With Tunable Sensitivity." Paper presented at IEEE SENSORS 2019, Montreal, CA. October 27, 2019 - October 30, 2019.

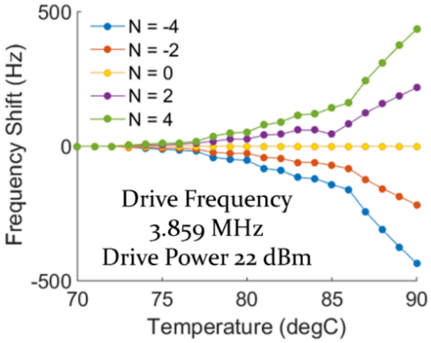

Figure 6: Temperature dependence of different lines, $\mathrm{N} = 0, \pm 2, \pm 4$, of the phononic frequency comb: $[\widetilde{\omega}_0 + \mathrm{N}(\widetilde{\omega}_0 - \omega_D)]$.

Figure 6 shows the temperature dependence of different comb lines of the phononic frequency comb. The higher order comb lines of $\mathrm{N} = \pm 4$ demonstrate greater shifts in frequency than those associated with the nearer lines $\mathrm{N} = \pm 2$. While the frequency comb in this experiment contains a sparser number of comb lines (Figure 5), it is desirable to engineer a broadband comb spectrum to achieve greater sensitivity by tracking the highest order line in the comb using narrowband electrical filtering. From Figure 6, we can see that there is a greater temperature gradient in the range of 85 ℃ to 90 ℃. Hence, for greater temperature sensitivity, it is desirable to operate the device in this band of temperatures, which can be practically implemented using *in situ* microheaters.

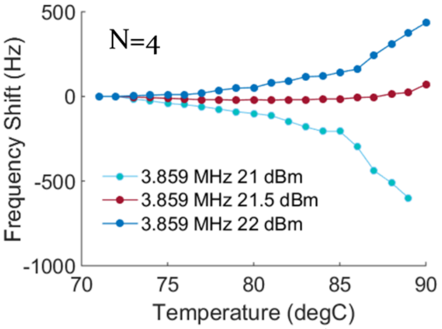

Figure 7: Temperature dependence of the 4th line of the phononic frequency comb $[\widetilde{\omega}_0 + \mathrm{N}(\widetilde{\omega}_0 - \omega_D)]$ at varying drive conditions.

While it is desirable to track the higher order comb line to achieve greater sensitivity (Figure 6), Figure 7 shows that even a slight increase in the drive power from 21 dBm to 22 dBm can reverse the nature of the temperature dependence, with the drive power of 21.5 dBm leading to temperature-insensitive frequency comb lines. Hence, without the need for sophisticated materials, fabrication, and ovenization, the temperature sensitivity can be actively tuned by the drive conditions. In comparison to Figure 3B, the frequency shift over the temperature range of 70 ℃ to 90 ℃ has increased by a factor of 5/3, which in turn can be improved by rigorous computational and experimental studies of the dynamics of phononic frequency combs.

V. SUMMARY

This paper demonstrates that the temperature sensitivity of MEMS resonators can be tuned using a newly documented physical mechanism: phononic frequency combs. The highest order line in the frequency combs offers 'N+1' fold enhancement in the sensitivity, with '$2\mathrm{N}+1$' being the number of comb lines. The sensitivity of these comb lines can be further tuned by the drive power and drive frequency. While we chose temperature as the physical variable to prove the concept of frequency comb-based sensing, the technique can be readily used for other sensing applications including particle detection. The concept of frequency comb-sensing is also relevant to other established frequency comb sources including microresonator-based frequency combs [19-22]. By integrating such multiwavelength optical sources with phononic frequency combs through dynamic optomechanical interactions, the number of comb lines $(2\mathrm{N}+1)$ can be drastically enhanced to achieve a greater magnitude of '$\mathrm{N}+1$' fold enhancement in the sensitivity.

A Unified Analytical Approach to Multi-Cell LBT-Based Spectrum Sharing Systems

Yao Ma, Susanna Mosleh, and Jason Coder
CTL, National Institute of Standards and Technology
325 Broadway, Boulder, Colorado, USA

***Abstract*— Future unlicensed spectrum sharing scenarios involve multi-cell, multi-tier access of incumbent and emerging wireless systems, such as wireless local area network (WLAN), New-Radio unlicensed (NR-U), and Long-Term Evolution (LTE) with Licensed-Assisted Access (LAA). Listen-before-talk (LBT) medium access control (MAC) is a common technique used for channel sensing and access control. Despite intense research efforts, the majority of available results have not accurately analyzed multi-cell LBT with imperfect spectrum sensing. Furthermore, while past studies involved two major spectrum sharing strategies – shared cell access (SCA) and exclusive cell access (ECA), they missed a systematic comparison between the two. In this paper, we develop a unified analytical approach which maps the effects of imperfect spectrum sensing and multi-cell, multi-tier LBT to the key performance indicators (KPIs) of LAA and WLAN cells. We provide an analytical comparison between the SCA and ECA schemes, and show that the SCA can provide a significantly higher system throughput than the ECA as a function of sensing thresholds. We program the SCA and ECA algorithms with a new simulation method and implement Monte Carlo simulations, which verify our analytical results. Numerical results provide insightful observations on effects of various parameters. These results provide powerful analytical and simulation tools to evaluate the performance of multi-tier LBT coexistence systems with imperfect sensing, and effectively support coexistence system optimization.**

Index Terms: Imperfect spectrum sensing, LTE-LAA, Multi-tier coexistence, Multi-cell LBT, WLAN.

I. Introduction

Spectrum sharing in heterogeneous 4G and 5G wireless systems [1]–[4] involves multiple radio access technologies (RATs) of emerging wireless systems such as cellular Long-Term Evolution (LTE) or New Radio (NR) systems with unlicensed or License Assisted Access (LAA) [1]–[3], and incumbent services such as wireless local area networks (WLANs) [5], [6]. In these systems, various listen-before-talk (LBT) medium access control (MAC) schemes are used for channel sensing and access control.

Regarding LBT-based multi-cell spectrum sharing, there are two popular assumptions or schemes which we call shared cell access (SCA) and exclusive cell access (ECA), respectively. Both schemes use clear channel assessment (CCA) and detect the channel busy/idle states of adjacent cells. Without loss of generality, we assume that each LAA small-cell base station (SBS) or WLAN access point (AP) does the sensing, and schedules downlink transmissions in each cell (or contention zone).

In the SCA model, each SBS/AP assumes imperfect sensing and can schedule transmissions when the received intercell interference (ICI) from adjacent cells is below the sensing threshold. This model allows several cells (or links) to transmit simultaneously when the mutual ICIs are below their sensing thresholds. The SCA methods for multi-cell networks have been considered in [7]–[10], to name a few.

The ECA scheme assumes that at any time a successful transmission happens when only one link is transmitting. It is consistent with the carrier sense multiple access with collision avoidance (CSMA/CA) performance modeling provided in [11]. The ECA scheme has been assumed in [12]–[16] for spectrum sharing. Certainly, the ECA scheme applies only to a small area of highly overlapped cells, when the SBS/AP sensing thresholds are set to be adequately low. The ECA scheme can be regarded as a special case of the SCA scheme.

In the studies mentioned above, the effect of ICI sensing errors on the network throughput has not been explicitly addressed. Furthermore, the LBT MAC features for the SCA have not been adequately modeled or studied. For example, [7], [8], [12] did not model an important MAC metric – average channel busy time to support a successful transmission. The effect of inter-SBS/AP ICI sensing errors was only implicitly studied in [12], and the LBT MAC feature (such as multistage backoff) was not adequately modeled. We have provided a novel analytical approach to evaluate the effect of CCA errors on the LAA and WLAN network throughput in [17] assuming an ECA scheme. The result in [17] cannot be readily applied to the SCA scheme.

In summary, analyzing the effect of CCA errors on the key performance indicators (KPIs) of multi-cell LBT coexistence systems has not been satisfactorily addressed in the literature. Furthermore, there is a lack of a systematic comparison of SCA and ECA models in a unified framework. It is interesting to investigate if the SCA can provide higher KPIs than the ECA even when cells are densely overlapped. Yet we could not find such a comparative analysis available in the literature. This comparative analysis is useful, for example, on the selection of sensing threshold and MAC parameters, and the design of better spectrum sharing algorithms.

The related computer simulation work is non-trivial, because the traditional discrete-event driven simulation methods, such as those targeted for the ECA (in [11], [15]) and/or perfect channel sensing, cannot be directly used. The imperfect sensing in a multi-cell network can cause multiple nodes to implement backoff or transmission simultaneously. The sim-

Ma, Yao; Mosleh, Susanna; Coder, Jason. "A Unified Analytical Approach to Multi-Cell LBT-Based Spectrum Sharing Systems." Paper presented at the 2020 IEEE 91st Vehicular Technology Conference: VTC2020-Spring, Antwerp, BE. May 25, 2020 - May 28, 2020.

ulation shall model the resulting mis-detection and collision events in a fine time step-size of a CCA duration, and follow the multicell LBT procedure. We are not aware of an open-source or commercial software that can readily simulate such a scenario.

In this paper, we address the challenging problem of modeling and analysis for multi-cell LAA and WLAN coexistence networks with imperfect sensing of ICIs, and treat the SCA and ECA schemes in a unified framework. We highlight the novel contributions as follows:

- We develop a new method on integrating effects of spectrum sensing detection probability and multi-cell LBT MAC features, and mapping them to the system KPIs, including the channel access probability (CAP), successful transmission probability (STP), and throughput.
- We provide a unified analysis and systematic comparison of the SCA and ECA schemes for LAA and WLAN coexistence networks.
- By developing a new simulation method, we program the SCA and ECA algorithms with multi-cell and multi-tier LBT, and implement Monte Carlo simulations, which validate our analytical results.

Numerical results show the effects of critical MAC and physical layer parameters such as sensing threshold and detection probability, and demonstrate the performance improvement of the SCA scheme over the ECA scheme. This technique provides significant progress on performance modeling and analysis of multi-cell LBT coexistence schemes, and support 4G and 5G multi-cell optimization in license-assisted or unlicensed spectrum bands.

II. System Model

We consider a two-tier channel access system on a 5 GHz industrial, scientific, and medical (ISM) radio band, where there is an LTE-LAA system with C_L small cells and a WLAN system with C_W cells (aka. contention zones), which are assumed to be the emerging and incumbent services, respectively. All cells share a single wide-band channel, and use CSMA/CA type of MAC channel access procedures specified in [1], [2], [5]. Each LAA and WLAN cell is controlled by an SBS and AP, respectively, or called scheduler in general, using LBT or distributed coordination function (DCF) protocols to sense the channel activity of other cells and schedule downlink transmissions. The system model is presented in Fig. 1, where each LTE-LAA SBS or WLAN AP senses channels and schedules downlink transmission to its associated users. Each user receives downlink ICIs of neighboring SBSs and APs, shown in red lines.

Let all cells be indexed by $c \in \{1, \ldots, C_{\text{tot}}\}$, where $C_{\text{tot}} = C_L + C_W$, $c \in \{1, \ldots, C_L\}$ refers to an LAA cell, and $c \in \{C_L+1, \ldots, C_{\text{tot}}\}$ refers to a WLAN cell. There are N_c users in cell c, and pair (c, n) denotes user node n in cell c. The downlink transmit power at cell c is denoted as $P_{T,c}$.

Throughout this paper, we use subscripts L, W, I, S, F, and P to denote LAA, WLAN, idle, successful transmission, failed transmission, and payload, respectively. For cell c, we define δ, $T_{P,c}$, $T_{S,c}$ and $T_{F,c}$ as durations of idle slot, payload, successful transmission, and failed transmission, respectively; and define τ_c, $P_{I,c}$, $P_{S,c}$ and $P_{F,c}$ as the probabilities of channel access, channel idle, successful transmission, and failed transmission.

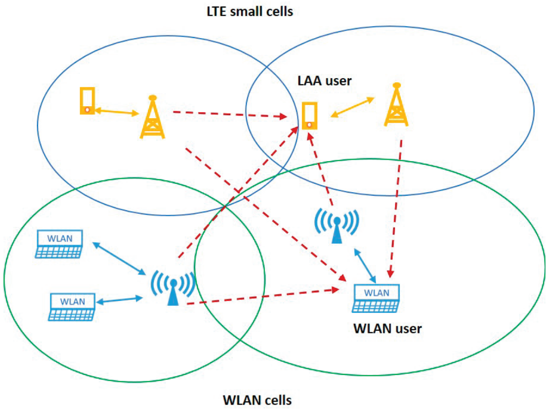

Fig. 1: Model of multi-cell LTE-LAA and WLAN systems.

We consider a frequency-flat Rayleigh block fading channel model for each communication and interference link, which is static in a block of milli-seconds level (which approximately corresponds to a transmission duration), then changes independently from block to block. The power of channel gain from scheduler c_2 to user (c, n) is denoted as $h_{(c,n),c_2}$, and the power of channel from scheduler c_2 to scheduler c is represented as g_{c,c_2}. The probability density function (PDF) of channel power $h_{(c,n),c_2}$ is given by

$$h_{(c,n),c_2}(P) = \exp(-P/\bar{P})/\bar{P}, \tag{1}$$

where $\bar{P}$ is the average power of fading channel gain. Based on [18], we have $\bar{P} = E[h_{(c,n),c_2}] = (4\pi/\lambda_c)^2 d_{(c,n),c_2}^{-\alpha_d}$, where λ_c is the carrier wavelength, $d_{(c,n),c_2}$ is distance between scheduler c_2 to node (c, n), and α_d is the path loss exponent.

Regarding the MAC parameters at scheduler c, we assume that the contention window size (CWS) is $W_{c,m}$ at backoff stage m (for $m = 0, 1, \ldots, M_c$), where M_c is the maximum backoff stage. We present the SCA and ECA schemes next.

Multi-cell Downlink SCA Scheme:

Each scheduler c implements the following procedure:

1) Based on a CSMA/CA protocol, scheduler c draws an initial backoff counter value within $(0, W_{c,m} - 1)$ based on the current CWS $W_{c,m}$.
2) Scheduler c senses channel activities and compares the received sum ICI power with sensing threshold $I_{d,c}$ during each sensing slot δ.
3) If ICI power exceeds threshold, scheduler c freezes its backoff counter; otherwise, it reduces counter value by one. Go back to Step 2) when counter is larger than zero; otherwise go to step 4).
4) Based on either request-to-send/clear to send (RTS/CTS) or basic access, scheduler c sends handshaking or payload signals to associated users.
5) If the majority of transmissions are successful, scheduler c reduces CWS to $W_{c,0}$; otherwise, it doubles the CWS,

unless the maximum CWS W_{c,M_c} is reached. Go back to step 1).

On the other hand, when the cells are highly overlapped spatially, and/or when the sensing threshold at every scheduler is very low, each scheduler can detect transmissions in any adjacent cell perfectly. We call this the Multi-cell Downlink ECA Scheduling Scheme.

To implement LBT or DCF, an SBS uses only one threshold based on energy detection (ED) $I_{L,\text{ed}}$ to sense transmissions in other cells, and an AP uses two thresholds – carrier sensing (CS) threshold $I_{W,\text{cs}}$ to sense WLAN transmissions of other cells, and ED threshold $I_{W,\text{ed}}$ to detect other type of transmissions (such as LAA signals), respectively. We use I_{d,c,c_2} to denote the sensing threshold of scheduler c to detect signals from a neighboring cell c_2, then

$$I_{d,c,c_2} = \begin{cases} I_{L,\text{ed}} & \text{for } c \in \{1, \dots, C_L\}, \text{ and any } c_2, \\ I_{W,\text{ed}} & \text{for } c \in \{C_L + 1, \dots, C_{\text{tot}}\}, \\ & \text{and } c_2 \in \{1, \dots, C_L\} \\ I_{W,\text{cs}} & \text{for } c \in \{C_L + 1, \dots, C_{\text{tot}}\}, \\ & \text{and } c_2 \in \{C_L + 1, \dots, C_{\text{tot}}\}. \end{cases}$$

Furthermore, we define $I_{f,c}$ as the ICI maximum tolerance threshold at scheduler c.

III. Performance Analysis

We first derive the multi-cell LAA and WLAN coexistence performance with the SCA, and then simplify the results to the ECA and discuss their relationship.

A. Shared Cell Access

In this method, we model the ICI from each source individually, and then combine the impacts. We use $\hat{H}_0$ and $\hat{H}_1$ to denote decisions of null and transmission, respectively. We define P_{d,c,c_2} as the detection probability of scheduler c_2 at scheduler c, when a transmission from cell c_2 with power P_{T,c_2} starts, with decision threshold I_{d,c,c_2} and local noise power spectrum density (PSD) $N_{0,c}$. Thus,

$$P_{d,c,c_2} \quad = \quad \Pr(P_{T,c_2} g_{c,c_2} + N_{0,c} < I_{d,c,c_2}).$$

Suppose that we use a sensing duration of δ_{SS} with sampling rate B_W, and obtain $[\delta_{SS} B_W]$ samples to make a block decision, where $[x]$ rounds x to its nearest integer. By default, $\delta = 9$ μs and $\delta_{SS} \geq 4$ μs at the 5 GHz ISM band [2], [5]. Typically, $\delta_{SS} B_W \gg 1$ holds. For example, when $\delta_{SS} = 5$ μs and $B_W = 20$ MHz, we have $[\delta_{SS} B_W] = 100$. With $\delta_{SS} B_W \gg 1$, the sum power of the sampled complex noise has a Gamma distribution with degree of freedom (DOF) $[2\delta_{SS} B_W]$, which approximates a constant. On the other hand, due to limited Doppler shift for small-cell communication, we model the inter-SBS/AP channel g_{c,c_2} as a slow Rayleigh fading channel, and its DOF is only 2 in the δ_{SS} sensing duration. In summary, the magnitude of the received ICI follows a Rayleigh distribution in the δ_{SS} duration (slow fading), and its power follows an exponential distribution.

We obtain the inter-cell detection probability as

$$\begin{aligned} P_{d,c,c_2} &= \Pr(P_{T,c_2} g_{c,c_2} < \tilde{I}_{d,c,c_2}) \\ &\simeq 1 - \exp(-\tilde{I}_{d,c,c_2} / [P_{T,c_2} \bar{g}_{c,c_2}]), \end{aligned} \qquad (2)$$

where $\tilde{I}_{d,c,c_2} = \max(I_{d,c,c_2} - N_{0,c}, 0)$, $\bar{g}_{c,c_2} = E[g_{c,c_2}]$, and $E[\cdot]$ here is with respect to the fading channel distribution.

Furthermore, we define P_{f,c,c_2} as the probability that ICI from cell c_2 causes transmission of cell c to fail. We obtain that $P_{f,c,c_2} = \Pr(P_{T,c_2} g_{c,c_2} < \tilde{I}_{f,c}) \simeq 1 - \exp(-\tilde{I}_{f,c} / [P_{T,c_2} \bar{g}_{c,c_2}])$, where $\tilde{I}_{f,c} = \max(I_{f,c} - N_{0,c}, 0)$.

Define $\tilde{P}_{\text{suc},c}$ as the conditional STP of scheduler c when its transmission starts, and $P_{\text{suc},c}$ as the average STP. We obtain $\tilde{P}_{\text{suc},c} = \prod_{\substack{c_2=1 \\ c_2 \neq c}}^{C_{\text{tot}}} (1 - \tau_{c_2} P_{f,c,c_2})$. Note that in $\tilde{P}_{\text{suc},c}$ the term $1 - \tau_{c_2} P_{f,c,c_2}$ can be decomposed to two parts: $1 - \tau_{c_2}$ which is probability that cell c_2 is not active and $\tau_{c_2}(1 - P_{f,c,c_2})$, which is probability that cell c_2 is active but its generated ICI does not cause transmission of cell c to fail.

The CAP of scheduler c is a function of $\tilde{P}_{\text{suc},c}, W_{c,0}$, and M_c. Based on [15], the CAP of scheduler c is given by:

$$\tau_c \quad = \quad \frac{2(1 - (1 - \tilde{P}_{\text{suc},c})^{M_c + 1})}{\tilde{P}_{\text{suc},c} \sum_{j=0}^{M_c} (1 - \tilde{P}_{\text{suc},c})^j (1 + W_c)}. \qquad (3)$$

We derive the average STP at cell c as

$$P_{\text{suc},c} = \tau_c \tilde{P}_{\text{suc},c}. \qquad (4)$$

We define $T_{\text{suc},c,n}$ as the normalized throughput duration (NTD) of user (c, n), which is given by

$$T_{\text{suc},c,n} = \alpha_{(c,n)} P_{\text{suc},c} T_{P,c} / T_{\text{ave},c},$$

where $\alpha_{(c,n)}$ is time ratio allocated to node n (with $\sum_{n=1}^{N_c} \alpha_{(c,n)} = 1$), and $T_{\text{ave},c}$ is the average time in cell c to support one successful transmission. The overall NTD at cell c is given by

$$T_{\text{suc},c} \quad = \quad \sum_{n=1}^{N_c} T_{\text{suc},c,n}. \qquad (5)$$

The NTD is conceptually similar to the successful channel occupancy efficiency, or called normalized throughput in [15]–[17]. Note that $\sum_{c=1}^{C_{\text{tot}}} T_{\text{suc},c} > 1$ can hold for the SCA scheme, but not for the ECA scheme. The NTD does not model the physical-layer data rate.

To model both MAC- and physical-layer features, we define the average throughput of user (c, n) as

$$\begin{aligned} S_{c,n} &= \alpha_{(c,n)} P_{\text{suc},c} T_{P,c} \\ &\quad \cdot B_{(c,n)} E[\log_2(1 + \beta_{(c,n)} \gamma_{(c,n)})] / T_{\text{ave},c}, \end{aligned} \qquad (6)$$

where $\gamma_{(c,n)}$ is the signal-to-interference-and-noise ratio (SINR) at user (c, n), $E[\cdot]$ is the expectation with respect to the distribution of $\gamma_{(c,n)}$, and $\beta_{(c,n)}$ is the signal-to-noise ratio (SNR) gap function [18], given by $\beta_{(c,n)} = -1.5 / \log(5\text{BER}_{(c,n)})$, where $\text{BER}_{(c,n)}$ is the target bit error rate (BER) for user traffic. The cell c sum-throughput is given by

$$S_c = \sum_{n=1}^{N_c} S_{c,n}. \qquad (7)$$

We derive $\gamma_{(c,n)}$ as

$$\gamma_{(c,n)} = \frac{P_{T,c} h_{(c,n),c}}{I_{\text{tot},(c,n)}(\hat{H}_0) + N_{0,c}}, \qquad (8)$$

where $I_{\text{tot},(c,n)}(\hat{H}_0)$ is the average total interference power at node (c,n) under $\hat{H}_0$ decision at cell c, when the scheduler c starts a downlink transmission. It is given by

$$I_{\text{tot},(c,n)}(\hat{H}_0) = \sum_{\substack{c_2=1\\c_2\neq c}}^{C_{\text{tot}}} P_{T,c_2}\tau_{c_2}\bar{h}_{(c,n),c_2}(1-P_{d,c,c_2}). \qquad (9)$$

where $\bar{h}_{(c,n),c_2} = E[h_{(c,n),c_2}]$. In (9), we introduce the factor $(1-P_{d,c,c_2})$ to represent the probability of experienced ICI at scheduler c.

Finally, we analyze the $T_{\text{ave},c}$ which is challenging to evaluate due to the multi-cell ICIs and CCA errors. To distinguish between LAA and WLAN cells, we use $T_{F,L}$ and $T_{F,W}$ to denote durations caused by failed transmission in an LAA and WLAN cell, and $T_{F,M} = \max(T_{F,L}, T_{F,W})$. After some manipulations, we derive $T_{\text{ave},c}$ as

$$\begin{aligned}T_{\text{ave},c} = P_{I,c}\delta + P_{\text{suc},c}T_{S,c} + \sum_{\substack{c_2=1\\c_2\neq c}}^{C_{\text{tot}}} P_{d,c,c_2}P_{\text{suc},c_2}T_{S,c_2}\\ +P_{F,L,c}T_{F,L} + P_{F,W,c}T_{F,W} + P_{F,LW,c}T_{F,M}, \qquad (10)\end{aligned}$$

where the first, second and third terms are related to events of system idle, successful transmission at cell c, and cell-c sensed successful transmissions of other cells, respectively; and in the 4th to 6th terms $P_{F,L,c}$, $P_{F,W,c}$, and $P_{F,LW,c}$ are, respectively, probabilities of failed transmissions (e.g. caused by collisions) at only LAA cells, at only WLAN cells, and at both LAA and WLAN cells. In detail, $P_{I,c}$ is the system idle probability sensed by scheduler c, given by

$$P_{I,c} = \prod_{c_2=1}^{C_{\text{tot}}}(1-\tau_{c_2}P_{d,c,c_2}), \qquad (11)$$

where $P_{d,c,c} = 1$ holds. In the 3rd term of (10), the factor P_{d,c,c_2} models an important fact that schedule c only freezes its counter when it can sense a downlink transmission in cell c_2. We can combine the second and third terms to $\sum_{c_2=1}^{C_{\text{tot}}} P_{d,c,c_2}P_{\text{suc},c_2}T_{S,c_2}$ by using the fact that $P_{d,c,c} = 1$ holds. Furthermore, we can obtain that in (10),

$$\begin{aligned}P_{F,L,c} &= \left[\prod_{c_2=C_L+1}^{C_{\text{tot}}}(1-\tau_{c_2}P_{d,c,c_2})\right]\\ &\cdot\left[1-\prod_{c_2=1}^{C_L}(1-\tau_{c_2}P_{d,c,c_2}) - \sum_{c_2=1}^{C_L}P_{d,c,c_2}P_{\text{suc},c_2}\right] \qquad (12)\\ P_{F,LW,c} &= \left[1-\prod_{c_2=1}^{C_L}(1-\tau_{c_2}P_{d,c,c_2})\right]\\ &\cdot\left[1-\prod_{c_2=C_L+1}^{C_{\text{tot}}}(1-\tau_{c_2}P_{d,c,c_2})\right], \qquad (13)\end{aligned}$$

where on the right handside of (12), the first factor models the probability of failed transmission event at LAA cells, and the second factor is the probability of idle channel event at WLAN cells, when both events happen and are sensed by scheduler c. The expression of $P_{F,W,c}$ can be obtained using a similar procedure, but is omitted here due to the space limitation.

When $T_{F,L} = T_{F,W} = T_F$ holds, we can simplify (10) to

$$T_{\text{ave},c} = P_{I,c}\delta + \sum_{c_2=1}^{C_{\text{tot}}} P_{d,c,c_2}P_{\text{suc},c_2}T_{S,c_2} + P_{F,c}T_F,$$

where

$$\begin{aligned}P_{F,c} &= P_{F,L,c} + P_{F,W,c} + P_{F,LW,c}\\ &= 1 - P_{I,c} - \sum_{c_2=1}^{C_{\text{tot}}} P_{d,c,c_2}P_{\text{suc},c_2}. \qquad (14)\end{aligned}$$

The novelty of our method can be briefly explained as follows: Our method is more accurate than several state-of-the-art results on modeling LBT MAC features and the impact of inter-SBS/AP ICI sensing errors. For example, [7]–[9], [12] did not model the CSMA/CA multistage backoff and/or average time to support one successful transmission, see (10). Furthermore, the provided throughput formulas in [7]–[13] did not explicitly address imperfect ICI sensing and its impact of KPIs. More generally, from the open literature we have not found validated multi-cell multi-tier KPI results for coexistence systems (such as LAA and WLAN) that flexibly take into account both CSMA/CA LBT MAC procedures and CCA sensing errors. These issues have been addressed in this paper. We show in Subsection III-B that our SCA result simplifies to that of ECA when the inter-cell detection probability approaches unity, and is equivalent to known results. In Section IV, we further provide Monte Carlo simulation results to validate the analysis.

B. Exclusive Cell Access

The ECA can be modeled by assuming perfect sensing $P_{d,c,c_2} = 1$ for all c and c_2. Certainly, this assumption is only valid for special cases, such as a region of highly overlapped cells, high transmission powers, and/or very sensitive sensing thresholds.

The average throughput at user (c,n) is given in the form of (6), but with the following changes: the τ_c, $\tilde{P}_{\text{suc},c}$, $P_{\text{suc},c}$, $\gamma_{(c,n)}$ and $T_{\text{ave},c}$ therein shall be changed by replacing $P_{d,c,c_2} = 1$ therein. Then we obtain

$$\tilde{P}_{\text{suc},c}^{\text{ECA}} = \prod_{\substack{c_2=1\\c_2\neq c}}^{C_{\text{tot}}}(1-\tau_{c_2}),$$

$P_{\text{suc},c}^{\text{ECA}} = \tau_c\tilde{P}_{\text{suc},c}^{\text{ECA}}$ and $\gamma_{(c,n)}^{\text{ECA}} = \frac{P_{T,c}h_{(c,n),c}}{N_{0,c}}$. Note that the SINR $\gamma_{(c,n)}$ in the SCA scheme becomes the SNR in the ECA scheme since ICI is avoided due to perfect inter-cell sensing.

To gain insight into LAA and WLAN coexistence, we assume that the C_L LAA cells have homogeneous CSMA/CA parameters, and so are the C_W WLAN cells. We also write the CAP, the idle, successful transmission, and failed transmission probabilities of all the LAA (or WLAN) cells as τ_L, $P_{I,L}$, $P_{S,L}$, and $P_{F,L}$ (or τ_W, $P_{I,W}$, $P_{S,W}$, and $P_{F,W}$), respectively.

Under assumptions of perfect sensing and ECA, we obtain:

$$\begin{aligned} P_{I,L} &= \prod_{c=1}^{C_L} (1-\tau_{c,L}), \\ P_{S,L} &= \sum_{c=1}^{C_L} \tau_{c,L} \left[\prod_{\substack{c_2=1 \\ c_2 \neq c}}^{C_L} (1-\tau_{c_2,L}) \right], \\ P_{F,L} &= 1 - P_{I,L} - P_{S,L}. \end{aligned}$$

When all SBS nodes have homogenous MAC parameters, i.e., $\tau_{c,L} = \tau_L$ for all c, we obtain:

$$\begin{aligned} P_{I,L} &= (1-\tau_{c,L})^{C_L}, \\ P_{S,L} &= C_L \tau_{c,L} (1-\tau_{c,L})^{C_L - 1}, \end{aligned}$$

and $P_{F,L} = 1 - P_{I,L} - P_{S,L}$. Similarly, $P_{I,W} = (1-\tau_{c,W})^{C_W}$,$P_{S,W} = C_W \tau_{c,W} (1-\tau_{c,W})^{C_W - 1}$, and $P_{F,W} = 1 - P_{I,W} - P_{S,W}$.

Furthermore, (10) is simplified to

$$\begin{aligned} T_{\text{ave}}^{\text{ECA}} = P_I^{\text{ECA}} \delta + P_{\text{suc},L}^{\text{ECA}} T_{S,L} + P_{\text{suc},W}^{\text{ECA}} T_{S,W} \\ + P_{F,L}^{\text{ECA}} T_{F,L} + P_{F,W}^{\text{ECA}} T_{F,W} + P_{F,LW}^{\text{ECA}} T_{F,M}, \qquad (15) \end{aligned}$$

where $P_I^{\text{ECA}} = P_{I,L} P_{I,W}$, $P_{\text{suc},L}^{\text{ECA}} = P_{I,W} P_{S,L}$, $P_{\text{suc},W}^{\text{ECA}} = P_{I,L} P_{S,W}$, $P_{F,L}^{\text{ECA}} = P_{I,W} P_{F,L}$, $P_{F,W}^{\text{ECA}} = P_{I,L} P_{F,W}$, and $P_{F,LW}^{\text{ECA}} = (1-P_{I,L})(1-P_{I,W})$. We can show that (15) is equivalent to a result given by eq. (19) in [15], when the latter is reduced from three transmission types to two types.

IV. Numerical Results

In this section, we provide both analytical and simulation results to validate our analysis, and show impact of critical parameters such as the sensing thresholds.

We develop a new simulator by using a constant simulation step-size (aka, event update interval) of an idle slot duration δ to track the effect of sensing error event. All schedulers (aka. SBSs and APs) follow multi-cell LBT procedures. We assume a slow fading channel, and the sensing result at each scheduler is updated when any transmission in the system starts or stops. The simulator tracks all the backoff, transmission, and sensing error events, and computes average KPIs.

Some CSMA/CA parameters and equations to compute $T_{S,L}$ (and $T_{F,L}$) from $T_{P,L}$, and to compute $T_{S,W}$ (and $T_{F,W}$) from $T_{P,W}$ are provided in [16]. Assume that there are N_L (or N_W) users in each LAA (or WLAN) cell, with CWS $W_{L,0}$ (or $W_{W,0}$), and maximum backoff stage M_L (or M_W), respectively. Unless otherwise stated, we assume that $\alpha_d = 3.5$, $\delta = 9\mu s$, total area has a rectangle shape with size $R_0 \times R_0$, and each cell has a disk shape with radius r_0. Further, we assume carrier frequency $f_c = 5.2$ GHz, $P_{T,c} = 23$ dBm, $B_{(c,n)} = 20$ MHz, $\text{BER}_{(c,n)} = 10^{-3}$, $\alpha_{(c,n)} = 1/N_c$ for all c and n, and background white Gaussian noise has PSD of -174 dBm/Hz. RTS/CTS is used for both LAA and WLAN cells. To model the effects of minimum link distance and limited modulation size, the SNR or SINR per link is truncated to 20 dB as an upper-bound. We choose these physical and MAC parameters to represent a feasible multicell coexistence scenario.

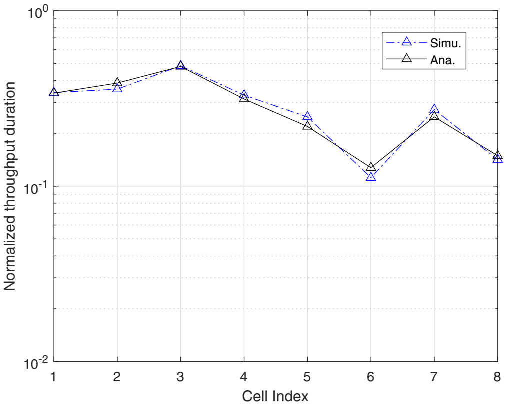

Fig. 2: Normalized cell-throughput duration of the LTE-LAA and WLAN system vs. cell index, and the first and next 4 cells are LAA and WLAN cells, respectively.

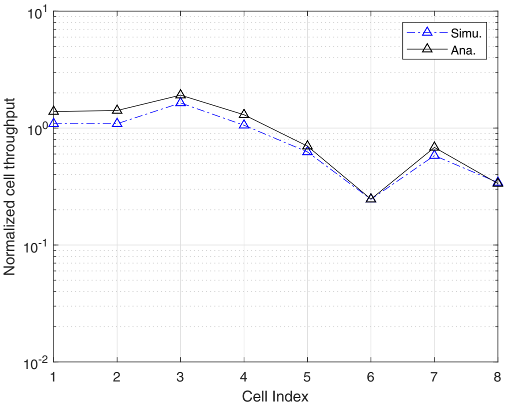

Fig. 3: Normalized cell throughput of the LTE-LAA and WLAN system vs. cell index, with the same system setting as for Fig. 2.

We provide analytical and simulation results on the per-cell NTD based on eq. (5) in Fig. 2, and throughput based on eq. (7) but normalized by the channel bandwidth in Fig. 3. For both figures, we assume that $N_L = N_W = 5$, $W_{L,0} = 8$, $W_{W,0} = 16$, $M_L = M_W = 1$, $I_{f,c} = I_{d,c} = -72$ dBm for all c, $T_{P,W} = T_{P,L} = 10\delta$, $R_0 = 100$ m, and $r_0 = 30$ m. We ran the algorithms for 2×10^4 time slots to obtain the average statistics. Due to random locations of SBSs, APs and users, the NTDs and normalized throughputs among the cells are heterogeneous. Figs. 2 and 3 illustrate consistent matching among analytical and simulation results, which account for effects of ICI and sensing errors. The minor mismatch between simulation and analytical results in Fig. 3 is likely caused by the difficulty of analytically evaluating the distribution of the sum ICIs experienced by each user when packets are received. This issue will be addressed in our future work.

Next, we show analytical numerical results on normalized

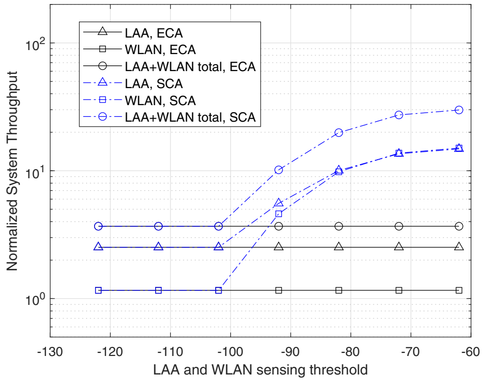

Fig. 4: Normalized system throughput of the LTE-LAA and WLAN systems vs. LAA and WLAN sensing threshold.

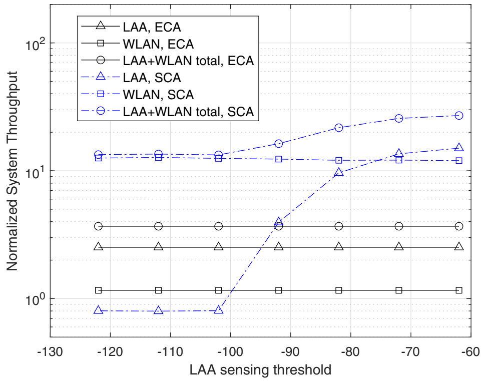

Fig. 5: Normalized system throughput of the LTE-LAA and WLAN systems vs. only LAA sensing threshold.

system throughput vs. sensing thresholds in Fig. 4 and Fig. 5, respectively, assuming $C_L = C_W = 6$, $N_L = N_W = 5$, $W_{L,0} = W_{W,0} = 16$, $M_L = 1$, $M_W = 4$, $I_{L,\text{ed}} = -72$ dBm, $I_{W,\text{cs}} = -82$ dBm, $I_{W,\text{ed}} = -62$ dBm, $T_{P,W} = T_{P,L} = 1$ ms, $R_0 = 200$ m and $r_0 = 30$ m. The results were obtained by averaging over 1000 random location profiles.

For Fig. 4, we assume that all LAA and WLAN sensing thresholds are equal and vary between [-122,-62] dBm. Fig. 4 verifies that when all sensing thresholds are reduced to about -102 dBm or lower (from the right to the left), the throughputs of the SCA scheme (LAA and WLAN) are reduced significantly and converge to those of the ECA scheme, as expected, because the inter-SBS/AP detection probabilities approach unity in this example. Fig. 5 provides throughput vs. LAA sensing threshold $I_{L,\text{ed}}$ which varies in the range of [-122,-62] dBm, but WLAN sensing thresholds are fixed. We observe that when LAA SBSs reduce their sensing threshold from -62 dBm to -102 dBm, the LAA throughput reduces significantly from about 15 to 0.8, but the WLAN throughput is insensitive to the LAA threshold change.

V. Conclusion

In this paper, we have modeled and analyzed the KPIs of LBT-related multi-cell 2-tier coexisting systems (LTE-LAA and WLAN), and provided a unified analysis of the multi-cell SCA and ECA schemes as function of detection probability and sensing thresholds. We have programmed an idle-slot step-size event-update simulation tool to better track sensing error events and provided reliable simulation results to verify our analysis. Numerical results demonstrate effects of various MAC and system parameters, such as LAA and WLAN sensing thresholds, and show that SCA with proper threshold setting provides significantly greater cell sum throughput than the ECA scheme. This result provides powerful analytical and simulation tools for performance evaluation of multi-tier coexistence systems with imperfect sensing, and supports system optimization in a practical way.

***Abstract*—This paper investigates the penetration loss of an office building in indoor-to-indoor (I2I) and outdoor-to-indoor (O2I) mobile scenarios. The measurements were collected using our 60 GHz double-directional switched-antenna channel sounder. During measurements, the transmitter, mounted on a tripod, was placed in an office and outside of the building, while the receiver, mounted on a mobile robot, moved along an interior hallway. The penetration loss for a variety of building materials was predicted versus incident angle by electromagnetic propagation theory using the International Telecommunication Union Radiocommunication Sector (ITU-R) Recommendation P.2040 model parameters and compared with the measurement results. The wooden door, plasterboard wall, and interior glass were observed to have penetration losses ranging from 25.5 dB to 40.5 dB, 11.8 dB to 31.6 dB, and 7.5 dB to 18.1 dB, respectively, while the exterior building materials exhibited even larger penetration losses, ranging from 31.1 dB to 66.5 dB.**

***Index Terms*—channel sounder, channel propagation model, 5G wireless communications, millimeter wave**

I. Introduction

Fifth generation (5G) wireless communications have created a growing demand for millimeter-wave (mmWave) channel sounding and modeling. The modeling and optimization of 5G cellular network technologies are highly dependent on the radio-wave propagation characteristics [1]. mmWave communications will operate below ideal capacity in non-line-of-sight conditions as a result of the properties of the obstructing materials that cause attenuation due to absorption and dispersion of the electromagnetic waves.

To date, several studies have been conducted to measure the signal attenuation of materials at mmWave frequencies and to model path loss in indoor and outdoor environments: Extensive measurements for the penetration loss of various materials at 28 GHz and 73 GHz in an indoor office environment were studied in [2]-[3]. An experimental investigation of a 60 GHz wireless local-area network system in an indoor cubicle environment was performed in [4]; the measurement campaigns were conducted using horn antennas at fixed points within an indoor environment; the study resulted in an empirical O2I building model for penetration loss. Analysis of reflection and penetration losses for common building materials at 28 GHz was presented in an urban outdoor environment [5]. The suburban residential neighborhood penetration loss at 28 GHz was also investigated in [6]. Wideband channel measurements in downtown Denver, CO at 9.6 GHz, 28.8 GHz and 57.6 GHz were collected in [7]; significant penetration loss was found to be caused by obstruction from an office building.

In general, previous literature dealing with penetration loss measurements has focused on stationary points using directional horn antennas with limited scan angles. Lacking to date is the effect on penetration loss of different points of incidence and different angles of incidence across the surface of building materials, to capture what a real communications system would experience during operation. To fill that void, this paper presents measured penetration loss at mmWave using an electronically switched double-directional channel sounder that was developed by the National Institute of Standards and Technology (NIST) [8]. The sounder has at the center frequency of 60.5 GHz: 2 GHz bandwidth, wide scan angle, and a mobile robot positioning platform. The measurement campaign was conducted in I2I and O2I environments. For the purpose of comparison, a theoretical analysis for the penetration loss of the building materials and its dependence on incident angle was also conducted.

The paper is organized as follows: The theoretical analysis and measurement setup are presented in Section II and Section III, respectively. Analysis of the penetration loss measurement results are described in Section IV, followed by conclusions in Section V.

II. Theoretical Analysis

Radio propagation at an interface with dielectric materials will depend on a number of parameters, most importantly the center frequency of the signal, the angle of incidence of the signal with the interface, and the material properties themselves. Generally speaking, transmission through materials degrade at higher frequencies, at shallower angles, and for denser materials. In order to provide a benchmark for comparison with our ensuing measurements, we first conducted a theoretical analysis of penetration loss by means of the Fresnel equations [9], which provide the reflection and transmission coefficients of electromagnetic waves incident on a flat surface. The material properties are represented through a complex relative permittivity η, expressed through real and imaginary components as

$$\eta = \eta' - j\eta''. \tag{1}$$

Jun, Sung Yun; Caudill, Derek; Chuang, Jack; Papazian, Peter; Bodi, Anuraag; Gentile, Camillo; Senic, Jelena; Golmie, Nada T. ”Penetration Loss at 60 GHz for Indoor-to-Indoor and Outdoor-to-Indoor Mobile Scenarios.” Paper presented at IEEE European Conference on Antennas and Propagation, Copenhagen, DK. March 15, 2020 - March 20, 2020.

TABLE I. MATERIAL PROPERTIES AT 60.5 GHZ

Material Class	Real part of relative permittivity (η')	Imaginary part of relative permittivity (η'')
Air	1	0
Metal	1	2.9719×10^{6}
Wood	1.99	0.1135
Plasterboard	2.94	0.0628
Glass	6.27	0.1703

The values of the frequency-dependent components were accordingly set to the center frequency of our channel sounder.

Table I shows the complex relative permittivity of several common construction materials at 60.5 GHz per the ITU-R Recommendation P.2040 [10]. We focused our theoretical analysis on wood, glass, and plasterboard only, the dominant materials in the environment where the measurements were collected. The thickness of the single-layered wood and glass materials was set as 45 mm and 9.5 mm, respectively, to match properties of the office building under investigation; the multi-layered wall, rather, was set to 12.7 mm for the two plasterboard sheets separated by an air pocket of 88.9 mm; in reality, as observed through the measurements, there were also metal studs in between the sheets.

Fig. 1 shows the theoretical attenuation of the three materials versus incident angle from 0° to 85°. The attenuation grows exponentially with incident angle. The wood and glass have attenuation in the range from 20.1 dB to 38.7 dB and from 5.8 dB to 19.9 dB, respectively. On the other hand, the multi-layer plasterboard attenuation varied from 5.5 dB to 32.3 dB over the same angle range. Interestingly, the ripple observed in the attenuation of the plasterboard can be traced to the multi-layered structure.

III. MEASUREMENTS

This section describes the channel sounder and the measurement campaign used to collect data for the I2I and O2I mobile scenarios.

A. Channel Sounder

Our 60 GHz double-directional switched array channel sounder is described in detail in [8]. The correlation-based system utilizes a pseudo-random noise (PN) sequence as the probing signal. For increased dynamic range to deal with greater range and greater penetration loss, a longer PN sequence of 32767 chips with chip rate of 2 Gbits/s was employed for the I2I scenario and the O2I scenario (at the expense of channel sweep time).

The transmitter (TX) is comprised of an intermediate frequency (IF) section, a radio frequency (RF) up-conversion section, and an eight-element antenna array with a switching multiplexer (MUX) (see Fig. 2(a,b)). The receiver (RX) contains an analog-to-digital converter section, an RF down-conversion section, and a sixteen-element antenna array with a MUX (see Fig. 2(c,d)). Both arrays contain scalar feed horns with 18.1 dBi gain and half-power beamwidth of 22.5°. Given the constellation of the elements, the synthesized antenna patterns of the TX and RX arrays provide 180° and 360° field-of-view (FoV), respectively, in the azimuthal plane whereas the FoV in the elevation plane is 45° for both.

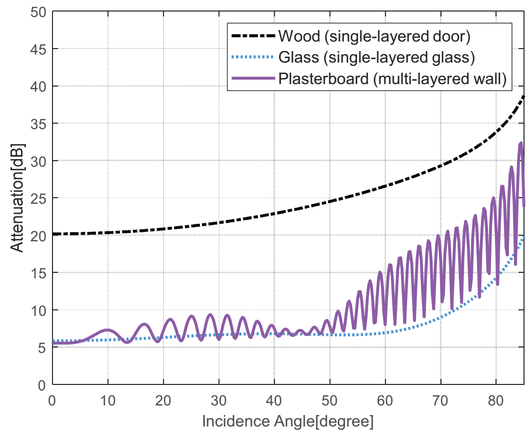

Fig. 1. Calculated transmission attenuation versus incidence angle for Wood, Plasterboard and Glass at 60.5 GHz.

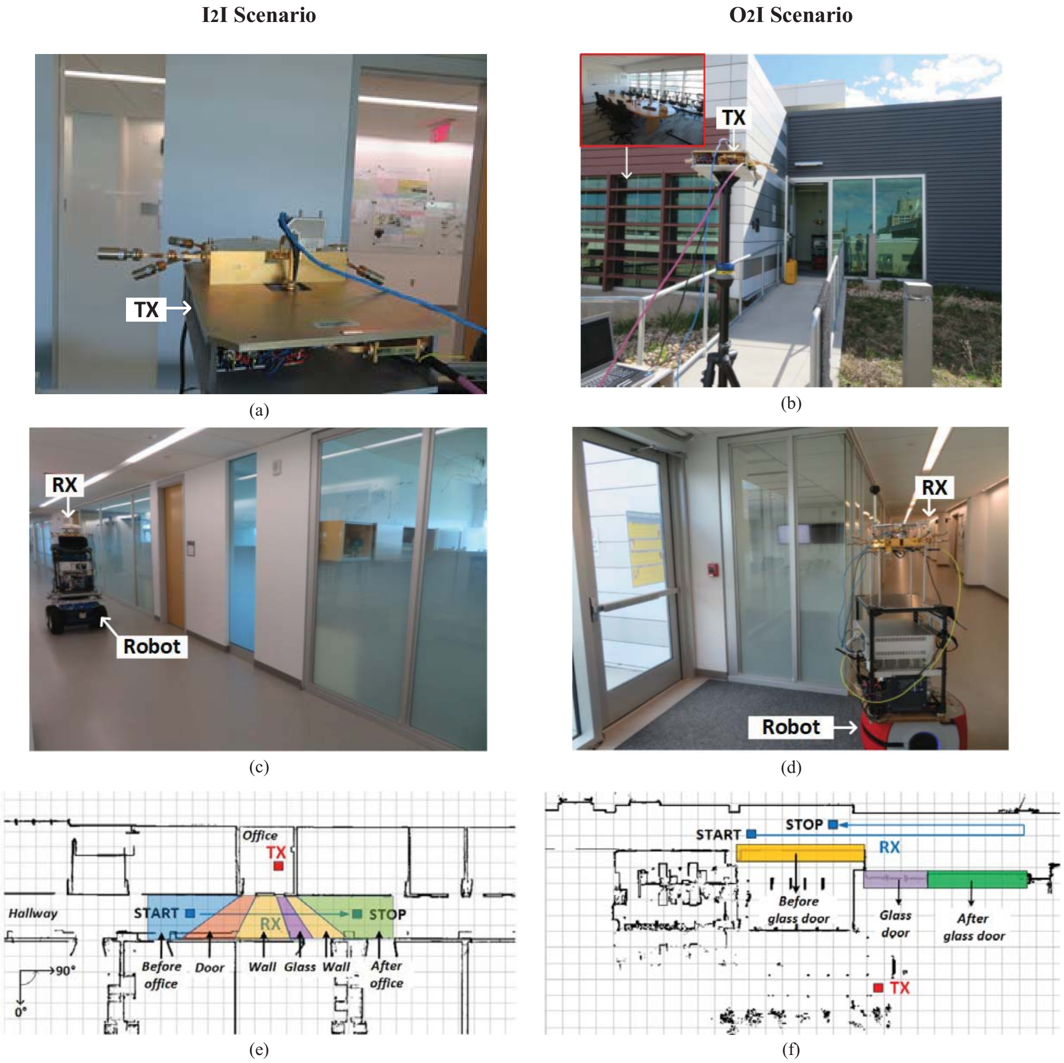
Two 10 MHz Rubidium time standards and timing control circuits are used for untethered timing synchronization between the TX and RX for switching transmission and reception of the PN sequences between the 8×16=128 channels. An arbitrary waveform generator (AWG) at the TX generates the PN sequence, which is modulated using Binary Phase Shift Keying at an IF frequency of 3 GHz and then up-converted to an RF frequency of precisely 60.5 GHz. The TX antenna array transmits the RF signal with an equivalent isotropic radiated power (EIRP) of 36 dBm. The received signal at the RX antenna array is then down-converted to the IF of 3 GHz and is digitized at 40 Gsamples/s per channel. Matched filtering of the digitized signal with the PN sequence to generate the channel impulse response for each TX-RX antenna pair is performed off-line to decrease the channel sweep time. The resultant data for one TX-RX measurement point therefore consists of 128 channel impulse responses.

To remove the systematic distortion effects caused by the system hardware, a back-to-back calibration method was applied, as described in [8]. The calibration significantly reduces distortions and internal reflections of the system, extending the dynamic range to 90 dB for the longer PN sequence. The antenna patterns of the directional horns were characterized in an anechoic environment and de-embedded from the measurements as part of the calibration procedures. The 128 channel impulse responses recorded are post-processed through the Space Alternating Generalized Expectation maximization (SAGE) algorithm [11] to extract the channel multipath components (MPCs) and their properties, namely the delay, angle-of-departure (AoD) and angle-of-arrival (AoA) (in both azimuth and elevation), and



I2I Scenario **O2I Scenario**

the path loss of each path identified. The aforementioned calibration procedures ensured that the features of the channel sounder were decoupled from the measurements such that properties of the extracted MPCs reflected the channel alone (and not the system).

B. *Measurement Setup*

The environment for the measurement campaign was a modern office building on the campus of the NIST in Boulder, CO, USA. Fig. 2(a,c) and Fig. 2(b,d) display photographs of the measurement setups for the I2I and O2I scenarios, respectively, and Fig. 2(e,f) show their maps. The maps were automatically generated by the laser-guided navigational system of the robot, furnishing precision localization to within a centimeter. For the I2I scenario, the fixed TX was mounted on a tripod inside an office at height 1.6 m and facing the adjacent hallway; the RX, mounted on a mobile robot, traversed the route shown in Fig. 2(e) from start to stop in the hallway, over which 57 data points were collected within the TX-RX distance range of 2.7 m to 6.1 m. For the O2I scenario, the TX was raised to 2.5 m and placed outside the building, still facing the hallway; the RX traversed a longer route in the same hallway, shown in Fig. 2(f), over which 93 data points were collected within the distance range of 9.4 m to 13.7 m. For both scenarios, the direct path between the TX and RX was obstructed by single- and multiple-layered materials.

"Penetration Loss at 60 GHz for Indoor-to-Indoor and Outdoor-to-Indoor Mobile Scenarios." Paper presented at IEEE European Conference on Antennas and Propagation, Copenhagen, DK. March 15, 2020 - March 20, 2020.

IV. Measurement Results

The penetration loss for each measurement point collected was computed as in [3]: First, the *penetrating path* was identified among all MPCs extracted per measurement point as the one that arrived first. Its delay (τ) was then mapped to the theoretical free-space path loss (PL_{FS}) through Friis transmission equation as

$$PL_{FS} = 20 \cdot log_{10}\left(\frac{4\pi c\tau}{\lambda}\right), \tag{2}$$

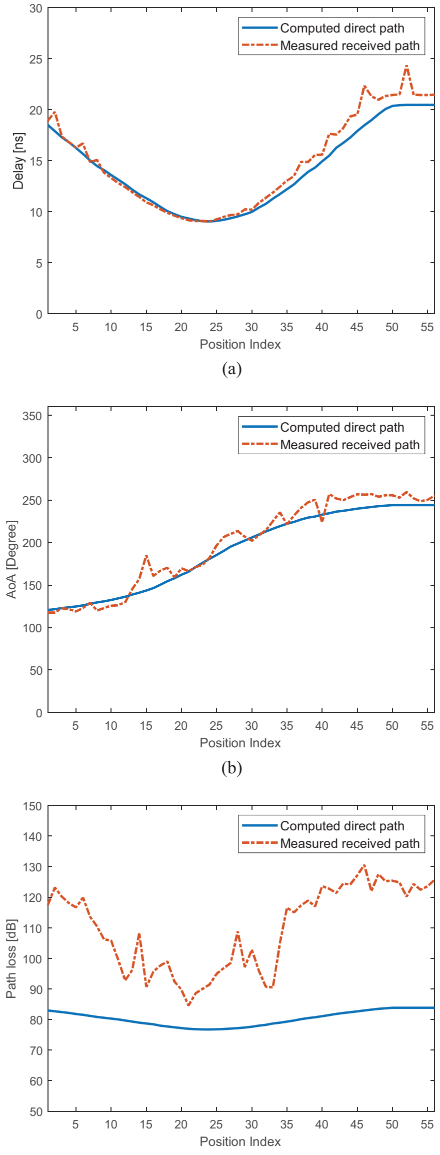
where c is the speed of light and $\lambda = 5$ mm is the wavelength corresponding to 60.5 GHz. Finally, the penetration loss was estimated by subtracting PL_{FS} from the measured path loss of the penetrating path. In the sequel, we present the estimated penetration loss for the I2I and O2I scenarios.

A. I2I Penetration Loss

For the purpose of verification, Fig. 3 displays the estimated delay, AoA, and path loss of the penetrating path (dashed red) versus the position index of the I2I scenario. Also displayed are the analogous theoretical values for the free-space direct path (solid blue), where its delay (τ_{DP}) and AoA were computed from the geometry of the known TX and RX positions and direct path loss (PL_{DP}) was computed by substituting τ_{DP} into (2). Aside from any system estimation error, the reason the estimated delay / AoA differ from the theoretical values is because the trajectory of the penetrating MPC deviated from the direct path due to reflection, refraction, and dispersion occurring at the material boundaries and/or in the environment; the difference in path loss, rather, is equivalent to the estimated penetration loss. Note that in general the deviation in delay / AoA increased with penetration loss.

In order to classify the estimated penetration loss according to the dominant materials in the environment, we partitioned the side of the hallway penetrated by the signal into *zones*; the partitioning was based on where the theoretical direct path intersected the side as the RX moved in the hallway. Fig. 2(e) displays the resultant partitioning with different colors: For the single penetration from the office, the side was constructed from a wooden door, plasterboard and glass sections; the measured penetration loss there ranged from 25.5 dB to 40.5 dB, from 11.8 dB to 31.6 dB, and from 7.5 dB to 18.1 dB, respectively. For the segments before and after the office, on the other hand, the side was constructed totally from plasterboard, through which multiple penetrations (including the adjacent vertical office walls) occurred; there the penetration loss increased in range from 34.4 dB to 40.5 dB and from 26.0 dB and 47.6 dB, respectively, as shown in Fig. 4(a). The interior glass featured the lowest penetration loss among the environment materials.

The penetration loss of the wooden door, plasterboard wall, and interior glass were slightly higher than the attenuation characteristics of the ITU-R P.2040 model (Fig. 1). It was determined that the door is made of fire-rated wood with a composite mineral core containing several different materials. The composite materials have more complex reflection and transmission effects, which cause the high attenuation versus the homogenous materials. Moreover, the multiple peaks of the penetration loss in the wall can be explained by the metal studs installed at regular spacing between the plasterboard sheets. The thin window film on the glass (for privacy) also provides a slightly higher penetration loss compared to clear glass (Fig. 1).



(a)

(b)

(c)

Fig. 3. Properties of the penetrating path identified from the I2I measurement versus the theoretical properties of the direct path. (a) delay (b) AoA and (c) path loss.

B. O2I Penetration Loss

Fig. 2(f) displays how the side of the hallway penetrated by the signal was partitioned based on the exterior construction materials for the O2I scenario, and Fig. 4(b) displays the corresponding results for the penetration loss estimated. Along the segment before the glass door with double-pane glass, there is the conference room between the TX and RX for which the penetrating path most likely went through an exterior double-pane window to the conference room and then out a single-pane interior window to the hallway. The exterior window consisted of a single, clear inner glass pane and a single, tinted outer glass pane separated by 19 mm (the outer pane tint had low emissivity coating applied to reject ultraviolet light). The interior windows were clear single pane glass. The segment after the glass door was an exterior wall. The segments before and after the glass door exhibited huge penetration losses, ranging between 52.3 dB to 66.5 dB and 40.3 dB to 59.2 dB, respectively. On the other hand, the glass door had a penetration loss in the range of 31.1 dB to 46.0 dB with an average value of 38.5 dB. It was observed that external building materials such as metal plating and low emissivity coatings caused high attenuation.

V. Conclusion

This paper presents measurements for penetration loss taken with our 60 GHz channel sounder over a variety of building materials in I2I and O2I mobile scenarios. Departing from previous efforts, the penetration loss was measured across continuous incident points and, by association, different incident angles along the surface of the building materials in the environment, to capture what an actual radio would experience in motion as opposed to a collection of separate, fixed-position measurements. As a means for comparison, the penetration loss for the building materials in the environment were modeled and analyzed theoretically through the Fresnel equations fit with the ITU-R P.2040 material parameters. The penetration loss through multiple layers was observed to be as high as 47.6 dB for I2I scenario, yet not as high as the 66.5 dB observed for the O2I scenario. In summary, we conclude that signals transmitted at 60 GHz both inside buildings and into buildings will suffer from severe penetration losses due to ambient building materials, heavily reducing coverage with respect to line-of-sight conditions. On the other hand, the high penetration loss of building materials can be a potential advantage to reduce interference from neighboring wireless network systems.

ABSTRACT

Mathematical notation, i.e., the writing system used to communicate concepts in mathematics, encodes valuable information for a variety of information search and retrieval systems. Yet, mathematical notations remain mostly unutilized by today's systems. In this paper, we present the first in-depth study on the distributions of mathematical notation in two large scientific corpora: the open access arXiv (2.5B mathematical objects) and the mathematical reviewing service for pure and applied mathematics zbMATH (61M mathematical objects). Our study lays a foundation for future research projects on mathematical information retrieval for large scientific corpora. Further, we demonstrate the relevance of our results to a variety of use-cases. For example, to assist semantic extraction systems, to improve scientific search engines, and to facilitate specialized math recommendation systems.

The contributions of our presented research are as follows: (1) we present the first distributional analysis of mathematical formulae on arXiv and zbMATH; (2) we retrieve relevant mathematical objects for given textual search queries (e.g., linking $P_n^{(\alpha,\beta)}(x)$ with 'Jacobi polynomial'); (3) we extend zbMATH's search engine by providing relevant mathematical formulae; and (4) we exemplify the applicability of the results by presenting auto-completion for math inputs as the first contribution to math recommendation systems. To expedite future research projects, we have made available our source code and data.

1 INTRODUCTION

Taking into account mathematical notation in the literature leads to a better understanding of scientific literature on the Web and allows one to make use of semantic information in specialized Information Retrieval (IR) systems. Nowadays applications in Math Information Retrieval (MathIR) [15], such as search engines [7, 17, 18, 22, 24, 27, 31], semantic extraction systems [23, 36, 37], recent efforts in math embeddings [10, 13, 25, 44], and semantic tagging of math formulae [6, 43] either consider an entire equation as one entity or only focus on single symbols. Since math expressions often contain meaningful and important subexpressions, these applications could benefit from an approach that lies between the extremes of examining only individual symbols or considering an entire equation as one entity. Consider for example, the explicit definition for Jacobi polynomials [8, (18.5.7)]

$$P_n^{(\alpha,\beta)}(x)=\frac{\Gamma(\alpha+n+1)}{n!\Gamma(\alpha+\beta+n+1)}\sum_{m=0}^{n}\binom{n}{m}\frac{\Gamma(\alpha+\beta+n+m+1)}{\Gamma(\alpha+m+1)}\left(\frac{x-1}{2}\right)^m. \quad (1)$$

Cohl, Howard; Greiner Petter, Andre; Schubotz, Moritz; Breitinger, Corinna; Muller, Fabian; Aizawa, Akiko; Gipp, Bela. "Discovering Mathematical Objects of Interest - A Study of Mathematical Notations." Paper presented at The Web Conference 2020, Taipei, TW. April 20, 2020 - April 24, 2020.

The *interesting* components in this equation are $P_n^{(\alpha,\beta)}(x)$ on the left-hand side, and the appearance of the gamma function $\Gamma(s)$ on the right-hand side, implying a direct relationship between Jacobi polynomials and the gamma function. Considering the entire expression as a single object misses this important relationship. On the other hand, focusing on single symbols can result in the misleading interpretation of Γ as a variable and $\Gamma(\alpha + n + 1)$ as a multiplication between Γ and $(\alpha + n + 1)$. A system capable of identifying the important components, such as $P_n^{(\alpha,\beta)}(x)$ or $\Gamma(\alpha + n+1)$, is therefore desirable. Hereafter, we define these components as *Mathematical Objects of Interest* (MOIs) [13].

The *importance* of math objects is a somewhat imprecise description and thus difficult to measure. Currently, not much effort has been made in identifying meaningful subexpressions. Kristianto et al. [23] introduced dependency graphs between formulae. With this approach, they were able to build dependency graphs of mathematical expressions, but only if the expressions appeared as single expressions in the context. For example, if $\Gamma(\alpha + n + 1)$ appears as a stand-alone expression in the context, the algorithm will declare a dependency with Equation (1). However, it is more likely that different forms, such as $\Gamma(s)$, appear in the context. Since this expression does not match any subexpression in Equation (1), the approach cannot establish a connection with $\Gamma(s)$. Kohlhase et al. studied in [19–21] another approach to identify essential components in formulae. They performed eye-tracking studies to identify important areas in rendered mathematical formulae. While this is an interesting approach that allows one to learn more about the insights of human behaviors of reading and understanding math, it is inaccessible for extensive studies.

This paper presents the first extensive frequency distribution study of mathematical equations in two large scientific corpora, the e-Print archive arXiv.org (hereafter referred to as arXiv[1]) and the international reviewing service for pure and applied mathematics zbMATH[2]. We will show that math expressions, similar to words in natural language corpora, also obey Zipf's law [33], and therefore follows a *Zipfian* distribution. Related research projects observed a relation to Zipf's law for single math symbols [6, 36]. In the context of quantitative linguistics, Zipf's law states that given a text corpus, the frequency of any word is inversely proportional to its rank in the frequency table. Motivated by the similarity to linguistic properties, we will present a novel approach for ranking formulae by their relevance via a customized version of the ranking function BM25 [34]. We will present results that can be easily embedded in other systems in order to distinguish between common and uncommon notations within formulae. Our results lay a foundation for future research projects in MathIR.

Fundamental knowledge on frequency distributions of math formulae is beneficial for numerous applications in MathIR, ranging from educational purposes [40] to math recommendation systems, search engines [7, 31], and even automatic plagiarism detection systems [28, 29, 39]. For example, students can search for the conventions to write certain quantities in formulae; document preparation systems can integrate an auto-completion or auto-correction service for math inputs; search or recommendation engines can adjust their ranking scores with respect to standard notations; and plagiarism detection systems can estimate whether two identical formulae indicate potential plagiarism or are just using the conventional notations in a particular subject area. To exemplify the applicability of our findings, we present a textual search approach to retrieve mathematical formulae. Further, we will extend zbMATH's faceted search by providing facets of mathematical formulae according to a given textual search query. Lastly, we present a simple auto-completion system for math inputs as a contribution towards advancing mathematical recommendation systems. Further, we show that the results provide useful insights for plagiarism detection algorithms. We provide access to the source code, the results, and extended versions of all of the figures appearing in this paper at https://github.com/ag-gipp/FormulaCloudData.

Related Work: Today, mathematical search engines index formulae in a database. Much effort has been undertaken to make this process as efficient as possible in terms of precision and runtime performance [7, 17, 26, 27, 45]. The generated databases naturally contain the information required to examine the distributions of the indexed mathematical formulae. Yet, no in-depth studies of these distributions have been undertaken. Instead, math search engines focus on other aspects, such as devising novel similarity measures and improving runtime efficiency. This is because the goal of math search engines is to retrieve relevant (i.e., similar) formulae which correspond to a given search query that partially [24, 26, 31] or exclusively [7, 17, 18] contains formulae. However, for a fundamental study of distributions of mathematical expressions, no similarity measures nor efficient lookup or indexing is required. Thus, we use the general-purpose query language XQuery and employ the BaseX[3] implementation. BaseX is a free open-source XML database engine, which is fully compatible with the latest XQuery standard [14, 41]. Since our implementations rely on XQuery, we are able to switch to any other database which allows for processing via XQuery.

2 DATA PREPARATION

LaTeX is the de facto standard for the preparation of academic manuscripts in the fields of mathematics and physics [11]. Since LaTeX allows for advanced customizations and even computations, it is challenging to process. For this reason, LaTeX expressions are unsuitable for an extensive distribution analysis of mathematical notations. For mathematical expressions on the web, the XML formatted MathML[4] is the current standard, as specified by the World Wide Web Consortium (W3C). The tree structure and the fixed standard, i.e., MathML tags, cannot be changed, thus making this data format reliable. Several available tools are able to convert from LaTeX to MathML [35] and various databases are able to index XML data. Thus, for this study, we have chosen to focus on MathML. In the following, we investigate the databases arXMLiv (08/2018) [12] and zbMATH[5] [38].

The arXMLiv dataset (≈1.2 million documents) contains HTML5 versions of the documents from the e-Print archive arXiv.org. The HTML5 documents were generated from the TeX sources

[5] https://zbmath.org/ [Accessed: Sep. 1, 2019]

via LaTeXML [30]. LaTeXML converted all mathematical expressions into MathML with parallel markup, i.e., presentation and content MathML. In this study we only consider the subsets *no-problem* and *warning*, which generated no errors during the conversion process. Nonetheless, the MathML data generated still contains some errors or falsely annotated math. For example, we discovered several instances of affiliation and footnotes, SVG[6] and other unknown tags, encoded in MathML. Regarding the footnotes, we presumed that authors falsely used mathematical environments for generating footnote or affiliation marks. We used the TeX string, provided as an attribute in the MathML data, to filter out expressions that match the string '`{}^{*}`', where '`*`' indicates any possible expression. In addition, we filtered out SVG and other unknown tags. We assume that these expressions were generated by mistake due to limitations of LaTeXML. The final arXiv dataset consisted of 841,008 documents which contained at least one mathematical formula. The dataset contained a total of 294,151,288 mathematical expressions.

In addition to arXiv, we investigated zbMATH, an international reviewing service for pure and applied mathematics which contains abstracts and reviews of articles, hereafter uniformly called abstracts, mainly from the domains of pure and applied mathematics. The abstracts in zbMATH are formatted in TeX [38]. To be able to compare arXiv and zbMATH, we manually generated MathML via LaTeXML for each mathematical formula in zbMATH and performed the same filters as used for the arXiv documents. The zbMATH dataset contained 2,813,451 abstracts, of which 1,349,297 contained at least one formula. In total, the dataset contained 11,747,860 formulae. Even though the total number of formulae is smaller compared to arXiv, we hypothesize that math formulae in abstracts are particularly meaningful.

2.1 Data Wrangling

Since we focused on the frequency distributions of visual expressions, we only considered presentational MathML (pMML). Rather than normalizing the pMML data, e.g., via MathMLCan [9], which would also change the tree structure and visual core elements in pMML, we only eliminated the attributes. These attributes are used for minor visual changes, e.g., stretched parentheses or inline limits of sums and integrals. Thus, for this first study, we preserved the core structure of the pMML data, which might provide insightful statistics for the MathML community to further cultivate the standard. After extracting all MathML expressions, filtering out falsely annotated math and SVG tags, and eliminating unnecessary attributes and annotations, the datasets required 83GB of disk space for arXiv and 6GB for zbMATH, respectively.

Listing 1: MathML representation of $P_n^{(\alpha,\beta)}(x)$.

```
 1 <math><mrow>
 2  <msubsup>
 3   <mi>P</mi>
 4   <mi>n</mi>
 5   <mrow>
 6    <mo>(</mo>
 7    <mi>α</mi>
 8    <mo>,</mo>
 9    <mi>β</mi>
10    <mo>)</mo>
11    <mo></mo>
12   </mrow>
13  </msubsup>
14  <mo></mo>
15  <mrow>
16   <mo>(</mo>
17   <mi>x</mi>
18   <mo>)</mo>
19  </mrow>
20 </mrow></math>
```

In the following, we indexed the data via BaseX. The indexed datasets required a disk space of 143.9GB in total (140GB for arXiv and 3.9GB for zbMATH). Due to the limitations[7] of databases in BaseX, it was necessary to split our datasets into smaller subsets. We split the datasets according to the 20 major article categories of arXiv[8] and classifications of zbMATH. To increase performance, we use BaseX in a server-client environment. We experienced performance issues in BaseX when multiple clients repeatedly requested data from the same server in short intervals. We determined that the best workaround for this issue was to launch BaseX servers for each database, i.e., each category/classification.

Mathematical expressions often consist of multiple meaningful subexpressions, which we defined as MOIs. However, without further investigation of the context, it is impossible to determine meaningful subexpressions. As a consequence, every equation is a potential MOI on its own and potentially consists of multiple other MOIs. For an extensive frequency distributional analysis, we aim to discover all possible mathematical objects. Hence, we split every formula into its components. Since MathML is an XML data format (essentially a tree-structured format), we define subexpressions of equations as subtrees of its MathML format.

Listing 1 illustrates a Jacobi polynomial $P_n^{(\alpha,\beta)}(x)$ in pMML. The `<mo>` element on line 14 contains the *invisible times* UTF-8 character. By definition, the `<math>` element is the root element of MathML expressions. Since we cut off all other elements besides pMML nodes, each `<math>` element has one and only one child element[9]. Thus, we define the child element of the `<math>` element as the root of the expression. Starting from this root element, we explore all subexpressions. For this study, we presume that every meaningful mathematical object (i.e., MOI) must contain at least one identifier.

Hence, we only study subtrees which contain at least one `<mi>` node. Identifiers, in the sense of MathML, are '*symbolic names or arbitrary text*' [10], e.g., single Latin or Greek letters. Identifiers do not contain special characters (other than Greek letters) or numbers. As a consequence, arithmetic expressions, such as $(1+2)^2$, or sequences of special characters and numbers, such as $\{1, 2, \ldots\} \cap \{-1\}$, will not appear in our distributional analysis. However, if a sequence or arithmetic expression consists of an identifier somewhere in the pMML tree (such as in $\{1, 2, \ldots\} \cap A$), the entire expression will be recognized. The Jacobi polynomial $P_n^{(\alpha,\beta)}(x)$, therefore consists of the following subexpressions: $P_n^{(\alpha,\beta)}$, (α, β), (x), and the single identifiers P, n, α, β, and x. The entire expression is also a mathematical object. Hence, we take entire expressions with an identifier into account for our analysis. In the following, the set of subexpressions will be understood to include the expression itself.

For our experiments, we also generated a string representation of the MathML data. The string is generated recursively by applying one of two rules for each node: (i) if the current node is a leaf, the node-tag and the content

[6] Scalable Vector Graphics

[7] A detailed overview of the limitations of BaseX databases can be found at http://docs.basex.org/wiki/Statistics [Accessed: Sep. 1, 2019].

[8] The arXiv categories *astro-ph* (astro physics), *cond-mat* (condensed matter), and *math* (mathematics) were still too large for a single database. Thus, we split those categories into two equally sized parts.

[9] Sequences are always nested in an `<mrow>` element.

[10] https://www.w3.org/TR/MathML3/chapter3.html [Accessed: Sep. 1, 2019]

will be merged by a colon, e.g., `<mi>x</mi>` will be converted to `mi:x`; (ii) otherwise the node-tag wraps parentheses around its content and separates the children by a comma, e.g., `<mrow><mo>(</mo><mi>x</mi><mo>)</mo></mrow>` will be converted to `mrow(mo:(,mi:x,mo:))`. Furthermore, the special UTF-8 characters for invisible times (U+2062) and function application (U+2061) are replaced by `ivt` and `fa`, respectively. For example, the gamma function with argument $x+1$, $\Gamma(x+1)$ would be represented by

$$\texttt{mrow(mi:}\Gamma\texttt{,mo:ivt,mrow(mo:(,mrow(mi:x,mo:+,mn:1),mo:)))}. \quad (2)$$

Between Γ and $(x+1)$, there would most likely be the special character for *invisible times* rather than for *function application*, because LaTeXML is not able to parse Γ as a function. Note that this string conversion is a bijective mapping. The string representation reduces the verbose XML format to a more concise presentation. Thus, an equivalence check between two expressions is more efficient.

2.2 Complexity of Math

Mathematical expressions can become complex and lengthy. The tree structure of MathML allows us to introduce a measure that reflects the complexity of mathematical expressions. More complex expressions usually consist of more extensively nested subtrees in the MathML data. Thus, we define the complexity of a mathematical expression by the maximum depth of the MathML tree. In XML the content of a node and its attributes are commonly interpreted as children of the node. Thus, we define the depth of a single node as 1 rather than 0, i.e., single identifiers, such as `<mi>P</mi>`, have a complexity of 1. The Jacobi polynomial from Listing 1 has a complexity of 4.

We perform the extraction of subexpressions from MathML in BaseX. The algorithm for the extraction process is written in XQuery. The algorithm traverses recursively downwards from the root to the leaves. In each iteration, it checks whether there is an identifier, i.e., `<mi>` element, among the descendants of the current node. If there is no such element, the subtree will be ignored. It seems counterintuitive to start from the root and check if an identifier is among the descendants rather than starting at each identifier and traversing upwards to the root. If an XQuery requests a node in BaseX, BaseX loads the entire subtree of the requested node into the cache (up to a specified size). If the algorithm traverses upwards through the MathML tree, the XQuery will trigger database requests in every iteration. Hence, the downwards implementation performs better, since there is only one database request for every expression rather than for every subexpression.

Since we only minimize the pMML data rather than normalizing it, two identically rendered expressions may have different complexities. For instance, `<mrow><mi>x</mi></mrow>` consists of two distinct subexpressions, but both of them are displayed the same. Another problem often appears for arrays or similar visually complicated structures. The extracted expressions are not necessarily logical subexpressions. We will consider applying more advanced embedding techniques such as special tokenizers [26], symbol layout trees [7, 45], and a MathML normalization via MathMLCan [9] in future research to overcome these issues.

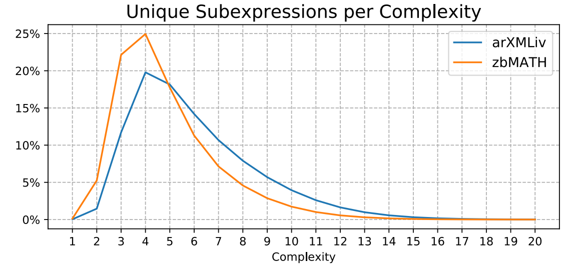

Figure 1: Unique subexpressions for each complexity in arXiv and zbMATH.

3 FREQUENCY DISTRIBUTIONS OF MATHEMATICAL FORMULAE

By splitting each formula into subexpressions, we generated longer documents and a bias towards low complexities. Note that, hereafter, we only refer to the mathematical content of documents. Thus, the length of a document refers to the number of math formulae—here the number of subexpressions—in the document. After splitting expressions into subexpressions, arXiv consists of 2.5B and zbMATH of 61M expressions, which raised the average document length to 2,982.87 for arXiv and 45.47 for zbMATH, respectively.

For calculating frequency distributions, we merged two subexpressions if their string representations were identical. Remember, the string representation is unique for each MathML tree. After merging, arXiv consisted of 350,206,974 unique mathematical subexpressions with a maximum complexity of 218 and an average complexity of 5.01. For high complexities over 70, the formulae show some erroneous structures that might be generated from LaTeXML by mistake. For example, the expression with the highest complexity is a long sequence of a polynomial starting with '$P_4(t_1, t_3, t_7, t_{11}) =$' followed by 690 summands. The complexity is caused by a high number of unnecessarily deeply nested `<mrow>` nodes. The highest complexity with a minimum document frequency of two is 39, which is a continued fraction. Since continued fractions are nested fractions, they naturally have a large complexity. One of the most complex expressions (complexity 20) with a minimum document frequency of three was the formula

$$\left(\sum_{j_1=1}^{n}\left(\sum_{j_2=1}^{n}\left(\cdots\left(\sum_{j_m=1}^{n}\left|T\left(e_{j_1},\ldots,e_{j_m}\right)\right|^{q_m}\right)^{\frac{q_{m-1}}{q_m}}\cdots\right)^{\frac{q_2}{q_3}}\right)^{\frac{q_1}{q_2}}\right)^{\frac{1}{q_1}} \leq C^{\mathbb{K}}_{m,p,\mathbf{q}}\|T\|. \quad (3)$$

In contrast, zbMATH only consisted of 8,450,496 unique expressions with a maximum complexity of 26 and an average complexity of 3.89. One of the most complex expressions in zbMATH with a minimum document frequency of three was

$$M_p(r,f) = \left(\frac{1}{2\pi}\int_0^{2\pi}\left|f\left(re^{i\theta}\right)\right|^p d\theta\right)^{1/p}. \quad (4)$$

As we expected, reviews and abstracts in zbMATH were generally shorter and consisted of less complex mathematical formulae. The

Category	arXiv	zbMATH
Documents	841,008	1,349,297
Formulae	294,151,288	11,747,860
Subexpressions	2,508,620,512	61,355,307

Average Complexity	5.01	3.89
Maximum Complexity	218	26

Table 1: Dataset overview. Average Document Length is defined as the average number of subexpressions per document.

dataset also appeared to contain fewer erroneous expressions, since expressions of complexity 25 are still readable and meaningful.

Figure 1 shows the ratio of unique subexpressions for each complexity in both datasets. The figure illustrates that both datasets share a peak at complexity four. Compared to zbMATH, the arXiv expressions are slightly more evenly distributed over the different levels of complexities. Interestingly, complexities one and two are not dominant in either of the two datasets. Single identifiers only make up 0.03% in arXiv and 0.12% in zbMATH, which is comparable to expressions of complexity 19 and 14, respectively. This finding illustrates the problem of capturing semantic meanings for single identifiers rather than for more complex expressions [37]. It also substantiates that entire expressions, if too complex, are not suitable either for capturing the semantic meanings [23]. Instead, a middle ground is desirable, since the most unique expressions in both datasets have a complexity between 3 and 5. Table 1 summarizes the statistics of the examined datasets.

3.1 Zipf's Law

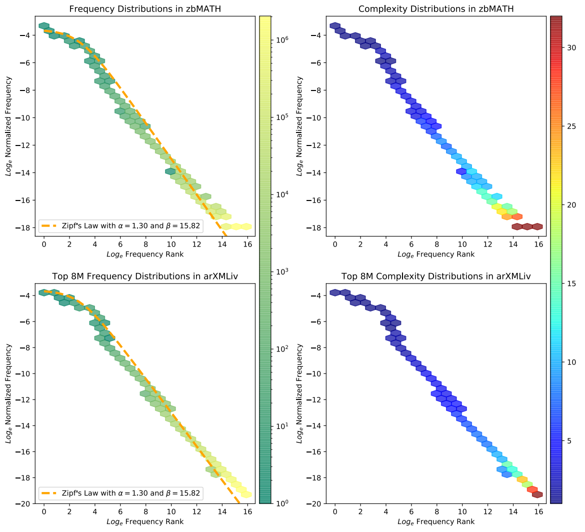
In linguistics, it is well known that word distributions follow Zipf's Law [33], i.e., the r-th most frequent word has a frequency that scales to

$$f(r) \propto \frac{1}{r^{\alpha}} \tag{5}$$

with $\alpha \approx 1$. A better approximation can be applied by a shifted distribution

$$f(r) \propto \frac{1}{(r+\beta)^{\alpha}}, \tag{6}$$

where $\alpha \approx 1$ and $\beta \approx 2.7$. In a study on Zipf's law, Piantadosi [33] illustrated that not only words in natural language corpora follow this law surprisingly accurately, but also many other human-created sets. For instance, in programming languages, in biological systems, and even in music. Since mathematical communication has derived as the result of centuries of research, it would not be surprising if mathematical notations would also follow Zipf's law. The primary conclusion of the law illustrates that there are some very common tokens against a large number of symbols which are not used frequently. Based on this assumption, we can postulate that a score based on frequencies might be able to measure the peculiarity of a token. The infamous TF-IDF ranking functions and their derivatives [1, 34] have performed well in linguistics for many years and are still widely used in retrieval systems [3]. However, since we split every expression into its subexpressions, we generated an anomalous bias towards shorter, i.e., less complex, formulae. Hence, distributions of subexpressions may not obey Zipf's law.



(a) Frequency Distributions **(b) Complexity Distributions**

Figure 2: Each figure illustrates the relationship between the frequency ranks (x-axis) and the normalized frequency (y-axis) in zbMATH (top) and arXiv (bottom). For arXiv, only the first 8 million entries are plotted to be comparable with zbMATH (≈ 8.5 million entries). Subfigure (a) shades the hexagonal bins from green to yellow using a logarithmic scale according to the number of math expressions that fall into a bin. The dashed orange line represents Zipf's distribution (6). The values for α and β are provided in the plots. Subfigure (b) shades the bins from blue to red according to the maximum complexity in each bin.

Figure 2 visualizes a comparison between Zipf's law and the frequency distributions of mathematical subexpressions in arXiv and zbMATH. The dashed orange line visualizes the power law (6). The plots demonstrate that the distributions in both datasets obey this power law. Interestingly, there is not much difference in the distributions between both datasets. Both distributions seem to follow the same power law, with $\alpha = 1.3$ and $\beta = 15.82$. Moreover, we can observe that the developed complexity measure seems to be appropriate, since the complexity distributions for formulae are similar to the distributions for the length of words [33]. In other words, more complex formulae, as well as long words in natural languages, are generally more specialized and thus appear less frequent throughout the corpus. Note that colors of the bins for complexities fluctuate for rare expressions because the color represents the maximum rather than the average complexity in each bin.

3.2 Analyzing and Comparing Frequencies

Figure 3 shows in detail the most frequently used mathematical expressions in arXiv for the complexities 1 to 5. The orange dashed line visible in all graphs represents the normal Zipf's law distribution from Equation (5). We explore the total frequency values without

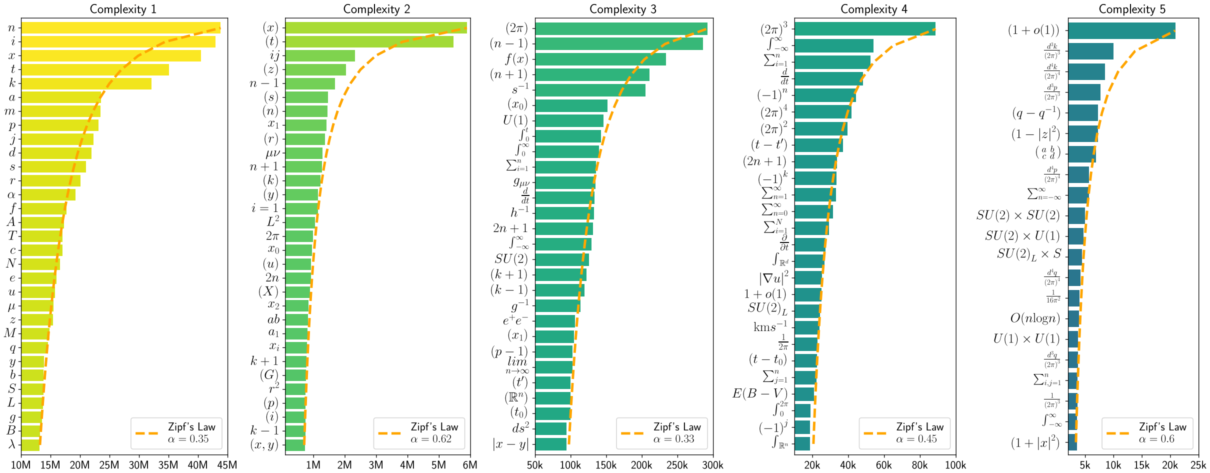


Figure 3: Overview of the most frequent mathematical expressions in arXiv for complexities 1-5. The color gradient from yellow to blue represents the frequency in the dataset. Zipf's law (5) is represented by a dashed orange line.

any normalization. Thus, Equation (5) was multiplied by the highest frequency for each complexity level to fit the distribution. The plots in Figure 3 demonstrate that even though the parameter α varies between 0.35 and 0.62, the distributions in each complexity class also obey Zipf's law.

The plots for each complexity class contain some interesting fluctuations. We can spot a set of five single identifiers that are most frequently used throughout arXiv: n, i, x, t, and k. Even though the distributions follow Zipf's law accurately, we can explore that these five identifiers are proportionally more frequently used than other identifiers and clearly separate themselves above the rest (notice the large gap from k to a). All of the five identifiers are known to be used in a large variety of scenarios. Surprisingly, one might expect that common pairs of identifiers would share comparable frequencies in the plots. However, typical pairs, such as x and y, or α and β, possess a large discrepancy.

The plot of complexity two also reveals that two expressions are proportionally more often used than others: (x) and (t). These two expressions appear more than three times as often in the corpus than any other expression of the same complexity. On the other hand, the quantitative difference between (x) and (t) is negligible. We may assume that arXiv's primary domain, physics, causes the quantitative disparity between (x), (t), and the other tokens. The primary domain of the dataset becomes more clearly visible for higher complexities, such as $SU(2)$ (C3[11]) or kms^{-1} (C4).

Another surprising property of arXiv is that symmetry groups, such as $SU(2)$, appear to play an essential role in the majority of articles on arXiv, see $SU(2)$ (C3), $SU(2)_L$ (C4), and $SU(2) \times SU(2)$ (C5), among others. The plots of higher complexities[12], which we do not show here, made this even more noticeable. Given a complexity of six, for example, the most frequently used expression was $SU(2)_L \times SU(2)_R$, and for a complexity of seven it was $SU(3) \times SU(2) \times U(1)$. Given a complexity of eight, ten out of the top-12 expressions were from symmetry group calculations.

It is also worthwhile to compare expressions among different levels of complexities. For instance, (x) and (t) appeared almost six million times in the corpus, but $f(x)$ (at position three in C3) was the only expression which contained one of these most common expressions. Note that subexpressions of variations, such as (x_0), (t_0), or $(t-t')$, do not match the expression of complexity two. This may imply that (x), and especially (t), appear in many different scenarios. Further, we can examine that even though (x) is a part of $f(x)$ in only approximately 3% of all cases, it is still the most likely combination. These results are especially useful for recommendation systems that make use of math as input. Moreover, plagiarism detection systems may also benefit from such a knowledge base. For instance, it might be evident that $f(x)$ is a very common expression, but for automatic systems that work on a large scale, it is not clear whether duplicate occurrences of $f(x)$ or $\Xi(x)$ should be scored differently, e.g., in the case of plagiarism detection.

Figure 3 shows only the most frequently occurring expressions in arXiv. Since we already explored a bias towards physics formulae in arXiv, it is worth comparing the expressions present within both datasets. Figure 4 compares the 25-top expressions for the complexities one to four. In zbMATH, we discovered that computer science and graph theory appeared as popular topics, see for example $G = (V, E)$ (in C3 at position 20) and the Bachmann-Landau notations in $O(\log n)$, $O(n^2)$, and $O(n^3)$ (C4 positions 2, 3, and 19).

From Figure 4, we can also deduce useful information for MathIR tasks which focus on semantic information. Current semantic extraction tools [37] or LaTeX parsers [35] still have difficulties distinguishing *multiplications* from *function calls*. For example as mentioned before, LaTeXML [30] adds an *invisible times* character

[11] We refer to a given complexity n with Cn, i.e., C3 refers to complexity 3.

between $f(x)$ rather than a *function application*. Investigating the most frequently used terms in zbMATH in Table 4 reveals that u is most likely considered to be a function in the dataset: $u(t)$ (rank 8), $u(x)$ (rank 13), u_{xx} (rank 16), $u(0)$ (rank 17), $|\nabla u|$ (rank 22). Manual investigations of extended lists reveal even more hits: $u_0(x)$ (rank 30), $-\Delta u$ (rank 32), and $u(x,t)$ (rank 33). Since all eight terms are among the most frequent 35 entries in zbMATH, it implies that u can most likely be considered to imply a function in zbMATH. Of course, this does not imply that u must always be a function in zbMATH (see $f(u)$ on rank 14 in C3), but this allows us to exploit probabilities for improving MathIR performance. For instance, if not stated otherwise, u could be interpreted as a function by default, which could help increase the precision of the aforementioned tools.

Figure 4 also demonstrates that our two datasets diverge for increasing complexities. Hence, we can assume that frequencies of less complex formulae are more topic-independent. Conversely, the more complex a math formula is, the more context-specific it is. In the following, we will further investigate this assumption by applying TF-IDF rankings on the distributions.

4 RELEVANCE RANKING FOR FORMULAE

Zipf's law encourages the idea of scoring the relevance of words according to their number of occurrences in the corpus and in the documents. The family of BM25 ranking functions based on TF-IDF scores are still widely used in several retrieval systems [3, 34]. Since we demonstrated that mathematical formulae (and their subexpressions) obey Zipf's law in large scientific corpora, it appears intuitive

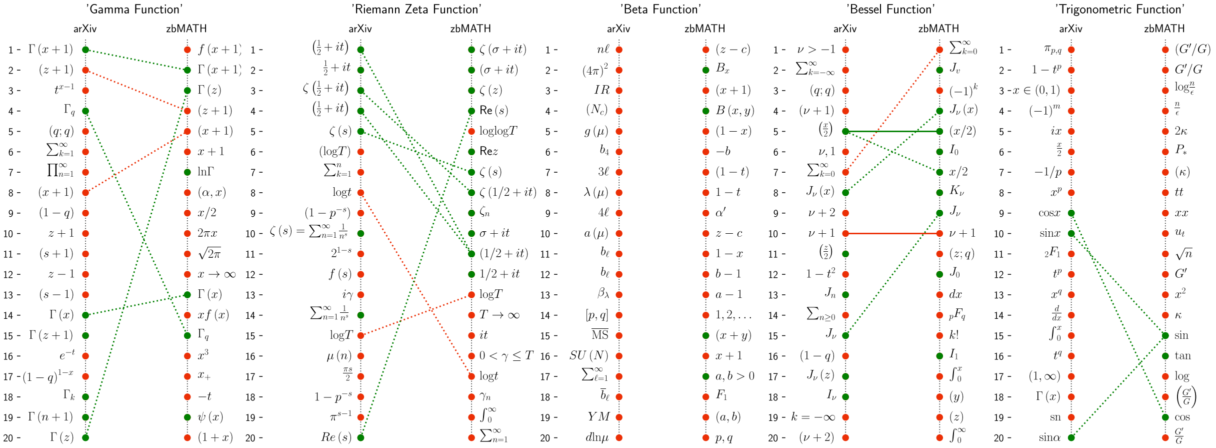

Figure 5: Top-20 ranked expressions retrieved from a topic-specific subset of documents D_q. The search query q is given above the plots. Retrieved formulae are annotated by a domain expert with green dots for relevant and red dots for non-relevant hits. A line is drawn if a hit appears in both result sets. The line is colored in green when the hit was marked as relevant.

to also use TF-IDF rankings, such as a variant of BM25, to calculate their relevance. In its original form [34], *Okapi BM25* was calculated as follows

$$\mathrm{bm25}(t,d) := \frac{(k+1)\,\mathrm{IDF}(t)\,\mathrm{TF}(t,d)}{\mathrm{TF}(t,d) + k\left(1 - b + \frac{b|d|}{\mathrm{AVG}_{\mathrm{DL}}}\right)}, \tag{7}$$

where $\mathrm{TF}(t,d)$ is the term frequency of t in the document d, $|d|$ the length of the document d (in our case, the number of subexpressions), $\mathrm{AVG}_{\mathrm{DL}}$ the average length of the documents in the corpus (see Table 1), and $\mathrm{IDF}(t)$ is the inverse document frequency of t, defined as

$$\mathrm{IDF}(t) := \log \frac{N - n(t) + \frac{1}{2}}{n(t) + \frac{1}{2}}, \tag{8}$$

where N is the number of documents in the corpus and $n(t)$ the number of documents which contain the term t. By adding $\frac{1}{2}$, we avoid $\log 0$ and division by 0. The parameters k and b are free, with b controlling the influence of the normalized document length and k controlling the influence of the term frequency on the final score. For our experiments, we chose the standard value $k = 1.2$ and a high impact factor of the normalized document length via $b = 0.95$.

As a result of our subexpression extraction algorithm, we generated a bias towards low complexities. Moreover, longer documents generally consist of more complex expressions. As demonstrated in Section 2.1, a document that only consists of the single expression $P_n^{(\alpha,\beta)}(x)$, i.e., the document had a length of one, would generate eight subexpressions, i.e., it results in a document length of eight. Thus, we modify the BM25 score in Equation (7) to emphasize higher complexities and longer documents. First, the average document length is divided by the average complexity $\mathrm{AVG}_{\mathrm{C}}$ in the corpus that is used (see Table 1), and we calculate the reciprocal of the document length normalization to emphasize longer documents.

Moreover, in the scope of a single document, we want to emphasize expressions that do not appear frequently in this document, but are the most frequent among their level of complexity. Thus, less complex expressions are ranked more highly if the document overall is not very complex. To achieve this weighting, we normalize the term frequency of an expression t according to its complexity $c(t)$ and introduce an inverse term frequency according to all expressions in the document

	arXiv	zbMATH

Min. DF	50	10
Max. DF	10k	10k

Table 3: Settings for the retrieval experiments.

$$\mathrm{ITF}(t,d) := \log \frac{|d| - \mathrm{TF}(t,d) + \frac{1}{2}}{\mathrm{TF}(t,d) + \frac{1}{2}}. \tag{9}$$

Finally, we define the score $\mathrm{s}(t,d)$ of a term t in a document d as

$$s(t,d) := \frac{(k+1)\,\mathrm{IDF}(t)\,\mathrm{ITF}(t,d)\,\mathrm{TF}(t,d)}{\max\limits_{t' \in d|_{c(t)}} \mathrm{TF}(t',d) + k\left(1 - b + \frac{b\,\mathrm{AVG}_{\mathrm{DL}}}{|d|\,\mathrm{AVG}_{\mathrm{C}}}\right)}. \tag{10}$$

The TF-IDF ranking functions and the introduced $\mathrm{s}(t,d)$ are used to retrieve relevant documents for a given search query. However, we want to retrieve relevant subexpressions over a set of documents. Thus, we define the score of a formula (mBM25) over a set of documents as the maximum score over all documents

$$\mathrm{mBM25}(t,D) := \max_{d \in D} \mathrm{s}(t,d), \tag{11}$$

where D is a set of documents. We used *Apache Flink* [16] to count the expressions and process the calculations. Thus, our implemented system scales well for large corpora.

Table 2 shows the top-7 scored expressions, where D is the entire zbMATH dataset. The retrieved expressions can be considered as meaningful and real-world examples of MOIs, since most expressions are known for specific mathematical concepts, such as

Riemann Zeta Function

Table 4: The top-5 frequent mathematical expressions in the result set of zbMATH for the search queries 'Riemann Zeta Function' (top) and 'Eigenvalue' (bottom) grouped by their complexities (left) and the hits reordered according to their relevance scores (right). The TF-IDF score was calculated with normalized term frequencies.

$\mathrm{Gal}(\overline{\mathbb{Q}}/\mathbb{Q})$, which refers to the Galois group of $\overline{\mathbb{Q}}$ over $\mathbb{Q}$, or $L^2(\mathbb{R}^2)$, which refers to the L^2-space (also known as *Lebesgue space*) over $\mathbb{R}^2$. However, a more topic-specific retrieval algorithm is desirable. To achieve this goal, we (i) retrieved a topic-specific subset of documents $D_q \subset D$ for a given textual search query q, and (ii) calculated the scores of all expressions in the retrieved documents. To generate D_q, we indexed the text sources of the documents from arXiv and zbMATH via elasticsearch (ES)[13] and performed the pre-processing steps: filtering stop words, stemming, and ASCII-folding[14]. Table 3 summarizes the settings we used to retrieve MOIs from a topic-specific subset of documents D_q. We also set a minimum hit frequency according to the number of retrieved documents an expression appears in. This requirement filters out uncommon notations.

Figure 5 shows the results for five search queries. We asked a domain expert from the National Institute of Standards and Technology (NIST) to annotate the results as related (shown as green dots in Figure 5) or non-related (red dots). We found that the results range from good performances (e.g., for the Riemann zeta function) to bad performances (e.g., beta function). For instance, the results for the Riemann zeta function are surprisingly accurate, since we could discover that parts of Riemann's hypothesis[15] were ranked highly throughout the results (e.g., $\zeta(\frac{1}{2}+it)$). On the other hand, for the beta function, we retrieved only a few related hits, of which only one had a strong connection to the beta function $B(x,y)$. We observed that the results were quite sensitive to the chosen settings (see Table 3). For instance, according to the beta function, the minimum hit frequency has a strong effect on the results, since many expressions are shared among multiple documents. For arXiv, the expressions $B(\alpha,\beta)$ and $B(x,y)$ only appear in one document of the retrieved 40. However, decreasing the minimum hit frequency would increase noise in the results.

Even though we asked a domain expert to annotate the results as relevant or not, there is still plenty of room for discussion. For instance, $(x+y)$ (rank 15 in zbMATH, 'Beta Function') is the argument of the gamma function $\Gamma(x+y)$ that appears in the definition of the beta function [8, (5.12.1)] $B(x,y) := \Gamma(x)\Gamma(y)/\Gamma(x+y)$. However, this relation is weak at best, and thus might be considered as not related. Other examples are $\mathrm{Re}z$ and $\mathrm{Re}(s)$, which play a crucial role in the scenario of the Riemann hypothesis (all non-trivial zeroes have $\mathrm{Re}(s) = \frac{1}{2}$). Again, this connection is not obvious, and these expressions are often used in multiple scenarios. Thus, the domain expert did not mark the expressions as being related.

Considering the differences in the documents, it is promising to have observed a relatively high number of shared hits in the results. Further, we were able to retrieve some surprisingly good insights from the results, such as extracting the full definition of the Riemann zeta function [8, (25.2.1)] $\zeta(s) := \sum_{n=1}^{\infty}\frac{1}{n^s}$. Even though a high number of shared hits seem to substantiate the reliability of the system, there were several aspects that affected the outcome negatively, from the exact definition of the search queries to retrieve documents via ES, to the number of retrieved documents, the minimum hit frequency, and the parameters in mBM25.

5 APPLICATIONS

The presented results are beneficial for a variety of use-cases. In the following, we will demonstrate and discuss several of the applications that we propose.

Extension of zbMATH's Search Engine: Formula search engines are often counterintuitive when compared to textual search, since the user must know how the system operates to enter a search query properly (e.g., does the system supports LaTeX inputs?). Additionally, mathematical concepts can be difficult to capture using only mathematical expressions. Consider, for example, someone

[13] https://github.com/elastic/elasticsearch [Accessed Sep. 2019]. We used version 7.0.0

[14] This means that non-ASCII characters are replaced by their ASCII counterparts or will be ignored if no such counterpart exists.

[15] Riemann proposed that the real part of every non-trivial zero of the Riemann zeta function is 1/2. If this hypothesis is correct, all the non-trivial zeros lie on the critical line consisting of the complex numbers $1/2 + it$.

Auto-completion for '$E = m$'			Suggestions for '$E = \{m, c\}$'		
Sug. Expression	TF	DF	Sug. Expression	TF	DF
$E = mc^2$	558	376	$E = mc^2$	558	376
$E = m\cosh\theta$	23	23	$E = \gamma mc^2$	39	38
$E = mv_0$	7	7	$E = \gamma m_e c^2$	41	36
$E = m/\sqrt{1-\dot{q}^2}$	12	6	$E = m\cosh\theta$	23	23
$E = m/\sqrt{1-\beta^2}$	10	6	$E = -mc^2$	35	17
$E = mc^2\gamma$	6	6	$E = \sqrt{m^2c^4 + p^2c^2}$	10	8

Table 5: Suggestions to complete '$E = m$' and '$E = \{m, c\}$' (the right-hand side contains m and c) with term and document frequency based on the distributions of formulae in arXiv.

who wants to search for mathematical expressions that are related to eigenvalues. A textual search query would only retrieve entire documents that require further investigation to find related expressions. A mathematical search engine, on the other hand, is impractical since it is not clear what would be a fitting search query (e.g., $Av = \lambda v$?). Moreover, formula and textual search systems for scientific corpora are separated from each other. Thus, a textual search engine capable of retrieving mathematical formulae can be beneficial. Also, many search engines allow for narrowing down relevant hits by suggesting filters based on the retrieved results. This technique is known as faceted search. The zbMATH search engine also provides faceted search, e.g., by authors, or year. Adding facets for mathematical expressions allows users to narrow down the results more precisely to arrive at specific documents.

Our proposed system for extracting relevant expressions from scientific corpora via mBM25 scores can be used to search for formulae even with textual search queries, and to add more filters for faceted search implementations. Table 4 shows two examples of such an extension for zbMATH's search engine. Searching for 'Riemann Zeta Function' and 'Eigenvalue' retrieved 4,739 and 25,248 documents from zbMATH, respectively. Table 4 shows the most frequently used mathematical expressions in the set of retrieved documents. It also shows the reordered formulae according to a default TF-IDF score (with normalized term frequencies) and our proposed mBM25 score. The results can be used to add filters for faceted search, e.g., show only the documents which contain $u \in W_0^{1,p}(\Omega)$. Additionally, the search system now provides more intuitive textual inputs even for retrieving mathematical formulae. The retrieved formulae are also interesting by themselves, since they provide insightful information on the retrieved publications. As already explored with our custom document search system in Figure 5, the Riemann hypothesis is also prominent in these retrieved documents.

The differences between TF-IDF and mBM25 ranking illustrates the problem of an extensive evaluation of our system. From a broader perspective, the hit $Ax = \lambda Bx$ is highly correlated with the input query 'Eigenvalue'. On the other hand, the raw frequencies revealed a prominent role of $\mathrm{div}(|\nabla u|^{p-2}\,\nabla u)$. Therefore, the top results of the mBM25 ranking can also be considered as relevant.

Math Notation Analysis: A faceted search system allows us to analyze mathematical notations in more detail. For instance, we can retrieve documents from a specific time period. This allows one to study the evolution of mathematical notation over time [4], or for identifying trends in specific fields. Also, we can analyze standard notations for specific authors since it is often assumed that authors prefer a specific notation style which may vary from the standard notation in a field.

Math Recommendation Systems: The frequency distributions of formulae can be used to realize effective math recommendation tasks, such as type hinting or error-corrections. These approaches require long training on large datasets, but may still generate meaningless results, such as $G_i = \{(x, y) \in \mathbb{R}^n : x_i = x_i\}$ [42]. We propose a simpler system which takes advantage of our frequency distributions. We retrieve entries from our result database, which contain all unique expressions and their frequencies. We implemented a simple prototype that retrieves the entries via pattern matching. Table 5 shows two examples. The left side of the table shows suggested autocompleted expressions for the query '$E{=}m$'. The right side shows suggestions for '$E{=}$', where the right-hand side of the equation should contain m and c in any order. A combination using more advanced retrieval techniques, such as similarity measures based on symbol layout trees [7, 45], would enlarge the number of suggestions. This kind of autocomplete and error-correction type-hinting system would be beneficial for various use-cases, e.g., in educational software or for search engines as a pre-processing step of the input.

Plagiarism Detection Systems: As previously mentioned, plagiarism detection systems [28, 29, 39] would benefit from a system capable of distinguishing conventional from uncommon notations. The approaches described by Meuschke et al. [29] outperform existing approaches by considering frequency distributions of single identifiers (expressions of complexity one). Considering that single identifiers make up only 0.03% of all unique expressions in arXiv, we presume that better performance can be achieved by considering more complex expressions. The conferred string representation also provides a simple format to embed complex expressions in existing learning algorithms.

Expressions with high complexities that are shared among multiple documents may provide further hints to investigate potential plagiarisms. For instance, the most complex expression that was shared among three documents in arXiv was Equation (3). A complex expression being identical in multiple documents could indicate a higher likelihood of plagiarism. Further investigation revealed that similar expressions, e.g., with infinite sums, are frequently used among a larger set of documents. Thus, the expression seems to be a part of a standard notation that is commonly shared, rather than a good candidate for plagiarism detection. Resulting from manual investigations, we could identify the equation as part of a concept called *generalized Hardy-Littlewood inequality* and Equation (3) appears in the three documents [2, 5, 32]. All three documents shared one author in common. Thus, this case also demonstrates a correlation between complex mathematical notations and authorship.

Semantic Taggers and Extraction Systems: We previously mentioned that semantic extraction systems [23, 36, 37] and semantic math taggers [6, 43] have difficulties in extracting the essential components (MOIs) from complex expressions. Considering the definition of the Jacobi polynomial in Equation (1), it would be beneficial to extract the groups of tokens that belong together, such as $P_n^{(\alpha,\beta)}(x)$ or $\Gamma(\alpha + m + 1)$. With our proposed search engine

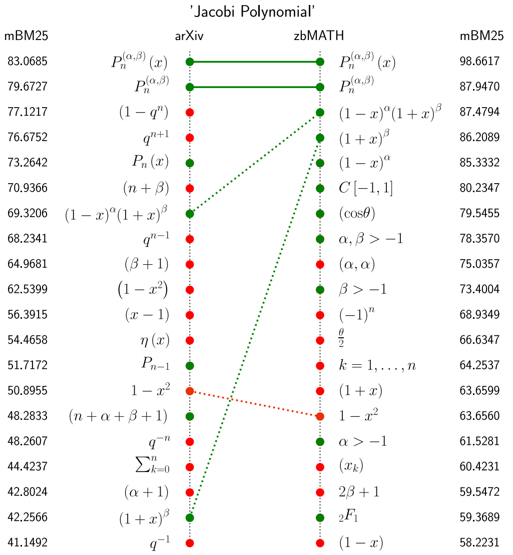

Figure 6: The top ranked expression for '*Jacobi polynomial*' in arXiv and zbMATH. For arXiv, 30 documents were retrieved with a minimum hit frequency of 7.

for retrieving MOIs, we are able to facilitate semantic extraction systems and semantic math taggers. Imagine such a system being capable of identifying the term 'Jacobi polynomial' from the textual context. Figure 6 shows the top relevant hits for the search query 'Jacobi polynomial' retrieved from zbMATH and arXiv. The results contain several relevant and related expressions, such as the constraints $\alpha, \beta > -1$ and the weight function for the Jacobi polynomial $(1-x)^\alpha(1+x)^\beta$, which are essential properties of this orthogonal polynomial. Based on these retrieved MOIs, the extraction systems can adjust its retrieved math elements to improve precision, and semantic taggers or a tokenizer could re-organize parse trees to more closely resemble expression trees.

6 CONCLUSION & FUTURE WORK

In this study we showed that analyzing the frequency distributions of mathematical expressions in large scientific datasets can provide useful insights for a variety of applications. We demonstrated the versatility of our results by implementing prototypes of a type-hinting system for math recommendations, an extension of zbMATH's search engine, and a mathematical retrieval system to search for topic-specific MOIs. Additionally, we discussed the potential impact and suitability in other applications, such as math search engines, plagiarism detection systems, and semantic extraction approaches. We are confident that this project lays a foundation for future research in the field of MathIR.

We plan on developing a web application which would provide easy access to our frequency distributions, the MOI search engine, and the type-hinting recommendation system. We hope that this will further expedite related future research projects. Moreover, we will use this web application for an online evaluation of our MOI retrieval system. Since the level of agreement among annotators will be predictably low, an evaluation by a large community is desired.

In this first study, we preserved the core structure of the MathML data which provided insightful information for the MathML community. However, this makes it difficult to properly merge formulae. In future studies, we will normalize the MathML data via MathMLCan [9]. In addition to this normalization, we will include wildcards for investigating distributions of formula patterns rather than exact expressions. This will allow us to study connections between math objects, e.g., between $\Gamma(z)$ and $\Gamma(x+1)$. This would further improve our recommendation system and would allow for the identification of regions for parameters and variables in complex expressions.

***Abstract*—Public safety incidents typically involve significant amount of group traffic and have a stringent requirement on connection reliability. Hence multicast could potentially improve network and user performance significantly. Towards this goal, in this paper we investigate Long-Term Evolution (LTE) Multicast Broadcast Single Frequency Network (MBSFN) from the perspectives of throughput, resource efficiency, sources of MBSFN gain, and outage. Firstly, we derive a realistic MBSFN Signal-to-Interference-plus-Noise Ratio (SINR) analytical model, with multiple antennas, multipath channel, and equalizer considered. Secondly, we develop an MBSFN system level simulator as well as a simulation platform to compare unicast and MBSFN performance. Thirdly, we perform comprehensive simulations on the metrics under study. Through simulations, we discover that while unicast may achieve higher information bits/symbol, MBSFN provides higher throughput, and MBSFN throughput increases with MBSFN area size. We then quantify the MBSFN SINR improvement due to diversity combining and interference reduction, respectively. Furthermore, we show that compared with unicast, MBSFN improves outage probability significantly, which is essential for public safety incidents. Finally, we show that all the above MBSFN performance improvements apply to different MBSFN area sizes, even when the MBSFN size is one cell.**

***Index Terms*—Public safety, LTE, MBSFN, SINR analytical model, outage probability, resource efficiency.**

I. Introduction

Public safety mission is essential to protect citizens' lives and properties, and effective communications among first responders during public safety incidents is crucial. Compared with commercial traffic, public safety incidents typically involve significant amount of group traffic among first responders [1], including traffic intensive applications, such as mission critical video. Using traditional point-to-point unicast transmission at physical (PHY) layer to serve this type of traffic would require significant amount of spectrum, and sometimes lead to severe network congestion. With the above in mind, using multicast to serve public safety traffic has been put on the table, and Multicast Broadcast Single Frequency Network (MBSFN) in Long-Term Evolution (LTE) is one candidate due to its multicast nature and potential Signal-to-Interference-plus-Noise Ratio (SINR) improvement especially at cell edges [2] [3].

From a technology perspective, while MBSFN was developed in LTE and uses Single Frequency Network (SFN), SFN itself was not new and had been investigated decades ago for classical broadcast technologies, such as Digital Audio Broadcasting (DAB) and Digital Video Broadcasting (DVB) [4] [5]. These early works demonstrated that SFN could improve coverage and spectrum usage.

While both LTE MBSFN and classical broadcasting technologies use SFN, LTE MBSFN operates under LTE architecture and follows LTE protocol stacks. System performance is hence different, which triggered studies of LTE MBSFN in recent years from various perspectives. In [6], the authors first derived an analytical expression for SINR at a given point in a cell, then evaluated MBSFN performance under different Modulation and Coding Schemes (MCSs), the length of cyclic prefix, and the impact of shadowing. In [7], the authors extended the work in [6] to femtocell and compared single cell transmissions with multicell transmissions. None of the above work considered multiple antennas at the transmitter side or the receiver side. These multiple antennas allow multiple-input and multiple-output (MIMO) in unicast, which is one major technology that made LTE successful. In addition, the performance between MBSFN and unicast are compared in [8], where the authors used average MCS for all user equipments (UEs) for performance calculation. In [9], the authors proposed an optimal UE grouping algorithm in MBSFN, where the UEs were associated with the same MCS in unicast and multicast transmissions. As shown in our previous work [10], this is not always the case. MCSs could be different for different UEs, and MCSs used for unicast and multicast could be different for the same UE as well.

In this paper we investigate LTE MBSFN from the perspectives of throughput, resource efficiency, MBSFN gain, and outage. Unlike commercial broadcasting in a large deployment area, public safety incidents could vary in size and happen within a small area. Therefore we also consider small MBSFN areas. Specifically, we first derive an SINR analytical model for MBSFN. Different from others' work, multiple antennas, multipath channel, and equalizer are considered. The resulting model is hence more realistic and accurate. Next, by closely following the 3rd Generation Partnership Project (3GPP) standards, we implement the MBSFN SINR model and develop an MBSFN system level simulator as well as a simulation platform to compare unicast and MBSFN performance. Different from others' work, here SINR values in unicast and MBSFN are calculated separately based on their unique models. The high fidelity MBSFN Block Error Rate (BLER) curves and Channel Quality Indicator (CQI) switch points from our previous work [10] are also employed for PHY abstraction. Then, through comprehensive simulations, we show that although unicast may have higher resource efficiency in terms of information bits/symbol, MBSFN would provide higher throughput since it uses the full bandwidth in each transmission that serves all first responders, while in unicast resources are shared among first responders. Simulation

Liu, Chunmei; Shen, Chen; Chuang, Jack; Rouil, Richard A.; Choi, Hyeong-Ah. "Evaluating Unicast and MBSFN in Public Safety Networks."
Paper presented at IEEE International Symposium on Personal, Indoor and Mobile Radio Communications (PIMRC) 2020, London, UK. August 31, 2020 - September 03, 2020.

results also confirmed that larger MBSFN area size would increase MBSFN throughput due to higher MBSFN diversity combining gain and less interference. We further quantify MBSFN SINR improvement from diversity combining and interference reduction, respectively. The results show that while at cell edge they are comparable, at cell center the gain from interference reduction dominates and is significantly higher. However, the large SINR gain at cell center would not improve performance significantly due to MCS cap and lack of MIMO support for MBSFN. Finally, simulation results show that compared with unicast, MBSFN improves outage probability significantly, which is essential for public safety incidents. The above MBSFN performance improvements hold even when the MBSFN area size is one cell, which applies to the case when the public safety incident area is small.

The rest of the paper is organized as follows. In Section II we briefly describe unicast and MBSFN details as specified in 3GPP that are relevant to our analysis. In Section III we derive the SINR analytical model for MBSFN. In Section IV we describe our simulation design, together with simulation results and analysis. In Section V we summarizes our findings.

II. Review of Unicast and MBSFN in LTE

In this section we review unicast and MBSFN as specified by 3GPP, with emphasis on factors that have direct impacts on our analysis. The public safety broadband network Band 14 (B14) 10 MHz bandwidth Frequency Division Duplexing (FDD) is used as an example [11], with a focus on downlink.

A. LTE Overview

3GPP specifies Orthogonal Frequency-Division Multiple Access (OFDMA) for LTE downlink, and Cyclic Prefix (CP) is used to avoid Inter-Symbol Interference (ISI) [12]. Both normal CP and extended CP are specified. While the normal CP is used in typical LTE deployments to achieve high data rate, the extended CP is used in special cases such as in very large cells and MBSFN. In this paper, normal CP is used in unicast analysis, and extended CP is used for MBSFN.

For FDD, 3GPP defines frame structure type 1 [13], where one radio frame is 10 ms in duration and divided into 10 subframes. The smallest time-frequency unit for downlink transmission is a resource element (RE), which consists of one Orthogonal Frequency Division Multiplex (OFDM) subcarrier for a duration of one OFDM symbol. Transmissions can be scheduled by Resource Blocks (RBs) [14], and data is carried in Transport Blocks (TBs), which are passed from the Media Access Control (MAC) layer to the PHY layer once per Transmission Time Interval (TTI) which is 1 ms.

UEs report channel quality back to eNodeB using different sets of CQI indices for different MCS sets the network may deploy. In this paper, we consider the MCS set of Quadrature Phase Shift Keying (QPSK), 16 Quadrature Amplitude Modulation (QAM), and 64QAM. The corresponding CQI indices and their interpretations are given in Table 7.2.3-1 in [13].

B. LTE Unicast Review

For unicast, RB is the basic unit when allocating resources. To improve data rate and robustness, LTE unicast utilizes MIMO technology such as transmit diversity, spatial multiplexing, and beamforming. Accordingly, 3GPP defines 10 transmission modes (TMs) and could support up to 8 layer transmissions using TM9 [14], which is the transmission mode used in this paper. In addition, since Hybrid Automatic Repeat Request (HARQ) is specified for unicast transmissions, in this paper the target BLER is selected to be 10 %.

C. LTE MBSFN Review

In MBSFN, data is transmitted from multiple cells to the destination UE, as shown in Figure 1. All cells involved are tightly synchronized and transmit the same content over the same subcarriers using the same waveform. These cells form a so-called MBSFN area. To avoid ISI, the transmissions from different cells are targeted to arrive at the UE within CP at the start of the symbol. Hence 3GPP specifies the extended CP for MBSFN. From the UE perspective, the UE could treat all the transmissions from MBSFN area in the same way as multipath components of a single cell transmission, and the SINR could improve especially at cell edge. Note that the SINR improvement comes from two folds. One is the diversity combining gain from multiple signal sources. Another is the reduction of inter-cell interference - the transmissions from additional MBSFN cells are now turned into constructive signals instead of inter-cell interference. In Section IV-C, we will quantify the SINR improvement from these two folds.

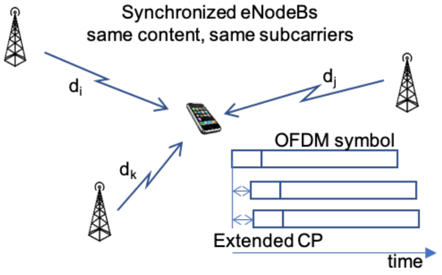

Fig. 1. MBSFN Transmission [15]

The composite channel from multiple cells in MBSFN requires a separate channel estimation from that performed from a single cell. 3GPP hence defines MBSFN subframe that carries MBSFN reference signals. MBSFN data is transmitted in MBSFN subframes only while unicast data is transmitted in non-MBSFN subframes, and MBSFN subframes and non-MBSFN subframes are interleaved in time. In addition, out of the 10 subframes within one radio frame, subframe 0, 4, 5, and 9 carry control information that is essential for network operation, such as paging occasions [14]. These four subframes are hence reserved for unicast transmissions and cannot be configured as MBSFN subframes. Therefore, there are at most six subframes available for MBSFN transmissions, or 60 % of the total resources.

3GPP also specifies that a single TB is generated per TTI for multicast channel (MCH) and uses all the MBSFN resources in that subframe [16] (e.g. 50 RBs for public safety band B14). In addition, no transmit diversity scheme is specified, and MCH is mapped on a single layer spatial multiplexing. Hence MBSFN could not take advantage of MIMO technologies. Furthermore, given its multicast nature, 3GPP specifies no radio link control retransmissions and no HARQ for MBSFN. Hence, in order to deliver acceptable service to upper layers, lower target BLER is typically used for MBSFN. In this paper we use 1 %.

III. MBSFN Analytical Model

In this section we derive an analytical model for MBSFN SINR, considering multiple antennas, multipath channel, and equalizer. We then convert it into Additive White Gaussian Noise (AWGN) equivalent SINR, which will later be fed into system level simulations.

A. *MBSFN Networks*

Consider a regular hexagonal network with three sectors per cell, as illustrated in Figure 2, where the numbers are cell identifiers (IDs). Let $\mathcal{I}$ denote the set of cells under consideration, and N denote the total number of cells in set $\mathcal{I}$. Index these N cells such that the first N_{M} cells are cells that participate in MBSFN transmissions within the MBSFN area (cell 1 to 21 in Figure 2), and denote them by set $\mathcal{I}_{\text{M}} = \{1, 2, \cdots, N_{\text{M}}\}$. Consequently, the cells with indices among $N_{\text{M}}+1, \cdots, N$ are the cells that do not participate in MBSFN transmissions (the cells that are not assigned an ID in Figure 2). Denote them by set $\mathcal{I}_{\text{L}} = \{N_{\text{M}}+1, N_{\text{M}}+2, \cdots, N\}$, where its size $N_{\text{L}} = N - N_{\text{M}}$. All cells have the same number of transmit antennas N_{Tx}, and all UEs have the same number of receiver antennas N_{Rx}.

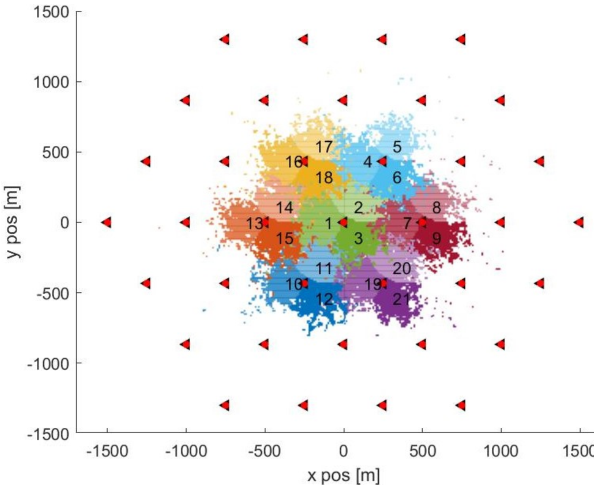

Fig. 2. Network Layout with Cell ID

Consider a UE within the MBSFN area. As shown in Figure 1, let d_i denote the distance between MBSFN cell $i \in \mathcal{I}_{\text{M}}$ and the UE, while MBSFN cell $k \in \mathcal{I}_{\text{M}}$ be the cell that is closest to the UE. As mentioned previously, in MBSFN, all MBSFN cells are tightly synchronized and transmit the same content simultaneously at the same subcarriers. Use the first signal received from cell k as the reference signal, and align to it all signals received after, including those from other MBSFN cells. Then the signals from cell i incur delay τ_i [6] [4]:

$$\tau_i = \frac{d_i - d_k}{s}, \tag{1}$$

where s is the speed of light. Note that given the relatively long CP length and signal frame - 16.67 μs for the extended CP length and 66.67 μs for the signal frame per 3GPP - the delays from different paths from the same cell i are not further differentiated, and are all approximated by the same τ_i.

The constructive and destructive portions of the signal from cell i, $i \neq k$ ($i \in \mathcal{I}_{\text{M}}$) can be captured by weight function ω_i and $1 - \omega_i$, respectively, where ω_i is as below [6] [4]:

$$\omega_i = \begin{cases} 1 & \text{when } 0 \leq \tau_i < T_{\text{CP}} \\ 1 - \dfrac{\tau_i - T_{\text{CP}}}{T_{\text{u}}} & \text{when } T_{\text{CP}} \leq \tau_i < T_{\text{CP}} + T_{\text{u}} \\ 0 & \text{otherwise} \end{cases} \tag{2}$$

where T_{CP} is the extended CP length defined in 3GPP for MBSFN, and T_{u} is the length of the useful signal frame.

Note that the destructive portion leads to ISI for the next symbol.

B. *RE Level SINR*

As mentioned in Section II, 3GPP specifies that a single TB per TTI is used for MBSFN transmission, and this TB uses all resources in that subframe. Let N_{RE} denote the total number of REs within one MBSFN subframe, and index the REs by $c = 1, 2, \cdots, N_{\text{RE}}$. Then the $(N_{\text{Rx}} \times 1)$-element UE received signal vector at RE c, denoted by $\boldsymbol{y}^c$, can be expressed as

$$\begin{aligned} \boldsymbol{y}^c = & \sum_{i=\mathcal{I}_{\text{M}}} \sqrt{\omega_i P_i^c} \boldsymbol{H}^{(i,c)} \mathbf{1}_{N_{\text{Tx}}} x_m \\ & + \sum_{i=\mathcal{I}_{\text{M}}} \sqrt{(1-\omega_i) P_i^c} \boldsymbol{H}^{(i,c)} \mathbf{1}_{N_{\text{Tx}}} x_m^- \\ & + \sum_{l=\mathcal{I}_{\text{L}}} \sqrt{P_l^c} \boldsymbol{H}^{(l,c)} \boldsymbol{W}^{(l,c)} \boldsymbol{\chi}_l + \boldsymbol{n}^c, \end{aligned} \tag{3}$$

where x_m is the MBSFN transmit signal, x_m^- is the previous MBSFN transmit signal; $\boldsymbol{\chi}_l$ is the $(N_{\text{Tx}} \times 1)$-element transmit signal vector from cell l, $l \in \mathcal{I}_{\text{L}}$ (i.e. $l \notin \mathcal{I}_{\text{M}}$); P_i^c and P_l^c ($i \in \mathcal{I}_{\text{M}}, l \in \mathcal{I}_{\text{L}}$) are the signal powers from cell i and l at RE c after taking into account path loss and shadowing but without small-scale fading, respectively; $\boldsymbol{H}^{(i,c)}$ and $\boldsymbol{H}^{(l,c)}$, ($i \in \mathcal{I}_{\text{M}}$, $l \in \mathcal{I}_{\text{L}}$) are the $(N_{\text{Rx}} \times N_{\text{Tx}})$-element matrices representing the frequency domain channel gains from cell i and l to the UE at RE c, respectively; $\boldsymbol{W}^{(l,c)}$ is the $(N_{\text{Tx}} \times N_{\text{Tx}})$ channel precoding matrix used by cell l on RE c, $l \in \mathcal{I}_L$; $\mathbf{1}_{N_{\text{Tx}}}$ is $(N_{\text{Tx}} \times 1)$ column vector with all elements being 1; and $\boldsymbol{n}^c$ represents thermal noise with zero mean and variance σ_N^2.

The first term in Eq. (3) represents the constructive portion of the signal. The second term represents the ISI from the destructive portion of the previous transmit signal, where the channel experienced by this destructive portion is approximated by the channel experienced by the current signal. The third term represents interference from the non-MBSFN cells. And the last term represents the thermal noise. Note that all MBSFN cells and all transmit antennas at each MBSFN cell transmit the same signal. Hence x_m applies to all MBSFN cell $i = 1, \cdots, N_{\mathrm{M}}$ and each of their transmit antennas. x_m is hence essentially a scalar.

Define

$$\boldsymbol{q}^c = \left[\sqrt{\omega_1 P_1^c}\boldsymbol{H}^{(1,c)}, \cdots, \sqrt{w_{N_{\mathrm{M}}} P_{N_{\mathrm{M}}}^c}\boldsymbol{H}^{(N_{\mathrm{M}},c)}\right]\mathbf{1}_{(N_{\mathrm{Tx}})(N_{\mathrm{M}})}, \tag{4}$$

where $\mathbf{1}_{(N_{\mathrm{Tx}})(N_{\mathrm{M}})}$ is $(N_{\mathrm{Tx}} \cdot N_{\mathrm{M}} \times 1)$-element column vector with all elements being 1. Then:

$$\boldsymbol{y}^c = \boldsymbol{q}^c x_m + \sum_{i=1}^{N_{\mathrm{M}}} \sqrt{(1-\omega_i)P_i^c}\boldsymbol{H}^{(i,c)}\mathbf{1}_{N_{\mathrm{Tx}}} x_m^- + \sum_{l=N_{\mathrm{M}}+1}^{N} \sqrt{P_l^c}\boldsymbol{H}^{(l,c)}\boldsymbol{W}^{(l,c)}\boldsymbol{\chi}_l + \boldsymbol{n}^c. \tag{5}$$

Eq. (5) shows that the system could be viewed as a Single Input Multiple Output (SIMO) system, with signals from transmit antennas of all MBSFN cells being treated as the same transmit signal from different paths. We could hence apply zero-forcing receiver

$$\boldsymbol{f}^c = [(\boldsymbol{q}^c)^H \boldsymbol{q}^c]^{-1}(\boldsymbol{q}^c)^H, \tag{6}$$

where the superscript $(\cdot)^H$ represents conjugate transpose. Then the post-equalization received signal becomes

$$r^c = \boldsymbol{f}^c \boldsymbol{y}^c \tag{7}$$

$$= x_m + \sum_{i=1}^{N_{\mathrm{M}}} \sqrt{(1-\omega_i)P_i^c}\boldsymbol{f}^c\boldsymbol{H}^{(i,c)}\mathbf{1}_{N_{\mathrm{Tx}}} x_m^- + \sum_{l=N_{\mathrm{M}}+1}^{N} \sqrt{P_l^c}\boldsymbol{f}^c\boldsymbol{H}^{(l,c)}\boldsymbol{W}^{(l,c)}\boldsymbol{\chi}_l + \boldsymbol{f}^c\boldsymbol{n}^c. \tag{8}$$

The post-equalization SINR for RE c can then be calculated as below:

$$\gamma^c = \left(\sum_{i=1}^{N_{\mathrm{M}}} (1-\omega_i)P_i^c \|\boldsymbol{f}^c\boldsymbol{H}^{(i,c)}\mathbf{1}_{N_{\mathrm{Tx}}}\|^2 + \sum_{l=N_M+1}^{N} P_l^c \|\boldsymbol{f}^c\boldsymbol{H}^{(l,c)}\boldsymbol{W}^{(l,c)}\|^2 + \|\boldsymbol{f}^c\|^2\sigma_N^2\right)^{-1} \tag{9}$$

C. AWGN Equivalent SINR

In our analysis, Mutual Information Effective SINR Mapping (MIESM) based PHY abstraction is employed to link system level simulation and link level simulation [17]. Let $f_m(\cdot)$ be the Bit-Interleaved Coded Modulation (BICM) capacity of modulation alphabet m that is associated with the MCS m. Then, across all N_{RE} REs used for the MBSFN TB transmission, the equivalent SINR over AWGN channel for modulation m is:

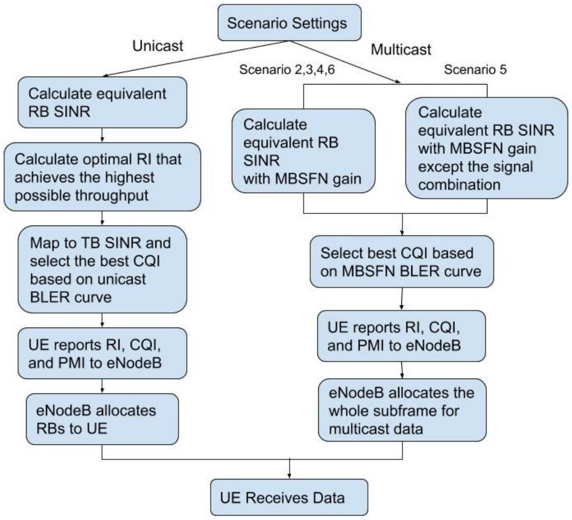
$$\gamma_m = f_m^{-1}\left[\frac{1}{N_{\mathrm{RE}}}\sum_{c=1}^{N_{\mathrm{RE}}} f_m(\gamma^c)\right]. \tag{10}$$

This AWGN equivalent TB SINR γ_m, together with the AWGN BLER curves, target BLER 1 %, and CQI switching points [10], is used for MCS selection and CQI reporting in system level simulations, as well as packet loss determination when the UE receives a packet.

IV. Simulation Design and Results

A. Simulation Design

The simulation flow chart is illustrated in Figure 3. For comparison purpose, there are two branches, one for unicast and one for MBSFN. Both are run for the same scenario settings. The unicast branch follows Vienna system level simulator [17][1], with TM9 selected. The MBSFN branch utilizes the analytical model derived in Section III. Due to the stringent requirement on transmission reliability in public safety incidents, the minimum MCS among first responders is selected for MBSFN transmissions.



Scenario Settings
Unicast
Multicast
Scenario 2,3,4,6
Scenario 5
Calculate equivalent RB SINR
Calculate optimal RI that achieves the highest possible throughput
Map to TB SINR and select the best CQI based on unicast BLER curve
UE reports RI, CQI, and PMI to eNodeB
eNodeB allocates RBs to UE
Calculate equivalent RB SINR with MBSFN gain
Calculate equivalent RB SINR with MBSFN gain except the signal combination
Select best CQI based on MBSFN BLER curve
UE reports RI, CQI, and PMI to eNodeB
eNodeB allocates the whole subframe for multicast data
UE Receives Data

Fig. 3. Simulation Flowchart

The network simulated is a regular hexagonal network with three sectors per cell, as shown in Figure 2, where the numbers are cell IDs and outer rings are included to simulate interference. Public safety band B14 is selected and consider 8 x 4 MIMO configuration. Channel models used are the urban and rural models defined by 3GPP [18] for path loss, Claussen model for shadowing [19], and International Telecommunication Union (ITU) PedB, VehA, and VehB for small scale fading, with speed 10 km/h, 30 km/h, and 120 km/

[1] Any mention of commercial products in the paper is for information only; it does not imply recommendation or endorsement by National Institute of Standards and Technology.

h, respectively. Inter-site-distance (ISD) studied are 500 m, 1299 m, and 1732 m. Later we use urban ISD1299 VehA to denote urban path loss, ISD 1299 m, and VehA with speed 30 km/h. Other channel notations can be explained similarly. The number of runs and TTIs are chosen to capture statistically stable results.

Table I summarizes the six scenarios simulated for performance analysis, where scenario 5 is designed for MBSFN gain analysis used in Section IV-C and will be described there. The scenarios with different MBSFN area sizes are illustrated in Figure 4, where each color represents a tri-sector site and different color transparency shows different cells within a site. Note that scenarios 2 to 4 have small MBSFN areas to cover public safety incidents with small areas, and scenario 6 has a large enough MBSFN area to cover public safety incidents with large areas.

TABLE I
SIMULATION SCENARIOS

Scenario	Transmission
1	Unicast
2	MBSFN area: cell 1
3	MBSFN area: cell 1-2
4	MBSFN area: cell 1-3
5	MBSFN area: cell 1-21, No Signal Combination
6	MBSFN area: cell 1-21

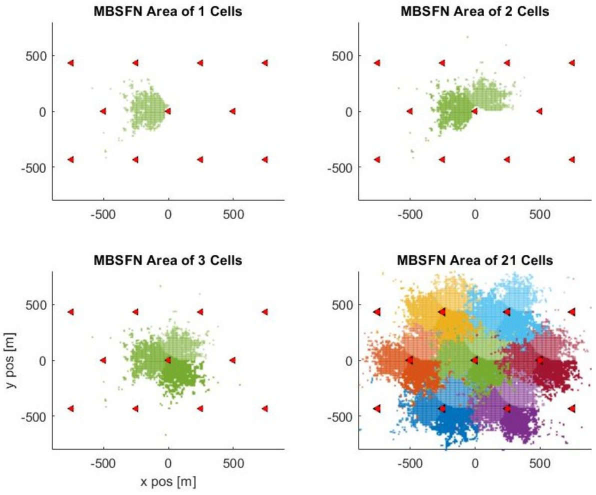


Fig. 4. MBSFN Deployment Scenarios

B. Resource Efficiency and Throughput

In this section we investigate resource efficiency for unicast and MBSFN as well as throughput experienced by first responders. For resource efficiency, the metric studied is information bits/symbol as in Table 7.2.3-1 in [13]. For unicast, in case there is more than one layer from spatial multiplexing, there are two codewords. Information bits/symbol is then the sum of bits/symbol from both codewords.

Scenario 1, 2, 3, 4, and 6 in Table I are simulated for this study, and 10 UEs are dropped uniformly within cell 1. Urban ISD1299 VehA channel is employed, proportional fairness is applied for scheduler, and 50 runs are performed. The resulting cumulative distribution function (CDF) of UE information bits/symbol is shown in Figure 5, where each UE contributes one sample. UE bits/symbol is calculated as the average bits/symbol over total resource units. Specifically, for unicast, it is averaged over all RBs and 300 TTIs. For MBSFN, it is averaged over all TTIs as a single TB is used per TTI (Section II).

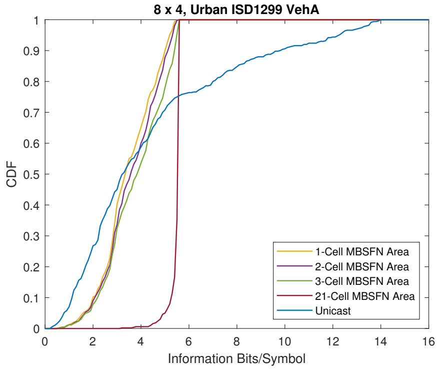

Fig. 5. Unicast vs MBSFN - Information Bits/Symbol

As expected, Figure 5 shows that larger MBSFN size leads to higher bits/symbol. This is because a larger MBSFN area implies more cells participating in MBSFN transmissions, hence the higher diversity combining gain, the less destructive interference, and the higher bits/symbol (Section III).

In addition, Figure 5 also shows that unicast has larger spread. The higher bits/symbol values come from multi-layer-transmissions due to spatial multiplexing in TM9 while the lower values are due to the lack of diversity combining gain.

Nevertheless, the possible higher bits/symbol of unicast does not necessarily imply higher throughput. The CDF of UE throughput from the same simulations is plotted in Figure 6.

Figure 6 shows that although unicast may have higher resource efficiency for individual UEs, MBSFN always has higher throughput. This holds even when the MBSFN area size is one cell. The reason is that in MBSFN each transmission serves all UEs and utilizes all RBs, whereas in unicast each transmission serves one UE and could use only a fraction of all RBs (10 UEs share the total RBs in each run). The more UEs being served, the less RBs each UE gets, and the less resulting throughput. Note that as mentioned in Section II, only 60 % of subframes are used in MBSFN. That is, MBSFN achieves higher throughput with only 60 % of the resources.

Figure 6 also shows that a larger MBSFN area leads to higher throughput. As with the previous analysis, this is because a larger MBSFN area leads to higher diversity combining gain and less destructive interference, and hence higher throughput.

Similar simulations were run for additional channels, and Table II lists the differences in median throughput between MBSFN and unicast, with unicast median throughput as the

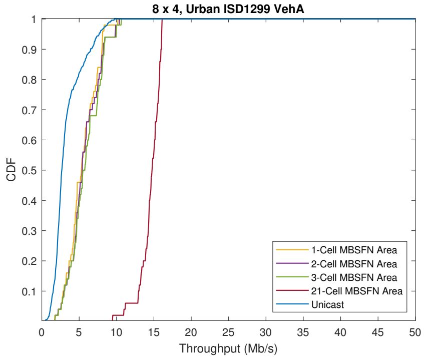

Fig. 6. Unicast vs MBSFN - Throughput

reference point. It can be seen that the trend of higher throughput with larger MBSFN size holds for all channels, and the median throughput delta between unicast and MBSFN can exceed 3 Mb/s.

TABLE II
THROUGHPUT DELTA BETWEEN UNICAST AND MBSFN (MB/S)

MBSFN area size	1 cell	2 cells	3 cells	21 cells
Rural ISD1299 VehB	0.5	0.6	0.6	3.1
Rural ISD1732 VehB	0.6	0.8	1.0	2.8
Urban ISD500 PedB	0.5	0.8	0.9	2.0
Urban ISD500 VehA	0.6	0.8	1.0	2.1
Urban ISD1299 VehA	0.1	0.3	0.6	2.3
Urban ISD1299 VehB	0.1	0.4	0.7	2.3

C. *Sources of MBSFN Gain*

As mentioned in Section II, the performance enhancement of MBSFN mainly comes from two sources: the diversity combining gain from multiple signal sources (cells), and the reduction of inter-cell interference. In this subsection we quantify the contribution of these two sources to MBSFN TB SINR incurred by a random UE (Equation 10). Note that the TB SINR for a UE directly reflects the physical channel experienced by the UE and is used for MCS selection. Hence it reflects the upper bound of the achievable throughput for the UE, and impacts its actual throughput as well.

For this purpose, the test scenario 5 is designed. In its SINR calculations and except for cell 1, power from other MBSFN cells is not included into neither the signal portion nor the interference portion. Hence, compared with scenario 2, inter-cell interference is removed. And compared with scenario 6, there is no diversity combining gain.

All these three scenarios - scenario 2, 5, and 6 - are simulated for 1000 TTIs, and UEs are dropped to cover the entire cell 1 (refer to Figure 4). Figure 7 plots the sorted MBSFN TB SINR in scenario 2, together with MBSFN gains from interference reduction, diversity combining, and the sum of both, respectively. Since the data is sorted by TB SINR, low UE index range maps to cell edge, and high UE index range maps to cell center. It can be seen that from cell edge to cell center, while the diversity combining gain decreases, the gain from interference reduction increases significantly. This is because the power from other MBSFN cells decreases when going from cell edge to cell center. Whereas at cell edge the two gains are comparable, around 5 dB, at cell center the gain from interference reduction dominates and the overall gain could be as high as around 20 dB. Unfortunately, this big SINR improvement at cell center would not lead to significant performance improvement due to the cap of the highest MCS (refer to Table I in [10]) and lack of MIMO technologies (Section II). Note that from the CQI switching points in the table, the maximum CQI 15 can be achieved when SINR is 20.5 dB or above, which can be achieved at cell center without the SINR improvement (the TB SINR in scenario 2). Figure 8 shows MBSFN TB SINR with UE locations, which further verifies the above analysis.

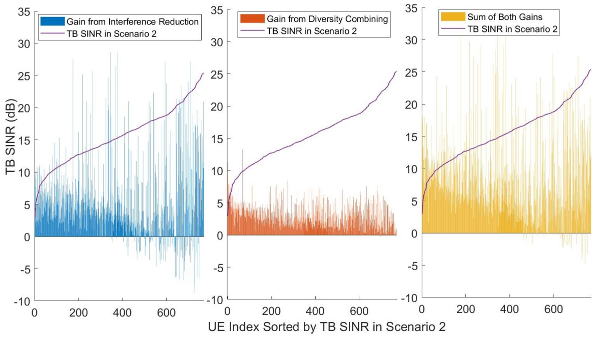

Fig. 7. Sources of MBSFN Gain

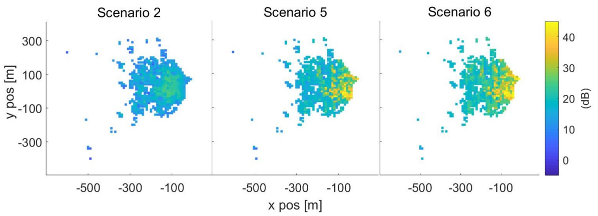

Fig. 8. TB SINR with UE Position

D. *Outage Probability*

In this subsection we quantify improvements in outage probability generated by using MBSFN. Consider a UE dropped randomly at a cell at a random time and being allocated a random resource chunk. In unicast, the resource chunk considered is five RBs, while in MBSFN it is one subframe. The outage probability considered in this paper is defined as the probability that the information bits/symbol of this UE is below a threshold.

To capture this outage probability, for each scenario listed in Table I except scenario 5, UEs are dropped to cover the entire cell 1, and simulations are run for 2000 TTIs. The resulting outage probability as a function of the threshold is plotted in Figure 9. The figure shows a significant decrease in outage probability when using MBSFN for all MBSFN sizes studied. As with the previous analysis, this is because of diversity combining and interference reduction in MBSFN. The larger the MBSFN area size, the smaller the outage probability is. For example, when the threshold is 1 bit/symbol, the outage probability for unicast is around 4.5 %, while for MBSFN it is less than 0.2 % for MBSFN area sizes of 1 to 3 cells, and 0 % for 21 cells. Note that the significant decrease in outage probability holds even for an MBSFN area size of one cell.

Table III shows the achievable information bits/symbol when the outage probability is 2 % and 5 %, respectively. With the same planned outage probability, the table also shows a significant increase in achievable bits/symbol from unicast to MBSFN. Due to quantization, the bits/symbol is the same with MBSFN area size of 1, 2, and 3 cells. While with area size of 21 cells, the achievable bits/symbol is significantly higher.

TABLE III
INFORMATION BIT/SYMBOL WITH OUTAGE PROBABILITY

Scenario	1	2	3	4	6
2 %	0.83	1.91	1.91	1.91	3.32
5 %	1.17	1.47	1.47	1.47	4.52

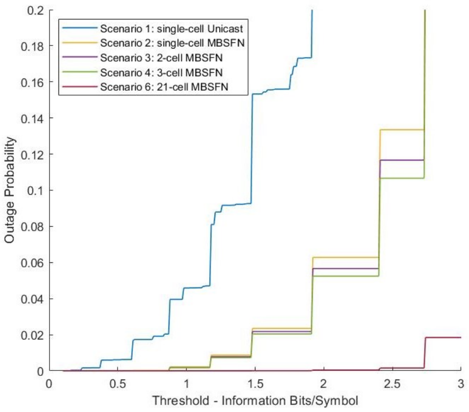

Fig. 9. Outage Probability with Threshold

V. CONCLUSION

To meet first responders' communication requirements, in this paper LTE MBSFN and unicast were investigated from the perspectives of throughput, information bits/symbol, sources of MBSFN gain, and outage probability. First, we derived an accurate MBSFN SINR analytical model. Then, through comprehensive MBSFN and unicast simulations, we showed that although the physical channels in unicast may be more efficient with higher information bits/symbol, MBSFN would provide higher throughput since the resources are not shared among UEs as in unicast. We also validated that a larger MBSFN area size would increase the MBSFN throughput due to higher MBSFN diversity combining gain and less interference. We further demonstrated that SINR improvement due to MBSFN diversity combining gains and interference reduction are comparable at cell edge, while the high MBSFN SINR improvement at cell center does not lead to significant performance improvement due to MCS cap and lack of MIMO support for MBSFN. Finally, compared with unicast, MBSFN improves outage probability significantly, which is essential for public safety incidents. All the above results hold not only for large MBSFN area sizes as in commercial networks, but also for small MBSFN area sizes, which cover cases where the incident area is small.

Since resource sharing is one major factor that limits unicast performance, our next step is to investigate the impact of number of first responders on MBSFN performance improvement over unicast. In addition to throughput, we will introduce other performance metrics as well, such as flight time, and further investigate the trade-offs between unicast and MBSFN.

Abstract

We report on a study of interconnects fabricated on organic and silicon interposers used to connect state-of-the art digital, analog and RF chiplets commissioned by the U.S. Defense Advanced Research Projects Agency (DARPA). The interconnects were characterized with state-of-the-art on-wafer measurement methods developed at the National Institute of Standards and Technology (NIST) and then simulated with the Cadence® Sigrity^{TM} simulation software package. The two-port, four-port and eight-port measurements and calibrations were performed to frequencies as high as 110 GHz using custom on-wafer calibrations to improve accuracy. We discuss the measurement and simulation methodologies and present detailed comparisons of the measurement and simulation results.

Biographies

Dylan F. Williams received a Ph.D. in Electrical Engineering from the University of California, Berkeley in 1986. He joined the Electromagnetic Fields Division of the National Institute of Standards and Technology in 1989 where he develops electrical waveform and microwave metrology. He has published over 80 technical papers and is a Fellow of the IEEE. He is the recipient of the Department of Commerce Bronze and Silver Medals, the Astin Measurement Science Award, two Electrical Engineering Laboratory's Outstanding Paper Awards, three Automatic RF Techniques Group (ARFTG) Best Paper Awards, the ARFTG Automated Measurements Technology Award, the IEEE Morris E. Leeds Award, the 2011 European Microwave Prize and the 2013 IEEE Joseph F. Keithley Award. Dylan also served as Editor of the IEEE Transactions on Microwave Theory and Techniques from 2006 to 2010 and as the Executive Editor of the IEEE Transactions on Terahertz Science and Technology.

Richard A. Chamberlin graduated from the University of California (Santa Barbara, CA) with a B.S. in physics in 1984, and obtained his Ph.D. in physics from the Massachusetts Institute of Technology (Cambridge, MA) in 1991. In 1995 he was the first winter-over scientist with the pioneering Antarctic Submillimeter Telescope and Remote Observatory which he helped design, build, and test while at Boston University. From 1996 to 2010 he was the Technical Manager of the Caltech Submillimeter Observatory located on the summit of Mauna Kea on the Island of Hawaii. Currently he is working in the High Speed Electronics Group at the National Institute of Standards and Technology in Boulder, Colorado.

Jerome Cheron received the Ph.D. degree in electrical engineering from the University of Limoges, France, in 2011. His research project was led at XLIM laboratory and Thales Air Systems, France. In 2012, he was Postdoctoral Fellow with the Fraunhofer IAF, Freiburg, Germany. In 2013, he joined NIST in Boulder, Colorado. His research interests include the design and optimization of microwave and millimeter-wave circuits in III-V technology.

Brent DeVetter received his Ph.D. in Electrical Engineering with a focus on plasmonic materials from the University of Illinois at Urbana-Champaign in 2016. He was a postdoctoral researcher at NIST working in the High-Speed Electronics Group performing high frequency measurements and electromagnetic simulations. He also completed a postdoctoral appointment at the Pacific Northwest National Laboratory focusing on infrared and terahertz spectroscopy of crystalline materials.

Sam Chitwood has focused on signal and power integrity analysis for 17 years. He has been a product engineer at Cadence Design Systems and an application engineer with Sigrity. He contributed to the DARPA CHIPS project through October 2019 while at Cadence. He has BSEE and MSECE degrees from Georgia Institute of Technology.

Ken Willis is a Product Engineering Group Director focusing on system-level analysis solutions at Cadence Design Systems. He has over 30 years of experience in the modeling, analysis, design, and fabrication of high-speed digital circuits. Prior to Cadence, Ken held engineering, technical marketing, and management positions with the Tyco Printed Circuit Group, Compaq Computers, Sirocco Systems, Sycamore Networks, and Sigrity.

Brad Butler is a Senior Application Engineer at Cadence Design Systems, focused on enabling advanced electronic systems design in the Aerospace and Defense sector. Prior to joining Cadence, he worked on vehicle dynamics, autonomous driving, and LIDAR applications at a small automotive startup. Brad earned B.S. degrees in Mechanical Engineering and Economics from North Carolina State University.

Farhang Yazdani is the President and CEO of BroadPak Corporation. Through his 20 years with the industry, he has served in various technical, management, and advisory positions with leading semiconductor companies worldwide. He is the author of the book "Foundations of Heterogeneous Integration: An Industry-Based, 2.5D/3D Pathfinding and Co-Design Approach". He is the recipient of 2013 NIPSIA award in recognition of his contribution to the advancement and innovations in packaging technologies. He has numerous publications and IPs in the area of 2.5D/3D Packaging and Assembly, serves on various technical committees and is a frequent reviewer for IEEE Journal of Advanced Packaging. He received his undergraduate and graduate degrees in Chemical Engineering and Mechanical Engineering from the University of Washington, Seattle.

I. Introduction

Large, monolithic ICs are being replaced by arrays of chiplets mounted on advanced interposers (passive integrated circuits supporting complex interconnects between the die mounted on them) in wide ranging applications of our industry. A few high-profile examples are Intel's "Foveros" and EMIB interposers [1, 2] and AMD's latest Ryzen processors [3, 4]. Chiplet-to-chiplet interconnects with micron and sub-micron widths pose new design, analysis and implementation challenges for digital and analog designers.

DARPA has supported work in heterogenous integration at RF frequencies though the Diverse Accessible Heterogeneous Integration (DAHI) Program [5-9] and this has helped lead a larger push for heterogenous integration at higher frequencies [10]. The National Institute of Standards and Technologies (NIST) performed work under this program characterizing heterogenous interconnects between several different technologies [11].

More recently DARPA has expanded this thrust to digital and analog integrated circuits with the Common Heterogeneous Integration and IP Reuse Strategies (CHIPS) Program [12, 13] under which this work was performed. In this paper, we report on a study of interconnects fabricated on build-up and silicon interposers used to connect state-of-the art digital, analog and RF chiplets supported by this program.

The study performed under the DARPA CHIPS Program focused on two interconnect types, an organic interposer supporting an Ajinomoto GX-92 build-up film (ABF) interconnect [14] covered with Hitachi SR7300 solder resist [15] and an inorganic silicon interposer with through-substrate vias (TSVs) supporting a silicon-dioxide (SiO_2) thin-film interconnect. The organic interposer provides an inexpensive but high-performance solution for integrating chiplets while the inorganic silicon interposer represents the state-of-the-art in interposer technologies. The interposers, and the calibration kits and test structures required to accurately characterize them, were designed and fabricated under the program for the purpose of obtaining the most accurate technology characterization possible to frequencies up to 110 GHz.

The goal of this paper is to study the accuracy of the Cadence® Sigrity^{TM} simulation software package, which includes an efficient hybrid solver for efficient S-parameter extraction of large interconnect structures and a slower but more accurate full-wave solver for more complicated 3-D structures. We first performed the simulations of the test structures on the interposer with the Sigrity hybrid solver using dimensional and other measurements performed by the manufacturer. Then, we compared the measurement and hybrid-solver simulation results and assessed the ability of the hybrid solver to predict interconnect performance in the two technologies we studied. Finally, in cases where we observed significant disagreement, we re-ran the simulations using the Sigrity full-wave solver. This allowed us to better assess when the faster hybrid solver was sufficient and when the slower but more accurate full-wave solver was needed.

II. Measurements

Most on-wafer measurements are calibrated with an “impedance-standard substrate” fabricated by the probe manufacturer. These are usually referred to as “probe-tip” calibrations. Probe-tip calibrations are performed under the assumption that the interaction between the probe tips and the contact pads on the wafer can be safely ignored. This is generally the case at lower microwave frequencies. However, the electrical parasitics associated with the interaction between the probe tips, contact pads, and even the device under test, increase roughly linearly with frequency [16-18]. For example, the admittance associated with the capacitance of the contact pads used to connect to a device will typically increase linearly with the frequency, causing measurement errors to increase with frequency as well [16-18]. There are more subtle errors introduced into probe-tip calibrations as well. For example, the inductance associated with a short bar printed on an impedance-standard substrate increases with the probe pitch, making it difficult to define the impedance of the short fabricated on the impedance-standard substrate. As the errors introduced into the calibrations are smooth and roughly linear, these errors are often not immediately apparent, but can nevertheless grow quite large at higher frequencies. For these reasons, the most accurate microwave calibrations are performed in transmission lines.

II.1. The Thru-Reflect-Line Calibration

The goal of a probe-tip calibration is to place the calibration and measurement reference planes at the tips of the probes, again with the assumption that the electrical parasitics associated with the interaction of the probe tips, contact pads and device under test can be ignored. The goal of an on-wafer thru-reflect-line (TRL) calibration, on the other hand, is to place the calibration and measurement reference planes in a transmission line fabricated on an integrated circuit or interconnect. In this environment, voltages, currents, scattering parameters and other electrical quantities can be rigorously defined (and measured) even at microwave frequencies [19-23], something that cannot be said of probe-tip calibrations. Furthermore, the result of cascading devices at these reference planes can be predicted with rigor from measurements performed at these reference planes [19]. Finally, the calibration and measurement reference plane can be moved to very close to the device under test, eliminating many parasitics in the measurement of the device. This generally proves more effective than conventional parasitic-extraction techniques used in transistor modeling, for example, as parasitics are first minimized before being estimated [24, 25].

An on-wafer microstrip TRL calibration kit fabricated in the interconnect stack of a silicon die is illustrated in Fig. 1 below. The TRL calibration kit includes a short “thru” line between the port 1 and port 2 contact pads, a number of longer lines, and a symmetric reflect (usually a short section of transmission line on each port terminated with an electrical open or an electrical short). These calibration standards are enough to perform a calibration in the transmission lines with a reference plane at the center of the thru line [19, 23].

Figure 2 illustrates the standards, their definitions (*i.e.* their properties), and their functions in the TRL calibration. The thru sets most of the calibration coefficients. The symmetric reflect allows the calibration to set the reference plane in the center of the thru. The lines set the reference impedance of the calibration to the characteristic impedance Z_0 of the transmission line and provide a measurement of the propagation constant γ of the transmission line.

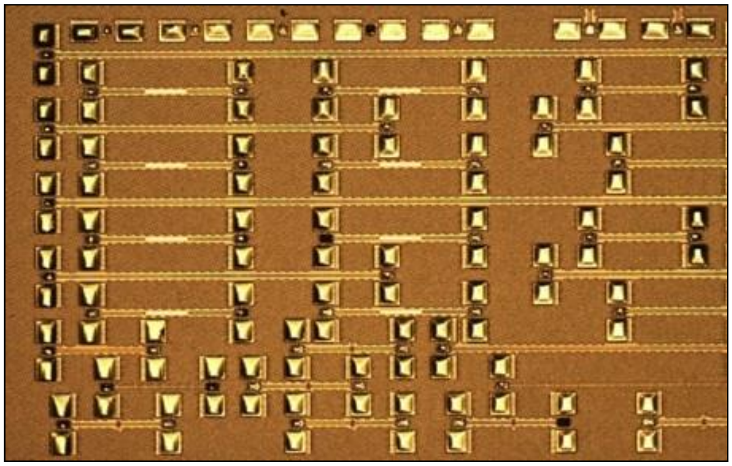

Figure 1. TRL calibration kit fabricated on a silicon die.

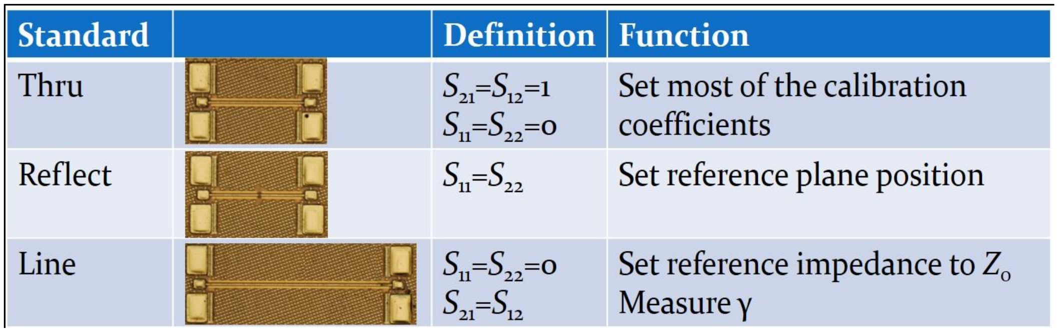

Standard		Definition	Function
Thru		$S_{21}=S_{12}=1$ $S_{11}=S_{22}=0$	Set most of the calibration coefficients
Reflect		$S_{11}=S_{22}$	Set reference plane position
Line		$S_{11}=S_{22}=0$ $S_{21}=S_{12}$	Set reference impedance to Z_0 Measure γ

Table 1. TRL calibration standards.

II.2. SiO₂ Transmission-Line Characteristic Impedance

Calibrations with a reference impedance equal to the characteristic impedance of a transmission line are not usually very useful, as the characteristic impedance is generally complex and frequency dependent [23]. Thus, the next step of the TRL calibration is to determine the characteristic impedance of the calibration.

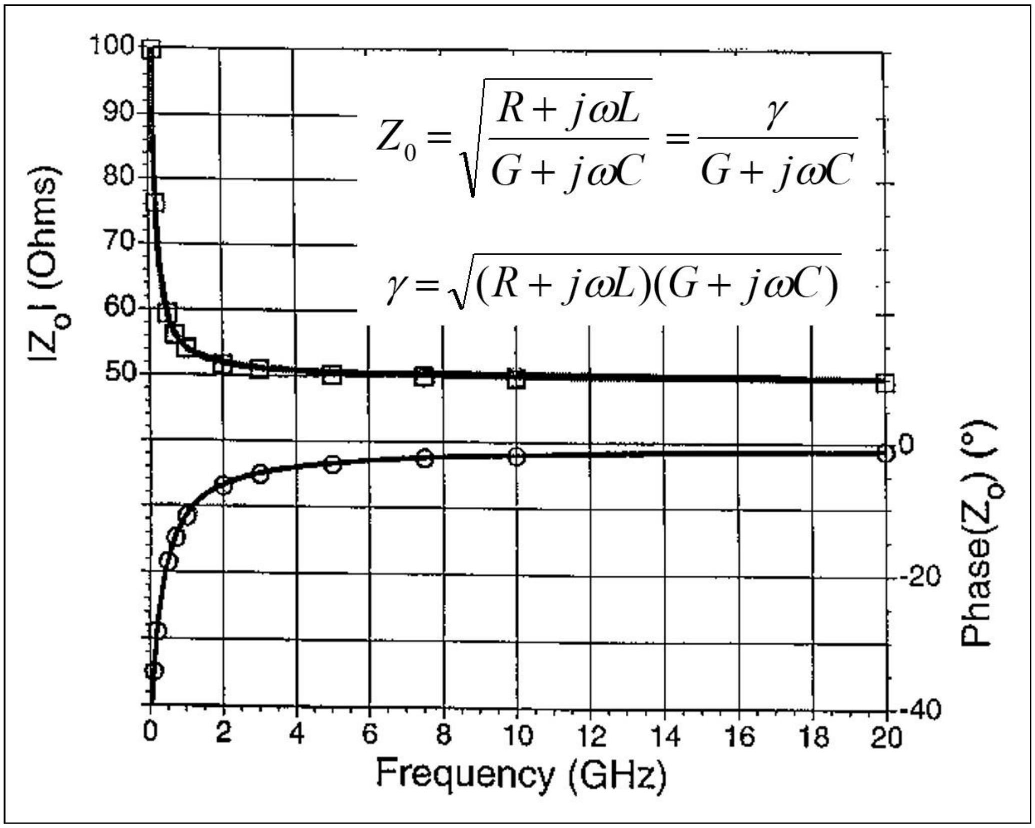

Figure 2. Measurement of the characteristic impedance Z_0 of a coplanar waveguide transmission line compared to calculation. The measurements are shown in solid lines. The calculated magnitude of Z_0 is shown in squares and the calculated phase of Z_0 is shown in circles. The formulas in the upper right were used to calculate Z_0. From [27].

We had two interconnect types to consider, the organic interconnect fabricated on a woven fiberglass core and the inorganic SiO_2 interconnect fabricated on a bulk silicon interposer. The SiO_2 has a roughly frequency-independent dielectric constant and a small loss tangent while the electrical behavior of the organic ABF is complicated by low-frequency dielectric relaxation. With this in mind, we start with the more straightforward analysis of the characteristic impedance of the microstip and stripline transmission lines fabricated in the SiO_2 interconnects.

Finding the characteristic impedance is quite straight forward in quasi-TEM transmission lines constructed from low-loss dielectrics, as the per-unit-length capacitance of the transmission line is very nearly frequency independent and the per-unit-length conductance of the transmission line is small. In this case, the capacitance of the transmission line can be determined from the measurement of a small resistor or the measurement of the per-unit-length DC resistance of the line and knowledge of the propagation constant γ estimated by the TRL calibration algorithm [26]. For these quasi-TEM lines fabricated on well-behaved dielectrics, the per-unit-length capacitance of the lines can even be easily determined by field solvers [26].

Once the per-unit-length capacitance C of the quasi-TEM transmission line has been determined, the characteristic impedance of the transmission line can be determined from the formulas in the upper-right of Fig. 2 [27]. In essence, the per-unit-length capacitance *C* and conductance *G* and the propagation constant γ of the transmission line are enough to determine the per-unit-length resistance *R* and inductance *L* of the transmission line. Once *R* and *L* have been determined, everything is known about the line, and the characteristic impedance Z_0 of the transmission line can be calculated directly with the upper formula in Fig. 2.

Figure 2 compares measurements (solid lines) of the magnitude and phase of the characteristic impedance Z_0 of a coplanar waveguide line to simulations (squares and circles) calculated with the full-wave method of [28], which includes field penetration into the metal in a rigorous way. As can be seen from the figure, the agreement is excellent. We used this approach to determine the dielectric constant of the microstrip and stripline transmission lines we used in our TRL calibrations on the SiO_2 interconnects fabricated on the bulk silicon. We determined the per-unit-length capacitance of the transmission lines from measurements of a small resistors fabricated in the interconnects, as described in [26].

II.3. ABF Transmission-Line Characteristic Impedance

The approach to determining the capacitance and conductance of transmission lines fabricated on low-loss inorganic dielectrics described in the last section cannot account for low-frequency transmission-line behavior due to dielectric relaxation. Therefore, the approach described in the last section is not applicable to the microstrip and stripline transmission lines we fabricated on the organic ABF interconnects. Instead, we first estimated the frequency-dependent dielectric constant and loss tangent of the ABF and then estimated the capacitance and conductance of the ABF transmission lines from their dimensions. Finally, we used capacitive parallel-plate test structures to check our result.

We estimated the frequency-dependent dielectric constant and loss tangent of the ABF from measurements of the ABF film performed at 1 GHz by the manufacturer and the low frequency and high frequency limits of the dielectric constant. We then applied the Djordjevic-Sarkar algorithm to extract a dielectric-relaxation model [29]. This model was independently suggested by Svensson in [30]. Figures 3 and 4 on the next page compare the extracted model to the measurements provided by the manufacturer.

We then estimated the capacitance and conductance of the ABF transmission lines from the model for the dielectric constant we determined and from the dimensions of the transmission lines provided by the manufacturer. This was enough to estimate the characteristic impedance Z_0 of the ABF transmission lines using the formulas in Fig. 2.

Williams, Dylan; Chamberlin, Richard; Cheron, Jerome; Chitwood, Sam; Willis, Ken; Butler, Brad; Yazdani, Farhang. "DARPA Organic Interconnect Characterization." Paper presented at DesignCon 2020, Santa Clara, CA, US. January 28, 2020 - January 30, 2020.

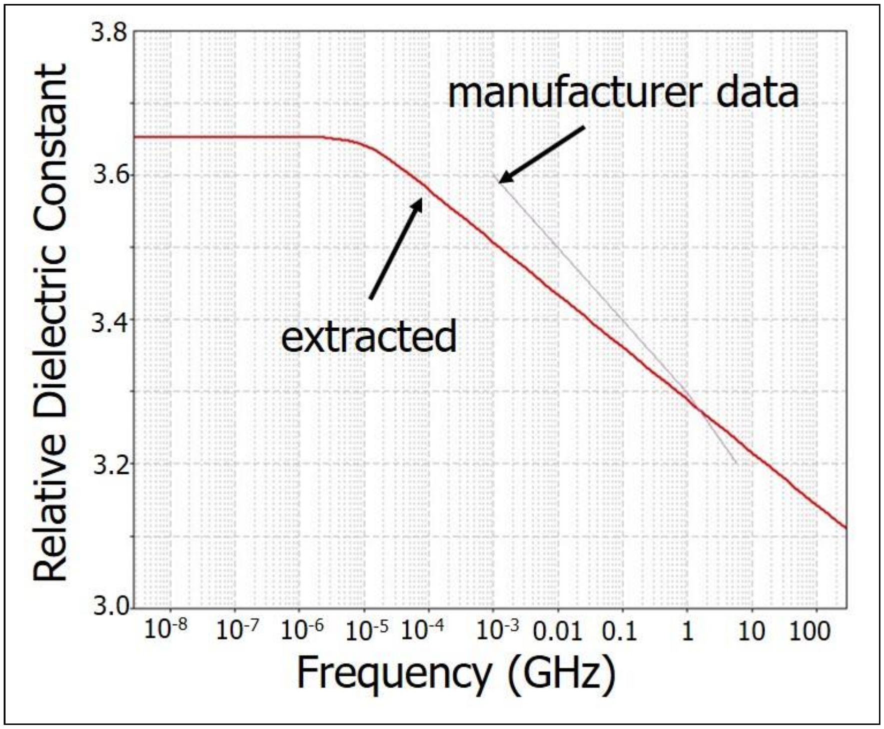

Figure 3. Comparison of the extracted relative dielectric constant and the measurements provided by the ABF manufacturer.

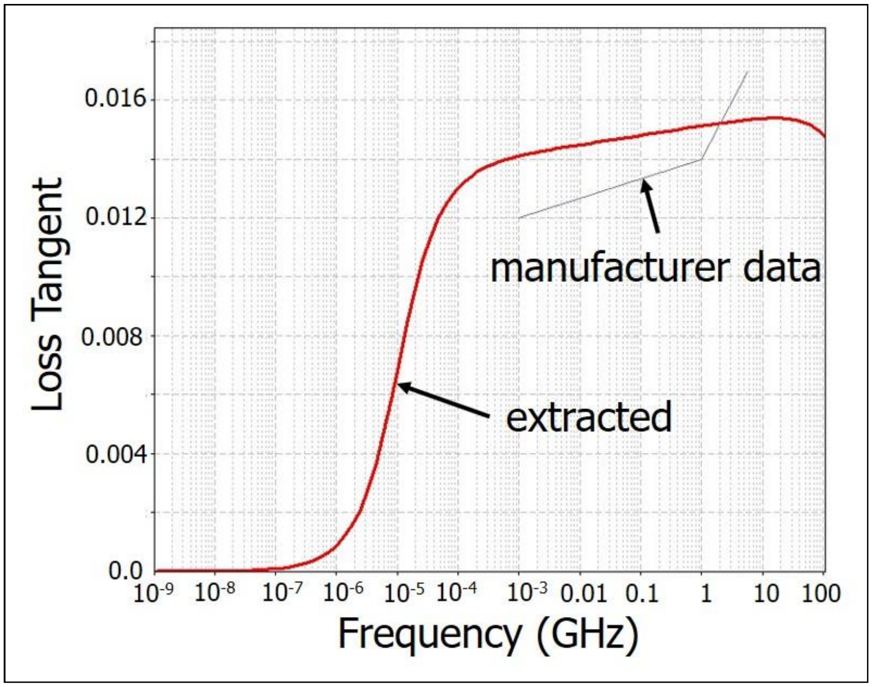

Figure 4. Comparison of the extracted loss tangent and the measurements provided by the ABF manufacturer.

Finally, we verified the dielectric constants and loss tangent we extracted for the organic ABF with large parallel-plate capacitors similar to those routinely created in the power distribution network of the interconnect. The positive plate of each capacitor was sandwiched between an upper and lower ground plate in the interconnect stackup. The two ground plates were stitched together periodically with vias that passed through small holes in the positive plate of the capacitor. We also used via stacks to connect the capacitor's positive plate and the two ground plates to contact pads on the top surface of the interconnect stackup with vias.

To test the capacitors, we first performed a TRL calibration on a fused silica wafer and moved the reference plane of the calibration back to the probe tips. A comparison of the measured and simulated magnitudes of the impedance of the capacitor at the measurement reference plane on the top surface of the ABF interconnect is shown in Fig. 5. While the calibration and extraction approach were both somewhat approximate, they clearly proved adequate for this purpose.

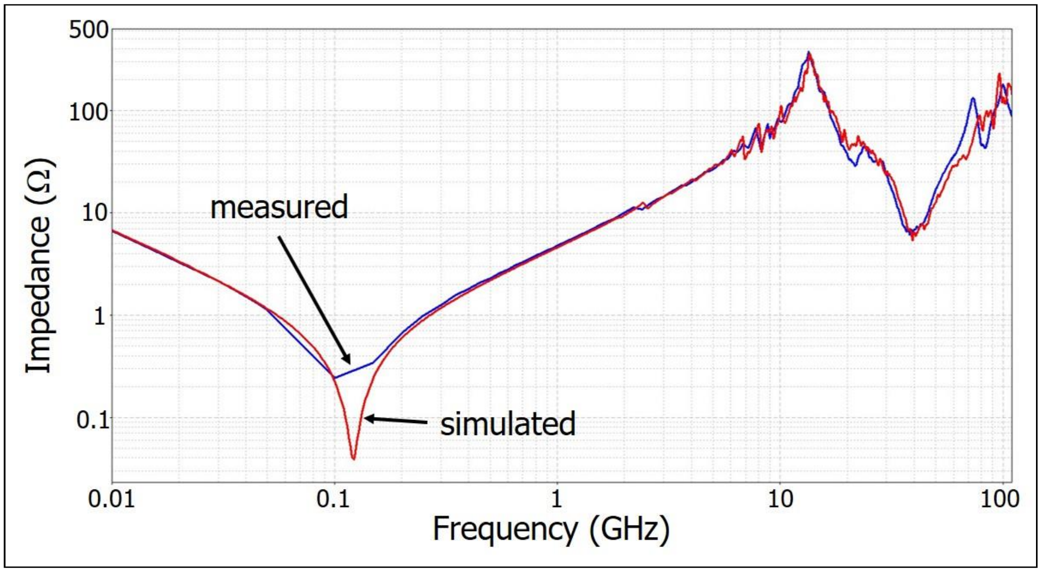

Figure 5. The measured and simulated impedances of one of the parallel-plate capacitors we used to verify extraction procedure we used, as implemented in the Cadence Sigrity software package.

III. Correlation Between Measurements and Simulations

We performed hundreds of TRL measurements and Sigrity hybrid-solver and full-wave solver simulations of test structures fabricated on the organic and silicon interposers and carefully examined the correlation between measurement and simulation. In most cases we were able to perform five or more independent calibrations and measurements of each test structure on different die, which allowed us to gauge the degree of correlation we obtained with the TRL measurements and Sigrity simulations. Here we present a few of these results on the organic ABF interposer performed with the Sigrity hybrid solver to illustrate the high degree of correlation we found between the two.

III.1. Coupled Lines on Organic ABF Interposer

Figure 6 below shows the layout of the organic ABF interposer. The design included microstrip and stripline TRL calibration kits shown in the upper and right-most sections of the layout, as well as a number of 2-port, four-port and eight-port test structures on other parts of the designs. Only the microstrip test structures fabricated in the top-metal levels are visible, but many more stripline test structures are buried in the interconnect stack and were also available for test.

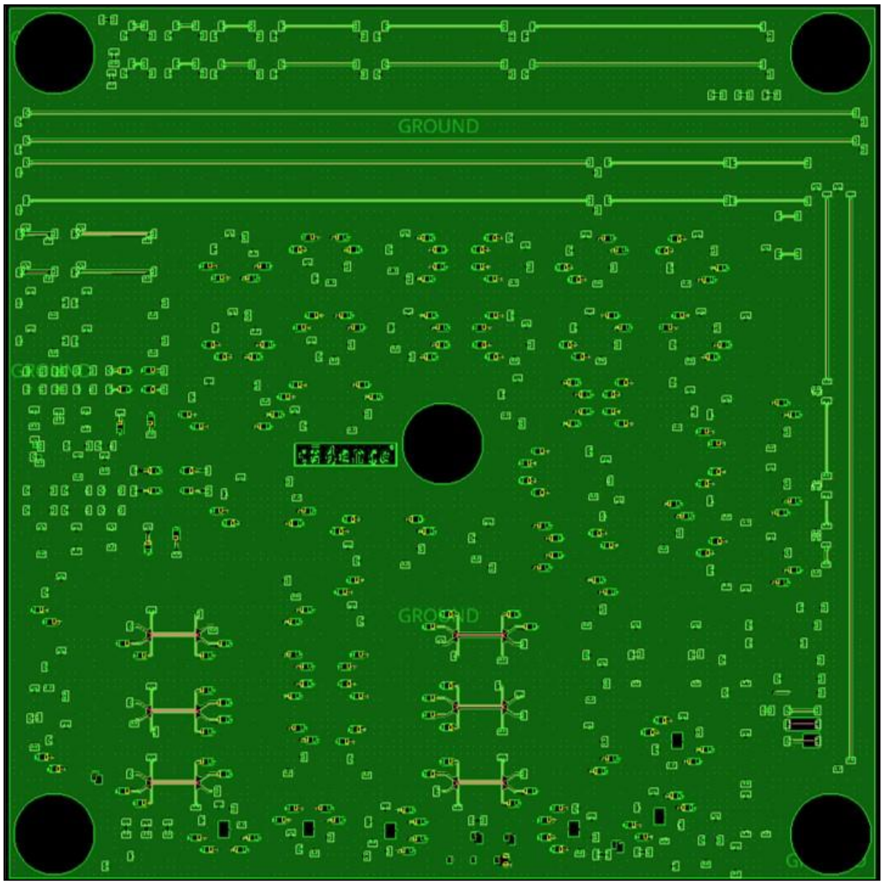

Figure 6. Top layer of the organic ABF Interposer layout.

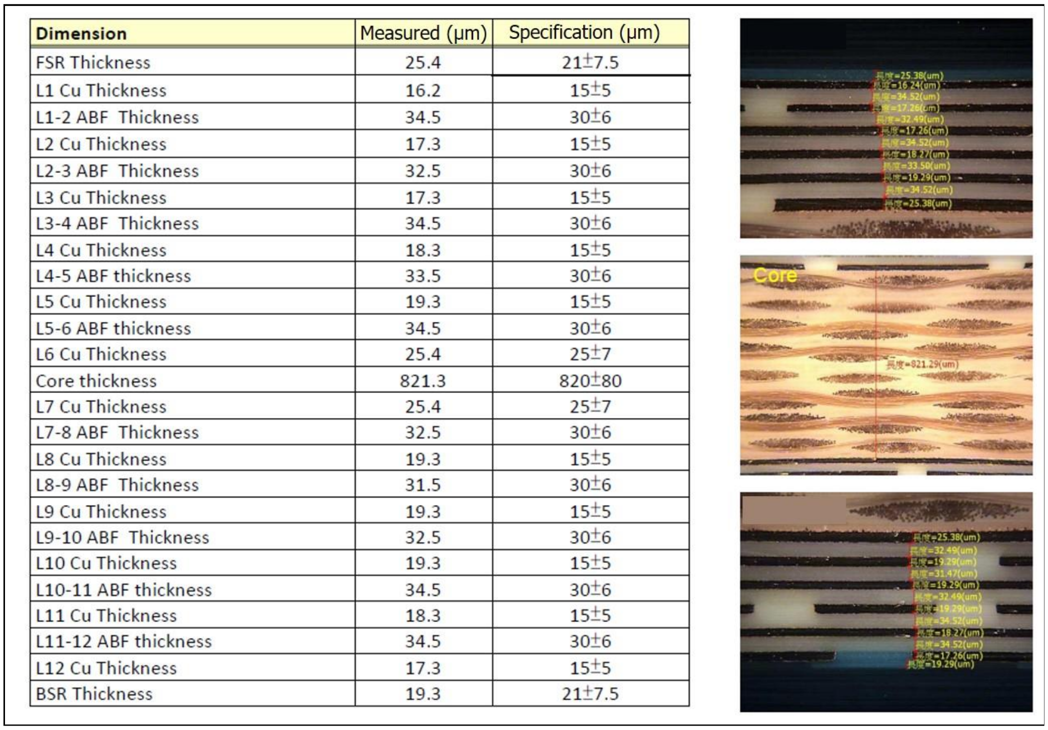
Williams, Dylan; Chamberlin, Richard; Cheron, Jerome; Chitwood, Sam; Willis, Ken; Butler, Brad; Yazdani, Farhang. "DARPA Organic Interconnect Characterization." Paper presented at DesignCon 2020, Santa Clara, CA, US. January 28, 2020 - January 30, 2020.

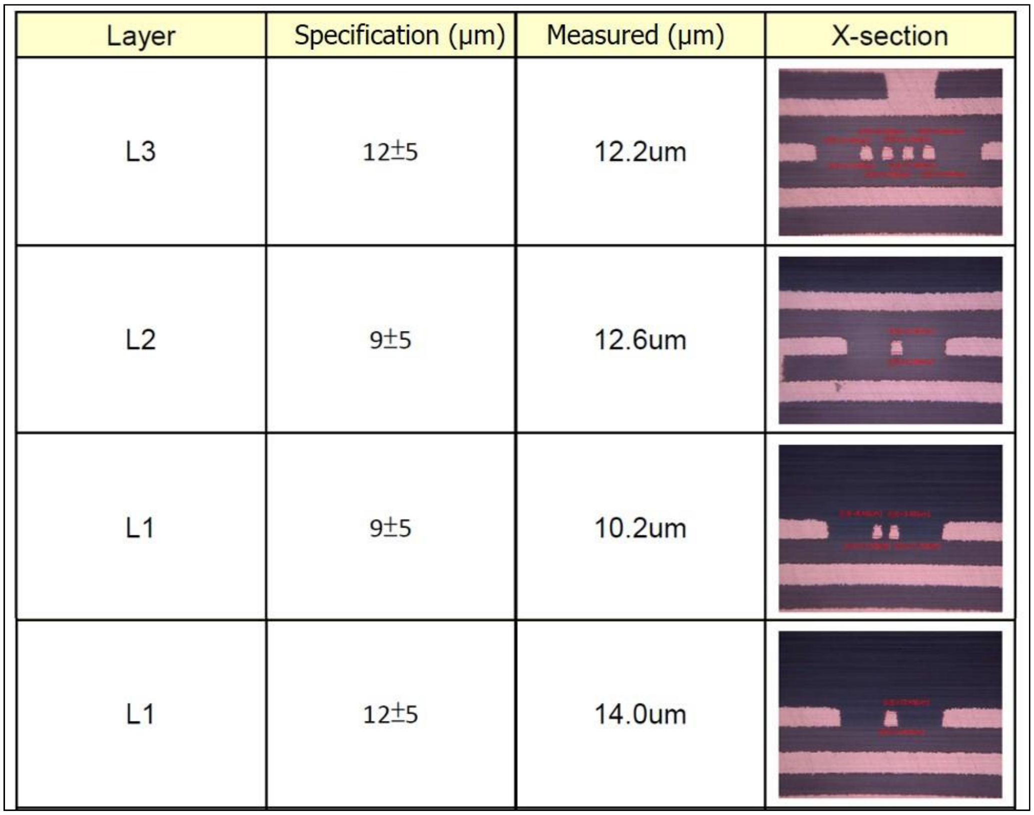
Table 2 shows the twelve-metal ABF interposer stackup. The first column in the table lists the layer names and materials, the second column lists the layer thicknesses measured by the manufacturer and the last column lists the manufacturer's specifications. The photos in the right of the figure are of actual cross sections of the interposers we designed and tested.



Dimension	Measured (μm)	Specification (μm)
FSR Thickness	25.4	21±7.5
L1 Cu Thickness	16.2	15±5
L1-2 ABF Thickness	34.5	30±6
L2 Cu Thickness	17.3	15±5
L2-3 ABF Thickness	32.5	30±6
L3 Cu Thickness	17.3	15±5
L3-4 ABF Thickness	34.5	30±6
L4 Cu Thickness	18.3	15±5
L4-5 ABF thickness	33.5	30±6
L5 Cu Thickness	19.3	15±5
L5-6 ABF thickness	34.5	30±6
L6 Cu Thickness	25.4	25±7
Core thickness	821.3	820±80
L7 Cu Thickness	25.4	25±7
L7-8 ABF Thickness	32.5	30±6
L8 Cu Thickness	19.3	15±5
L8-9 ABF Thickness	31.5	30±6
L9 Cu Thickness	19.3	15±5
L9-10 ABF Thickness	32.5	30±6
L10 Cu Thickness	19.3	15±5
L10-11 ABF thickness	34.5	30±6
L11 Cu Thickness	18.3	15±5
L11-12 ABF thickness	34.5	30±6
L12 Cu Thickness	17.3	15±5
BSR Thickness	19.3	21±7.5

Table 2. ABF interposer stackup with measured layer thicknesses, specifications and cross sections. FSR = front-side solder resist, L*n* = metal layer *n*, L*n*-*m* = ABF layer thickness between L*n* and L*m*, BSR = back-side solder.

Table 2 shows some additional cross sections and width measurements performed by the manufacturer. As can be seen in the tables in Tables 2 and 3, the tolerances on the dimensional specifications were quite large and many of the measured transverse dimensions differed significantly from the nominal specifications. Because of the large variations in manufactured line width and no way to measure physical line widths for specific signals under test, this parameter was used as a "tuning parameter" in simulations. That is, with all other material and geometry parameters held constant, the line width was varied across the tolerance to observe the best match against the measured results. We optimized all of the simulated results we will present below in this way.



Layer	Specification (µm)	Measured (µm)	X-section
L3	12±5	12.2um	
L2	9±5	12.6um	
L1	9±5	10.2um	
L1	12±5	14.0um	

Table 3. Trace widths for selected structures fabricated on the ABF interposers. Spec = designed width for selected structure. X-section data = measured width for selected structure.

Correlations between the 2-port, 4-port and 8-port test structures we designed and tested, and simulations performed with the Sigrity hybrid solver (the faster of the two Sigrity solvers), were generally excellent. We present data here only for a single four-port and a single eight-port device.

III.2. Four-Port Coupled Lines on Organic ABF Interposer

Figure 7 shows the 4-port layout we used to assess measurement and simulations of coupled microstrip and striplines. We used the NIST Microwave Uncertainty Framework [31] to perform the four-port calibrations. This software package allows a lateral “east-west” two-port TRL calibration and a vertical “north-south” two-port TRL calibration to be combined with the use of an additional unknown bend to form a rigorous four-port calibration. We also took advantage of the Uncertainty Framework to move the calibration and measurement reference planes through the microstrip lines and vias, placing them in the striplines where the coupled structures buried in the ABF interconnect stack began and ended. We did not take advantage of the ability of this software package to evaluate measurement uncertainty in this work.

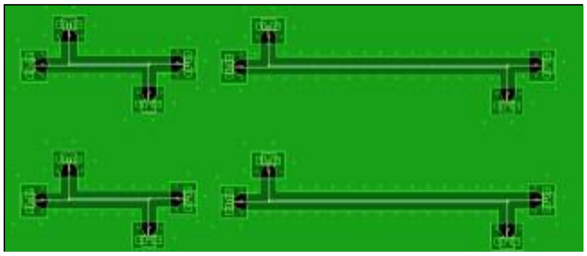


Figure 7. 4-port coupled-line layout.

The following figures illustrate the high-degree of correlation we observed between measurements and simulations performed on two coupled 9 µm wide 1 mm long coupled striplines spaced 9 µm apart apart and buried in the third level of metal in the ABF interconnect stack. Simulations are shown in thick solid lines and measurements performed on other die are shown in thinner lines.

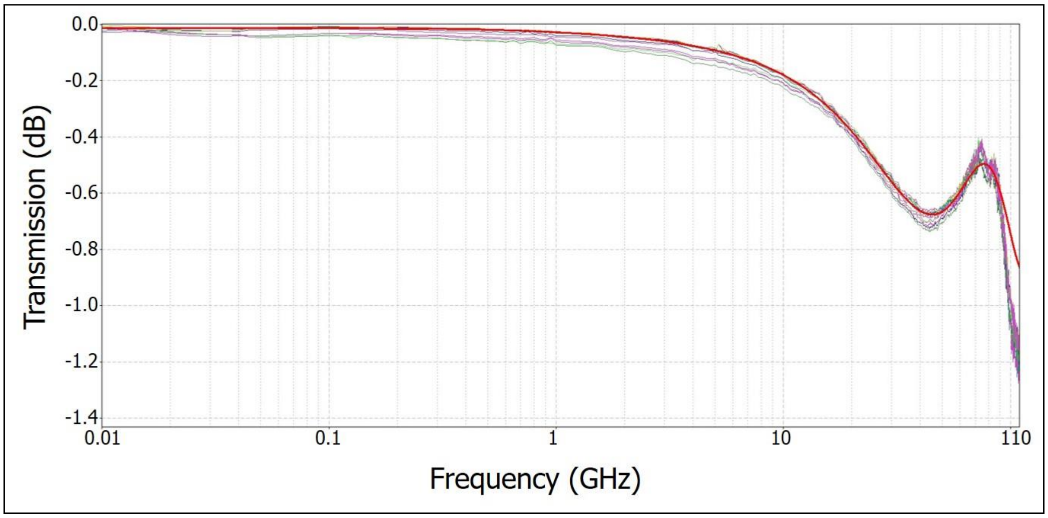

Figure 8. Transmission coefficient through a single 9 µm wide and 1 mm long stripline coupled to an adjacent line 9 µm apart and buried in the third level of metal in the ABF interconnect stack. Simulations are shown in thick solid lines and measurements performed on other die are shown in thinner lines. The hybrid solver was used for the simulations and only the line width was adjusted in the simulation.

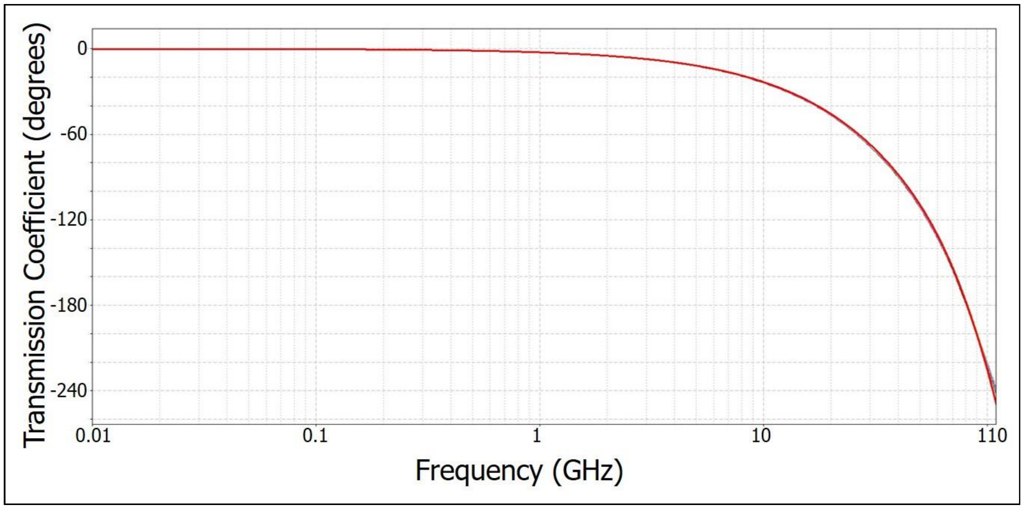

Figure 9. Phase of the transmission coefficient through a single 9 µm wide and 1 mm long stripline coupled to an adjacent line 9 µm apart and buried in the third level of metal in the ABF interconnect stack. Simulations are shown in thick solid lines and measurements performed on other die are shown in thinner lines. The hybrid solver was used for the simulations and only the line width was adjusted in the simulation. (Deviations of measurements are too small to be seen.)

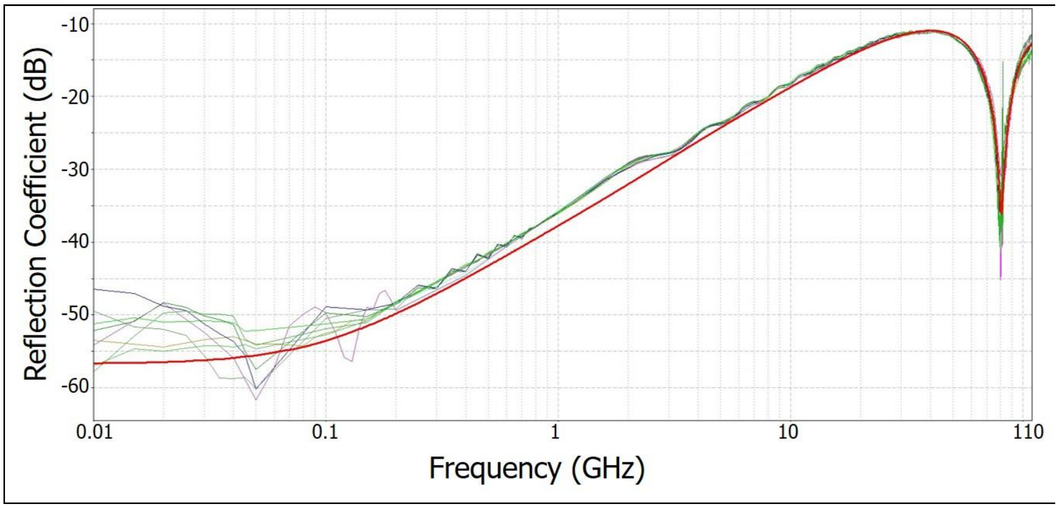

Figure 10. Reflection coefficient of a single 9 µm wide and 1 mm long stripline coupled to an adjacent line 9 µm apart and buried in the third level of metal in the ABF interconnect stack. Simulations are shown in thick solid lines and measurements performed on other die are shown in thinner lines. The hybrid solver was used for the simulations and only the line width was adjusted in the simulation.

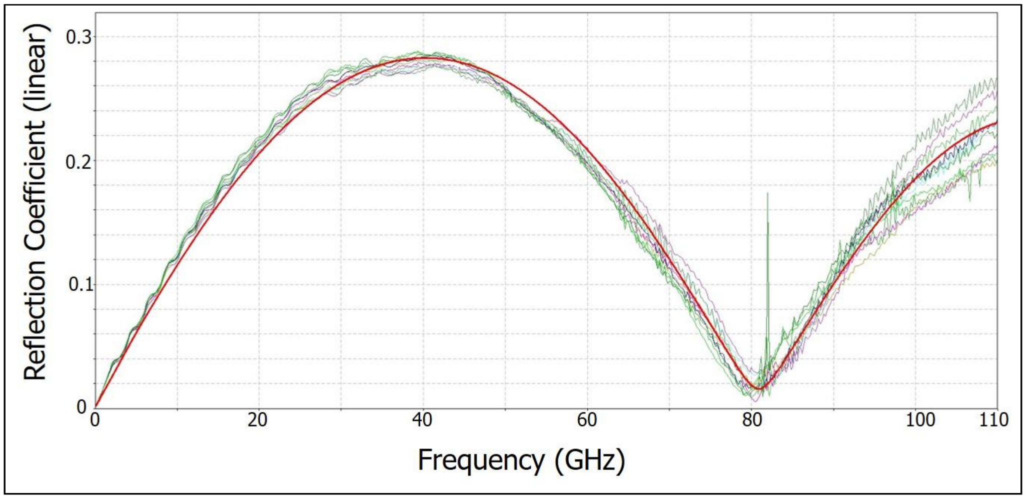

Figure 11. Reflection coefficient of a single 9 µm wide and 1 mm long stripline coupled to an adjacent line 9 µm apart and buried in the third level of metal in the ABF interconnect stack. Simulations are shown in thick solid lines and measurements performed on other die are shown in thinner lines. We do not believe that there is any significance to the isolated spike in the measurements at 82 GHz. The hybrid solver was used for the simulations and only the line width was adjusted in the simulation.

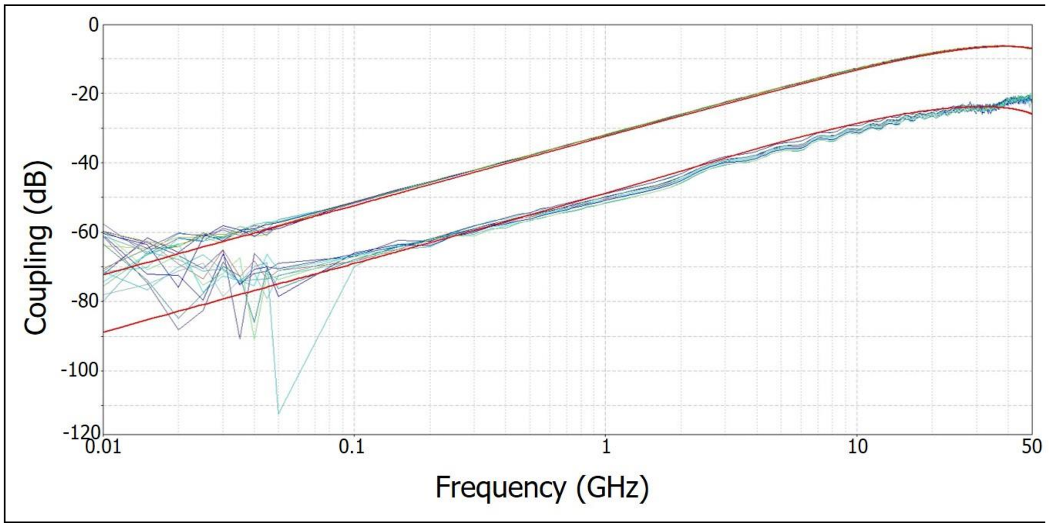

Figure 12. Near-end and far-end coupling between two 9 µm wide and 1 mm long striplines spaced 9 µm apart and buried in the third level of metal in the ABF interconnect stack. Simulations are shown in thick solid lines and measurements performed on other die are shown in thinner lines. The hybrid solver was used for the simulations and only the line width was adjusted in the simulation. The hybrid solver was used for the simulations and only the line width was adjusted in the simulation.

III.3. Eight-Port Coupled Lines on Organic ABF Interposer

Figure 13 shows layouts for two 8-port coupled lines of different lengths. As we did not have access to an 8-port vector network analyzer, we fabricated six versions of each 8-port test structure and connected four of the ports to probe contact pads and terminated the remaining four ports with 50 Ω chip resistors soldered to contact pads on the top of the ABF interposer. These six versions of the 8-port test structures were designed so as to allow us to measure each of the elements of the 8 by 8 scattering-parameter matrix of the coupled lines.

Then we used our four-port analyzer calibrated to a reference plane where the eight-port coupled lines begin and end to measure the various scattering parameters of each of the six test structures. Finally, after compensating for the measured impedances of the chip resistors, we extracted the eight-port scattering parameters of the coupled lines using the Microwave Uncertainty Framework with an algorithm similar to those of [32, 33], except based on a regression fit rather than multiport impedance transformations.

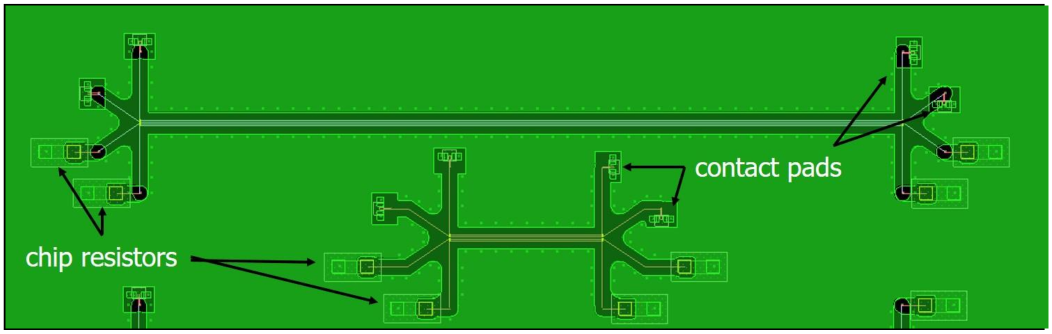

Figure 13. 8-port coupled-line layout.

The manufacturer of the ABF interposer reported much larger variations (as high as ±5 μm) in the line-width measurements performed on the 8-port coupled lines than found on the single-ended and 4-port test structures on the ABF interposer. As a result, we did not expect the level of agreement between the 8-port measurements and simulations as for the other test structures we tested.

In addition, the calibration approach we used was based on the assumption that all of the chip resistors terminating the 8-port coupled lines had an impedance equal to those we measured in a set of chip resistors we characterized separately with a two-port TRL calibration. However, we observed some significant differences between the measurements we performed of the impedances of these chip resistors, possibly due to differences in how each resistor was soldered to the ABF interposer. These measured differences led us to believe that there were also differences in the chip resistors connected to the unmeasured ports of our six 8-port test structures, possibly leading to some additional degradation of the accuracy of the 8-port scattering parameters of the coupled lines we extracted from the measurements.

Williams, Dylan; Chamberlin, Richard; Cheron, Jerome; Chitwood, Sam; Willis, Ken; Butler, Brad; Yazdani, Farhang. "DARPA Organic Interconnect Characterization." Paper presented at DesignCon 2020, Santa Clara, CA, US. January 28, 2020 - January 30, 2020.

Despite the variation in the measured 8-port linewidths and the impedance of the chip resistors on the ABF interposer, we found that our eight-port measurements and simulations agreed quite well. For example, Figs. 14 and 15 compare measurements and simulations of first-neighbor and second-neighbor coupling levels in four 10 mm long 12 µm wide coupled striplines fabricated in the third level of metal in the ABF interconnect stack and separated from each other by 12 µm. The agreement is quite good for first-neighbor coupling and still quite reasonable for the smaller second-neighbor coupling.

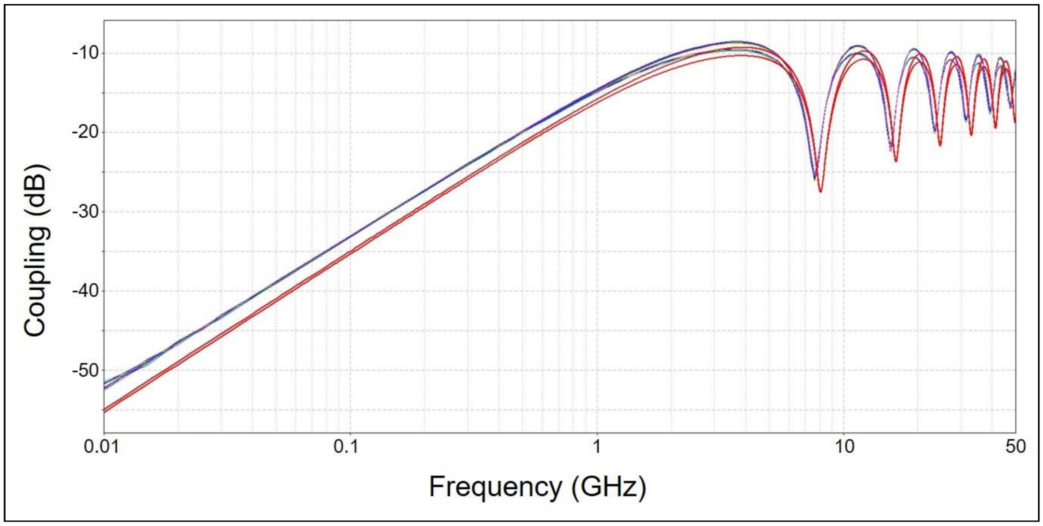

Figure 14. Coupling between first-neighbor 12 µm wide and 10 mm long striplines spaced 12 µm apart and buried in the third level of metal in the ABF interconnect stack. Measurements are shown in thinner lines.

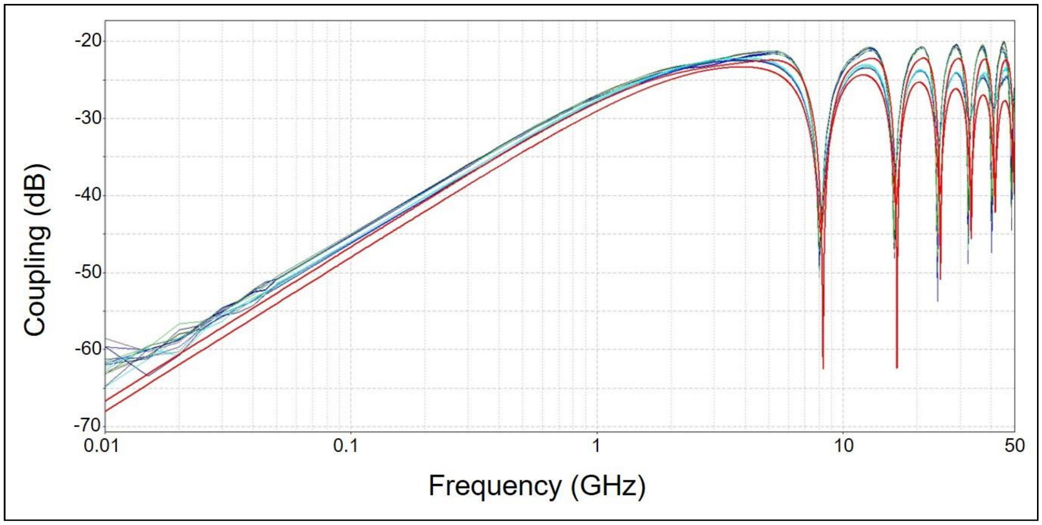

Figure 15. Coupling between second-neighbor 12 µm wide and 10 mm long striplines spaced 12 µm apart and buried in the third level of metal in the ABF interconnect stack. Measurements are shown in the thinner lines.

IV. Conclusion

The measurements and simulations we performed of test structures fabricated in the ABF interconnect stack correlated extremely well, as illustrated by the coupled stripline measurements presented in the last section. We will present more measurements in the conference, including measurements performed on test structures fabricated on the silicon interposer. We will also examine some of the cases we explored on the silicon interposer in which the agreement between the measurements and simulations were not as good as those we observed on the ABF interposer presented here. In general, we found that the slower but more accurate Sigrity full-wave solver was able to provide results that agree closely with the measurements in these cases.

Extending NIST's CAVP Testing of Cryptographic Hash Function Implementations

Nicky Mouha and Christopher Celi

National Institute of Standards and Technology, Gaithersburg, MD, USA
`nicky@mouha.be, christopher.celi@nist.gov`

Abstract. This paper describes a vulnerability in Apple's CoreCrypto library, which affects 11 out of the 12 implemented hash functions: every implemented hash function except MD2 (Message Digest 2), as well as several higher-level operations such as the Hash-based Message Authentication Code (HMAC) and the Ed25519 signature scheme. The vulnerability is present in each of Apple's CoreCrypto libraries that are currently validated under FIPS 140-2 (Federal Information Processing Standard). For inputs of about 2^{32} bytes (4 GiB) or more, the implementations do not produce the correct output, but instead enter into an infinite loop. The vulnerability shows a limitation in the Cryptographic Algorithm Validation Program (CAVP) of the National Institute of Standards and Technology (NIST), which currently does not perform tests on hash functions for inputs larger than 65 535 bits. To overcome this limitation of NIST's CAVP, we introduce a new test type called the Large Data Test (LDT). The LDT detects vulnerabilities similar to that in CoreCrypto in implementations submitted for validation under FIPS 140-2.

Keywords: CVE-2019-8741, FIPS, CAVP, ACVP, Apple, CoreCrypto, hash function, vulnerability.

1 Introduction

The security of cryptography in practice relies not only on the resistance of the algorithms against cryptanalytical attacks, but also on the correctness and robustness of their implementations. Software implementations are vulnerable to software faults, also known as bugs.

A (cryptographic) hash function turns a message of a variable length into an output of a fixed length, often called a message digest, or digest. This fixed-length output can then serve as a "fingerprint" for the message, in the sense that it should be computationally infeasible to construct two messages that result in the same digest. Hash functions are crucial to the security of many higher-level cryptographic algorithms and protocols.

In the context of digital signature schemes, hash functions are used to ensure that only the given message and the corresponding signature (along with the public key) passes the signature verification process. Digital signatures provide authentication in a similar manner to signatures in the real world. For example, a web browser can verify a package that is downloaded comes from a specific

Mouha, Nicky; Celi, Christopher. "Extending NIST's CAVP Testing of Cryptographic Hash Function Implementations." Paper presented at CT-RSA 2020: Cryptographers' Track at the RSA Conference, San Francisco, CA, US. February 24, 2020 - February 28, 2020.

website by verifying the signature that was provided with the download using the known, trusted public key of the website. As a part of this verification process, the browser hashes the downloaded data so that the fixed-length digest can stand in place of the large variable-length data in the digital signature scheme.

A recent study by Mouha et al. [12] of the National Institute of Standards and Technology (NIST) SHA-3 (Secure Hash Algorithm) competition found that about half of the implementations submitted to the SHA-3 competition contained bugs, including two out of the five finalists. It appears that cryptographic algorithms can be difficult to implement, given that even the designers of the algorithm can have trouble to develop a correct implementation. Furthermore, even for a secure and well-designed cryptographic algorithm, bugs can be particularly severe with respect to the cryptographic properties of the algorithm's implementation.

For example, in the case of all submitted implementations of the BLAKE [4] algorithm to the SHA-3 competition, given one message and its corresponding hash function output, it is easy to construct another message that produces the same hash value. This "second preimage attack" is not due to a weakness in the BLAKE algorithm specification, but due to an implementation bug that remained undiscovered for seven years.

In [12], Mouha et al. did not find any bugs in the submission packages of Keccak [6], the hash function algorithm that won the SHA-3 competition and that is now standardized in Federal Information Processing Standard (FIPS) 202 [17]. In this paper, we explore whether implementations of hash functions that are standardized by NIST and currently used in commercial products may also contain bugs. Furthermore, we investigate how these bugs can impact more complex cryptographic operations such as digital signature schemes.

2 Testing within NIST's CAVP

NIST maintains the Cryptographic Algorithm Validation Program (CAVP), which provides validation testing for the NIST-recommended cryptographic algorithms. The CAVP is a prerequisite for validating cryptographic implementations according to FIPS 140-2 under the Cryptographic Module Validation Program (CMVP). Since the Federal Information Security Management Act (FISMA) of 2002, U.S. Federal Agencies no longer have a statutory provision to waive FIPS 140-2. This means that commercial vendors must validate their cryptographic implementations, also known as modules, according to CAVP/CMVP before they can be deployed by U.S. Federal Agencies.

The CAVP testing methodology is derived directly from the algorithm specification, independent of the actual code that a vendor's implementation uses. Therefore, it is realistic to expect three main limitations of the CAVP:

1. The CAVP does not require that the internals of an implementation are known in order to generate tests, and is therefore restricted to black-box testing. For many widely-used cryptographic libraries, however, the software

is either open source or available on the vendor's website, which may be used to reveal additional bugs through static analysis (including checking software coding standards), or white-box testing.

2. The CAVP tests only the capabilities of the implementation that are declared by the vendor. For example, a hash function implementation may declare that it can only process messages up to 65 535 bits, corresponding to the largest test vectors currently in the CAVP, even though it may encounter much larger inputs under typical use. When NIST introduces tests for larger inputs, it is therefore the vendor's responsibility to declare whether or not their implementation supports such inputs. However, it is in the vendor's interest to avoid bugs and therefore declare the capabilities of the implementations as broadly as possible.
3. The CAVP focuses mostly on the correct processing of valid inputs (positive testing), rather than the rejection of invalid inputs (negative testing). Because of the nature of black-box testing, the CAVP provides test vector data to the implementation. A developer of the module must program a test harness to submit this data to the interfaces of the cryptographic library itself and collect the output to send back to the CAVP. As the test harness is outside the bounds of the CAVP, it is difficult to know from a validation perspective whether invalid inputs are handled by the module, or by the test harness. There are a few notable exceptions to this, such as the CAVP tests for digital signature schemes that test whether the implementation can recognize valid versus invalid signatures.[1]

Furthermore, the focus of most cryptographic algorithm testing is on correctness towards common cases within the specification. This may leave cryptographic algorithms vulnerable to malicious inputs that manifest themselves very rarely under random testing. Notable examples exploit bugs in modular arithmetic [7], incorrect group order validation [21], or improper primality testing [1] to result in full or partial key recovery attacks on OpenSSL and other implementations. These examples show the importance to consider not just random but also "rare" and "unusual" inputs for cryptographic implementations, as they may lead to catastrophic security failures.

In spite of these limitations, the CAVP can be highly effective at detecting many types of bugs. This is because the CAVP test design is aware of the internals of "typical" implementations of cryptographic algorithms. The focus of the CAVP is not just conformance testing but also regression testing, as the CAVP test design is also aware of how changes to the implementations may lead to certain bugs. To see this, we now explain how the CAVP tests are generated.

The two test types in the CAVP are the Algorithm Functional Test (AFT), and the Monte Carlo Test (MCT). They were introduced in 1977 by the National Bureau of Standards (NBS), the former name of NIST, in the (now-withdrawn) Special Publication (SP) 500-20 [13] to test the Data Encryption

[1] For the signature verification operation, the CAVP also includes some invalid padding tests.

Standard (DES). In this standard, static AFTs known as Known Answer Tests (KATs) were provided in order to “fully exercise the non-linear substitution tables” (S-boxes), whereas MCTs contained “pseudorandom data to verify that the device has not been designed just to pass the [fixed] test set.” Additionally, the large amount of data of the MCT was intended to detect whether it can “cause the device to hang or otherwise malfunction,” for example due to a memory leak [8] in present-day implementations. The spirit and design of these tests was carried over to other algorithms such as the Advanced Encryption Standard (AES) in FIPS 197 [14] and hash functions.

This paper focuses on testing for hash functions within the CAVP at NIST. FIPS 180-4 [16] standardizes the hash functions SHA-1, SHA-224, SHA-256, SHA-384, SHA-512, SHA-512/224, and SHA-512/256. As these hash functions closely resemble each other, they are considered functionally equivalent for the purpose of this document. Testing for SHA-3 was added after the publication of FIPS 202 [16], and with the exception of the SHAKE extendable-output functions (XOFs), mimics the testing done for the FIPS 180-4 hash functions. As with the other CAVP tests, the Secure Hash Algorithm Validation System (SHAVS) [5] specifies both AFTs and MCTs.

Testing by the CAVP was done for many years using the Cryptographic Algorithm Validation System (CAVS) tool. An implementation under test (IUT) is accompanied with a declaration to the CAVS tool of which digest sizes it supports along with a couple of other properties such as whether or not it can hash an empty message, whether or not it can hash incomplete bytes (i.e. a 7-bit message), and the maximum message size. The maximum message size allowed by the tool is 65 535 bits.

As of 2019, the CAVP is undergoing a transition to use the Automated Cryptographic Validation Protocol (ACVP) to enable the generation and validation of standardized algorithm test vectors. This involves a shift of generating and validating tests at remote, approved laboratories, to performing these actions on NIST-hosted servers. The concept of first-party testing is introduced to allow vendors to test and validate their implementations without laboratories as intermediaries. This combined with hosting a demo server (a sandbox environment for algorithm testing), allows vendors to incorporate continuous testing of crypto implementations in their development process. The ACVP thereby significantly speeds up testing and validation.

The ACVP uses a JSON (JavaScript Object Notation) format to specify the test cases. The client to the NIST ACVP servers would then correspond to the test harness in the previous CAVS model, and is responsible for communicating with the server and exercising the proper interfaces on the module. In the JSON examples below, some of the original content has been trimmed for readability. For more information on the protocol itself, as well as the complete examples, we refer to the GitHub repository of the ACVP [11].

2.1 Algorithm Functional Test (AFT)

AFTs take a single message as input, and verify the correctness of the corresponding output. A JSON file is sent from the server to the client, which usually provides inputs to a cryptographic algorithm, and is very simple for an individual test case:

```
{
 "msg": "BCE7",
 "len": 16
}
```

where "msg" corresponds to the message represented as hexadecimal, and "len" corresponds to the length in bits of the message. The messages have fixed values that have been drawn uniformly at random from the space of messages of a certain bit length, ranging from the client's specified minimum to their specified maximum or 65 535, whichever comes first. The expected response to this test case is another simple JSON object:

```
{
 "md": "1FA29E9B23060562F9370453EF817E18C56AE844E5B85F2ED34B4B38"
}
```

where "md" corresponds to the message digest. The hash function in this example is SHA-224.

AFTs can vary in length from byte-oriented messages (i.e., "len" is a multiple of 8) or bit-oriented messages (with any bit lengths). This allows implementations to specify their properties to the CAVP to receive appropriate test cases.

These tests are intended to provide assurance that an implementation can handle messages of various sizes. However, the assurance that the AFTs currently offer may be limited, as they may not test more than one message of any specific bit length.

2.2 Monte Carlo Test (MCT)

MCTs, on the other hand, construct a chain of hash outputs by combining the previous three hash outputs into a single message, and use it to produce the next hash output. Each chain consists of 1000 iterations, and returns the hash output that is obtained at the end. This whole process is repeated 100 times with the original message replaced by the latest hash output.

The initial condition for an MCT is as follows:

```
{
 "msg": "B4FCB616B3A4A7C9E6AF1D836CF1576709A67F16141217B827E52611",
 "len": 224
}
```

where `"msg"` becomes the `seed` in the pseudocode of the MCT, which is given in Alg. 1. The `seed` is not fixed, but is drawn uniformly at random for every invocation of the test.

Algorithm 1 The Monte Carlo Test (MCT) for hash functions

```
Require: seed (random string of same length as hash output)
  for $i = 1$ to 100 do
      MD[0] = MD[1] = MD[2] = seed;
      for $j = 3$ to 1002 do
          Msg[$j$] = MD[$j - 3$] || MD[$j - 2$] || MD[$j - 1$];
          MD[$j$] = Hash(Msg[$j$]);
      end for
      seed = MD[1002];
      Output seed;
  end for
```

The response is an array of 100 hash outputs as follows:

```
{
"resultsArray": [
 {
  "md": "7B893BC7322AA6578A2EC565593B86776FB8376AC16B0A354E6DA016"
 },
 {
  "md": "4BCB655F36D976ADAAE620B485DA7FD8ED321E0BF060E0FE2B5F9AFE"
 },
 {
  "md": "57AA388954B3D52645BFAC69E87F48B3D57A86CF385F38A2549FE957"
 }
]
}
```

shortened to only three outputs for brevity, and again using the SHA-224 hash function in the example. The CAVP makes an implicit assumption here that the client's implementation can handle a message that is three times the size of the hash output.

These tests are intended to provide assurance that an implementation is correct for valid inputs over thousands of iterations. However, the assurance that the MCTs currently offer may be limited, as the bit lengths of the messages do not vary between test cases. Furthermore, as this bit length is three times the digest size, the MCTs only cover a negligibly small percentage of the total input space of the given bit length.

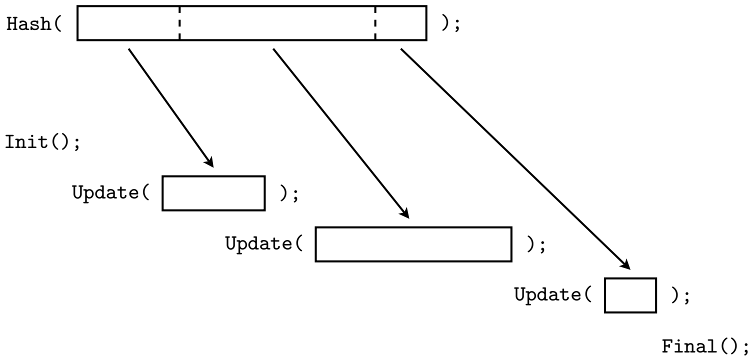

Fig. 1. Hash functions are commonly implemented using a `Hash` interface that takes a variable-length message, and returns a fixed-length output. It is common to also have an `Init-Update-Final` interface, which can be convenient to process large messages on the fly.

3 Common Hashing Interfaces

Although not mentioned in the NIST hash function standards [16, 17], many cryptographic implementations have at least two distinct functional interfaces for hash operations, as shown in Fig. 1. One of the two interfaces, or both interfaces, may be available to a consumer of the module or to higher-level algorithms within the module. The first is an `Init-Update-Final` interface. This structure allows implementations to constantly stream smaller chunks of data into `Update()` repeatedly, rather than keep the message as a single large chunk. Perhaps the entire message is not available at once, or perhaps there is a limit to the capacity of a single `Update()` call.

The other interface is a more intuitive `Hash()` call that expects the whole message up front. This is different from the previous interface and the same module could potentially behave differently under these two interfaces [12].

In practice, the `Init-Update-Final` interface can be convenient to hash the concatenation of various elements. For example, the American National Standards Institute (ANSI) X9.63 Key Derivation Function (KDF) [2] computes the hash of a secret value Z, a counter, and an optional `SharedInfo` string that is shared between two entities. This hash can be computed using one `Init()` call, followed by an `Update()` call to process Z, another `Update()` call for the counter, and then an optional third `Update()` call for `SharedInfo`. The `Final()` call can then be used to compute the hash function output.

To hash the contents of a file, there are two approaches that are commonly encountered in practice. One approach is to loop through the contents of the file (e.g., using `fread()` in C), and process each chunk using a call to `Update()`. Another common approach is to map the file to the virtual address space (e.g., using `mmap()` in C), and then compute the hash by calling `Hash()`. This second approach must be used when the interface requires the data to be located in memory. For example, the interface of the Ed25519 signature scheme in Apple's CoreCrypto requires a pointer for the data to be hashed, therefore if an application wants to compute (or verify) a digital signature on a file (e.g., containing a large software update), it must first use `mmap()` to map this file into memory.

4 Vulnerability in Apple's CoreCrypto Library

We show how adding test cases beyond the current coverage of the CAVP can reveal previously undiscovered bugs in cryptographic implementations.

First, we look the SHAVS document [5], which states that:

> *"While the specification for SHA specifies that messages up to at least $2^{64} - 1$ bits are possible, these tests only test messages up to a limited size of approximately 100,000 bits. This is adequate for detecting algorithmic and implementation errors."*

In contrast, the SHA-3 Competition Test Suite [15] also contains an "Extremely Long Message Test," which contains a message of 2^{33} bits (1 GiB), with the intention of checking whether messages of more than 2^{32} bits were processed correctly. This test from the SHA-3 competition is not adopted by the CAVP however. We now explain how adding a similar test for large messages reveals a bug in the widely-used Apple CoreCrypto library.

Apple makes the source code of its CoreCrypto library publicly available [3] to allow for "verification of its security characteristics and correct functioning."[2] The CoreCrypto library provides low-level cryptographic primitives that are fundamental to the security of Apple's products, and is currently deployed in iPhone, iPad, and Mac devices worldwide. The library has also undergone rigorous testing, and is currently present in 20 FIPS 140-2-validated modules.

In the latest CoreCrypto library, the bug is present in the `ccdigest_update.c` file, which is located in the `ccdigest/src` subdirectory. This code is shared by all implemented hash functions except for MD2. The full code of the function is given in App. A. All the implemented hash functions are iterated hash functions, which means that an underlying compression function processes the message in multiples of a block size that is specific to the algorithm. Part of the code to process message in multiples of the block size is as follows:

```
//low-end processors are slow on division
if (di->block_size == 1<<6 ){ //sha256
  nblocks = len >> 6;
  nbytes = len & 0xFFFFffC0;
} else if(di->block_size == 1<<7 ){ //sha512
```

[2] We refer to the latest CoreCrypto that is available online at the time of writing (November 25, 2019). It does not appear to have a version number, but can be identified by the year 2018 in the copyright notice.

```
  nblocks = len >> 7;
  nbytes = len & 0xFFFFff80;
} else {
  nblocks = len / di->block_size;
  nbytes = nblocks * di->block_size;
}
```

In this code, the variables `len`, `nblocks`, and `nbytes` are declared as `size_t`, which corresponds to a 64-bit unsigned integer on a 64-bit architecture. The `len` variable is the length of the message in bytes. In case `len` is less than 2^{32}, the value of `nblocks` is the number of complete blocks to be hashed: `len` divided by the block size (in bytes), whereas `nbytes` is the number of bytes of these complete blocks.

However, for block sizes of 64 or 128 bytes (i.e., when `di->block_size` is `1<<6` or `1<<7`), the calculation of `nbytes` contains a bug: the four highest bytes of `size_t` are incorrectly set to zero by the bitwise AND (`&`) operation. Consequently, when `len` is at least 2^{32} (corresponding to messages of at least 4 GiB), the value of `nbytes` does not contain the correct number of complete blocks. Therefore, later in the code, the statement `len -= nbytes` does not decrement `len` by the correct amount; instead `len` remains 2^{32} or larger. Given that all these statements are contained in a while-loop with condition `len > 0`, the program enters into an infinite loop.

A list of affected hash function implementations is given in Table 1.

Table 1. Hash function implementations in Apple's CoreCrypto library.

Algorithm	Block size (in bytes)	vulnerable
MD2	16	✗
MD4	64	✓
MD5	64	✓
RIPEMD-128	64	✓
RIPEMD-160	64	✓
RIPEMD-256	64	✓
RIPEMD-320	64	✓
SHA-1	64	✓
SHA-224	64	✓
SHA-256	64	✓
SHA-384	128	✓
SHA-512	128	✓

When this code was written, perhaps the assumption was made that `size_t` corresponds to a 32-bit value, in which case the code would have been correct. When `size_t` is 64 bits, however, the integer constant used to perform the AND operation is incorrect.

One way to avoid this type of bug, could be to follow software coding standards, such as the Computer Emergency Response Team (CERT) C Coding

Standard. This standard states in INT17-C: "Define integer constants in an implementation-independent manner" [19], and gives an example that is very similar to the bug in Apple's CoreCrypto library. Note that it is possible to avoid masks altogether, by using `nbytes = nblocks << 6` or `nbytes = nblocks << 7` for 64-byte and 128-byte blocks respectively.

4.1 Experimental Verification

We downloaded the latest CoreCrypto library from Apple's website [3], and compiled it using the Xcode IDE (Integrated Development Environment) on macOS 10.14 (Mojave) on a mid 2015 MacBook Pro, as well as using Clang 8 under Ubuntu 14.04 on an Intel Skylake processor. For Linux, the README.md file warns that the Linux Makefile is not up-to-date, therefore we needed to make some minor changes to the Makefile to allow compilation.

Because the bug is due to incorrect C code, we expect that the bug will manifest itself on any 64-bit platform for which the code is compiled. To confirm that the executable is stuck in an infinite loop, we added some source code instrumentation.

In our proof of concept code, we generated an input with a length of 2^{32} bytes. Because the actual value of the input is not relevant for the bug, we arbitrarily set all bits to zero in our experiments. When this input is provided to MD4, MD5, RIPEMD-128, RIPEMD-160, RIPEMD-256, RIPEMD-320, SHA-1, SHA-224, SHA-256, SHA-384, or SHA-512, we verified that the implementation enters into an infinite loop. We mentioned earlier that the MD2 implementation does not share the code of `ccdigest_update.c`, and we also confirmed that the same input does not cause an infinite loop for MD2. This provides experimental confirmation for the results of Table 1.

Then, we looked into higher-level cryptographic operations. We found that the implementation of the ANSI X9.63 KDF is not vulnerable when provided with a secret value Z of length 2^{32} bytes. This is due to a range check in the input length, which is documented by the following source code comment in CoreCrypto: "`ccdigest_update only supports 32bit length`."

However, such a range check is not applied to every hash function calculation, and most other cryptographic algorithms inside Apple's CoreCrypto library that use hash functions are vulnerable. We verified that HMAC enters into an infinite loop for all the vulnerable algorithms in Table 1 when provided with a message of 2^{32} bytes.

For the Ed25519 signature scheme, we found that a message of at least $2^{32} + 64$ bytes is needed to trigger the bug. To explain this, note that the Ed22519 algorithm always prepends some data to the message before computing the hash value using SHA-512. This is implemented in Apple's CoreCrypto using the `Init-Update-Final` interface. When there are 64 bytes already in the buffer, the first 64 bytes of the message are used to complete a 128-byte block, which we recall is the block size for the SHA-512 algorithm. After processing the first 64 bytes of the message, if there are at least 2^{32} bytes or more left, then the bug is triggered. For details, we refer to the full code of the `ccdigest_update()` function in App. A.

We verified that the Ed25519 implementation indeed enters into an infinite loop when a message of $2^{32} + 64$ bytes is digitally signed or verified. Note that in order to trigger the bug in the verification operation, it is not necessary to provide a valid signature. Therefore, even if the private key is stored properly and never used to sign long messages, the verification operation still enters into an infinite loop for an incorrectly-signed message of $2^{32} + 64$ bytes or more. Note that digitally signed messages typically come from untrusted sources, because the concern that a message can be modified by an adversary is typically the reason to apply a digital signature in the first place.

Another cryptographic operation in Apple's CoreCrypto that uses hash functions, is the Secure Remote Password (SRP) protocol. This protocol is run between a client and a server, which can create additional security concerns when communication is done over a network and the adversary controls either the client or the server, and may therefore send malicious inputs. In CoreCrypto's SRP implementation, the username is provided as a null-terminated string.

We verified that when this string contains 2^{32} repetitions of the `'a'` character followed by a null character, then the SRP implementation of both the client and the server enter into an infinite loop. Note that in contrast to the previous examples, the length in this case is not provided by the adversary as a separate parameter, but it is derived inside CoreCrypto using C's `strlen()` function. Therefore, range checking all input length values to CoreCrypto would not have been effective to avoid this attack using a long null-terminated string.

In Sect. 2, we recalled that an input that would "cause the device to hang" was already a concern when the MCT test was introduced for DES in 1977. But an infinite loop is also a security vulnerability, categorized under Common Weakness Enumeration (CWE) 835 [20], where it is also known as a "Loop with Unreachable Exit Condition." More specifically, an adversarially-crafted input that causes an implementation to enter an infinite loop, can lead to a "denial of service" (DoS) attack when it consumes excessive CPU resources.

5 Proposing the Large Data Test (LDT)

In the current CAVP tests, the length of the largest message is 65 535 bits. Such small testing sizes are not realistic towards normal usage. We propose a new Large Data Test (LDT) for the CAVP to provide a greater assurance for the implementations that undergo validation.

The LDT would be a type of AFT, and could be specified similarly to the example in Sect. 2.1. Implementations could specify the size of the largest message size that they can handle, for example on the order of 2 GiB to 8 GiB. The ACVP server can select one of many large supported arbitrary sizes to craft messages. However, a test for such messages may be impractical to communicate natively within the normal JSON structures. To work around this limitation, the LDT employs a simple function to generate the test input, as defined in Alg. 2.

Algorithm 2 The Large Data Test (LDT)

```
Require: Msg (a non-zero number of bytes), fullLength (in bits)
  FullMsg = "";
  for $i = 0$ to ceil( fullLength / bitlength(Msg) ) do
      FullMsg = FullMsg || Msg;
  end for
  FullMsg = truncate(FullMsg, fullLength);
  Output FullMsg;
```

Due to the truncation at the end, it is possible for the LDT to output messages of any number of bits, instead of only multiples of the size of the repeating Msg pattern. The Msg pattern itself needs to be an integer number of bytes, in order to greatly simplify implementations in C-like programming languages. This is, however, not an actual restriction to the messages that can be output. The reason is that any 7-bit repeating pattern (for example) can also be written as a 56-bit (= 7-byte) repeating pattern, where 56 is the least common multiple of 7 and 8 (the number of bits in one byte).

With a generator function defined to expand a short message of a few bytes, into a large message of any arbitrary size, we can define the JSON structure for the LDT as the following:

```
{
  "largeMsg": {
    "content": "D6F7",
    "contentLength": 16,
    "fullLength": 34359738368,
    "expansionTechnique": "repeating"
  }
}
```

We define an "expansionTechnique" to allow extensibility in the future for other methods of producing a message of the proper size. In this example "repeating" corresponds to the repeating nature of Alg. 2.

After the test generates a message of a specific number of bits, this message would then be hashed on the server to produce a single hash output similar to the AFTs. Once the test is sent to the client, this could flush out implementations for faults from long messages that produce incorrect outputs. As hashing is a core operation to many other cryptographic operations, it is important to consider scenarios where an adversary may maliciously generate large inputs.

Note that to unearth the bug in the Apple CoreCrypto library, it is necessary to use either the Hash() interface on a message of 4 GiB or more, or the Init-Update-Final interface where at least one of the Update() calls contains 4 GiB or more. In the latter case, it may be necessary to make the message a few bytes longer, as explained in Sect. 4.1.

Given that the LDT is designed to work with large data, we need to take into consideration that the implementation may run out of memory. When allocating dynamic memory (e.g., using `malloc()` in C) or mapping files to the virtual address space (e.g., using `mmap()` in C) are unsuccessful on the target platform, it may be an option to consider increasing the memory available to the platform or even simulating the environment for the purposes of testing.

6 Discussion

As hash functions are a core primitive within many other cryptographic algorithms, it is critically important to ensure correctness under all valid inputs. Yet the methods with which these algorithms are tested are still based on techniques from 1977. While the original tests are still valid, an automated system allows the CAVP to continually add test types and boost the assurances gained from the program. With a publicly standardized JSON protocol, and open-source test harnesses such as libacvp [9], the CAVP is in a good position to move forward with improved testing techniques. We suggest the LDT as a way to directly improve the assurances gained from the CAVP. Of course, one needs to design, specify, publicly review the tests, etc. before they can be used in a program such as CAVP. Openness and transparency are important for acceptance in this highly sensitive domain.

To test the limits of common variable types such as 32-bit unsigned integers, the LDT would need to be on the order of 2^{32} bytes or 4 GiB. This would be sufficient to detect the CoreCrypto bug, and potentially similar bugs in other cryptographic implementations.

However, an inherent limitation of the CAVP and of software testing in general, is that it is a selection process, where a very small subset is selected from the total number of possible test cases. Therefore, testing is not a method to prove the correctness over all types of inputs for an implementation. As stated by Dijkstra, “Program testing can be used to show the presence of bugs, but never to show their absence!” Indeed, the entire goal of software testing is to determine how to perform this selection process, in order to try to quantify the assurance that we get from testing.

Furthermore, the CAVP only tests the capabilities that are declared by the vendor, and would therefore not detect the bug if it only declares support for short messages. While this is reflected in the final validation certificate the vendor receives, this shows the potential need for a wider amount of negative testing. Negative tests are those that test not only well-defined inputs that may be beyond the advertised capabilities, but also invalid inputs.

We note the potential hazards of exposing multiple entry points to a single set of functionality. As mentioned, hash functions often provide at least two interfaces: an `Init-Update-Final` interface and a `Hash()` interface. Often both are exposed such as within CoreCrypto.

Lastly, it can be interesting to explore the parallels between different levels at which vulnerabilities can be handled, as we now explain.

A security vulnerability report to the vendor can allow for a rapid response to address a vulnerability. The FIPS 140-2 Implementation Guidance (IG) [18] encourages this process by providing the vendors with a "means to quickly fix, test and revalidate a module that is subject to a security-relevant CVE." A CVE (Common Vulnerability and Exposure) is security-relevant if it affects how the module meets the requirements of the FIPS 140-2 standard.

For FIPS 140-2 validated cryptographic modules, publishing a vulnerability with a CVE can accelerate the time for end users to obtain crucial security updates. Yet the very nature of the CVE system is an ad hoc procedure, and there is no mechanism in place to ensure that a vendor has learned from such a vulnerability. A vendor may implement test cases within their own development process to detect similar issues in the future, but this holds a very limited scope. The implementations of other vendors could be susceptible to similar issues, but there may be no incentive to react.

If the CAVP implements tests based on CVEs (e.g., as done by Project Wycheproof [10]), then lessons learned from a CVE are not restricted to a single implementation. The requirement of FIPS validation would then also provide stronger assurances to government and private entities that rely on the program. If a CVE can be detected via existing test types, a static test could be seamlessly included from the NIST server. By using an existing test type, no additional code is needed from a test harness to understand how to process the test. In addition, with the speed of testing under ACVP, it is mutually beneficial to constantly test while developing cryptographic implementations.

7 Conclusion

Apple's CoreCrypto library contains a bug due to the implementation-dependent manner in which integer constants are specified. Due to this bug, the MD4, MD5, and the RIPEMD and SHA family hash function implementations enter into an infinite loop for messages of 4 GiB or larger. The bug affects all implemented hash functions (except MD2), and higher-level operations such as HMAC, Ed25519, and SRP. To detect the bug in NIST's CAVP, we proposed a new Large Data Test (LDT) to calculate the hash value for large messages. We also pointed out that stricter coding standards might be helpful to avoid this type of bug.

Responsible Disclosure. The Apple Product Security team was notified of the vulnerability described in this paper on May 30, 2019, and has since taken steps to address the issue. In a conference call on July 17, 2019, Apple Product Security clarified that they do not object to the publication of the research results presented in this paper. On July 23, 2019, Apple Product Security informed us that they are planning to assign a CVE to this issue. On October 29, 2019, Apple publicly announced CVE-2019-8741 to address the vulnerability described in this paper for macOS Catalina 10.15, tvOS 13, watchOS 6, iOS 13, iTunes 12.10.1 for Windows, and iCloud for Windows 7.14.

Acknowledgments. The authors would like to thank the anonymous reviewers and their NIST colleagues for providing useful comments and suggestions. Special thanks go to Patrick Kamongi, Andrew Regenscheid, Apostol Vassilev, and Jeffrey Marron for their detailed feedback. Certain algorithms and commercial products are identified in this paper to foster understanding. Such identification does not imply recommendation or endorsement by NIST, nor does it imply that the algorithms or products identified are necessarily the best available for the purpose.

A The `ccdigest_update()` function of Apple's CoreCrypto

Here, we provide the implementation of the `ccdigest_update()` in Apple CoreCrypto, which is made available to the public on Apple's website [3]. For readability, we made minor changes to the indentation, corrected the spelling of the word "division" and expanded the `CC_MEMCPY` macro to `memcpy`.

```
void ccdigest_update(const struct ccdigest_info *di, ccdigest_ctx_t ctx,
                     size_t len, const void *data) {
  const char * data_ptr = data;
  size_t nblocks, nbytes;

  while (len > 0) {
    if (ccdigest_num(di, ctx) == 0 && len > di->block_size) {
      //low-end processors are slow on division
      if (di->block_size == 1<<6 ){ //sha256
        nblocks = len >> 6;
```

Mouha, Nicky; Celi, Christopher. "Extending NIST's CAVP Testing of Cryptographic Hash Function Implementations." Paper presented at CT-RSA 2020: Cryptographers' Track at the RSA Conference, San Francisco, CA, US. February 24, 2020 - February 28, 2020.

```
    nbytes = len & 0xFFFFffC0;
   } else if(di->block_size == 1<<7 ){ //sha512
    nblocks = len >> 7;
    nbytes = len & 0xFFFFff80;
   } else {
    nblocks = len / di->block_size;
    nbytes = nblocks * di->block_size;
   }

   di->compress(ccdigest_state(di, ctx), nblocks, data_ptr);
   len -= nbytes;
   data_ptr += nbytes;
   ccdigest_nbits(di, ctx) += nbytes * 8;
  } else {
   size_t n = di->block_size - ccdigest_num(di, ctx);
   if (len < n)
    n = len;
   memcpy(ccdigest_data(di, ctx) + ccdigest_num(di, ctx), data_ptr, n);
   /* typecast: less than block size, will always fit into an int */
   ccdigest_num(di, ctx) += (unsigned int)n;
   len -= n;
   data_ptr += n;
   if (ccdigest_num(di, ctx) == di->block_size) {
    di->compress(ccdigest_state(di, ctx), 1, ccdigest_data(di, ctx));
    ccdigest_nbits(di, ctx) += ccdigest_num(di, ctx) * 8;
    ccdigest_num(di, ctx) = 0;
   }
  }
 }
}

Abstract: A summary and overview of a public workshop on machine learning for optical Communication systems held on August 2nd 2019, by the Communications Technology Laboratory at the National Institute of Standards and Technology in Boulder, CO.

1. Introduction

Expected increased demand and functionality on optical networks to address higher speeds, lower latency, and higher reliability poses opportunities for improvement from both hardware and software infrastructure. However, the complexity and analog nature of the optical network poses challenges for software control. As these demands increase along with the implementation of smarter components and subsystem the use of artificial intelligence (AI) and machine learning (ML) to improve network function and automation makes increasing sense. Over recent years many use case scenarios have been introduced for ML and AI in optical communication systems; however, to date agreement on implementing ML on a larger scale across the industry and for specific applications is still lacking and debated. Many factors both technical and non-technical play a role in the implementation of ML in optical communication systems (MLOCS).

In an effort to expand discussion on the topic of machine learning (ML) and artificial intelligence (AI) in optical communication systems a public workshop was organized and held at the Boulder campus of the National Institute of Standards and Technology (NIST) by the Communications Technology Laboratory (CTL). On August 2nd 2019, members of industry, academia and government convened to participate in talks, panel discussions and breakout session discussions addressing various subtopics of ML in optical communication systems. The workshop was designed to provide opportunities for attendee participation where scheduled talks transitioned to panel discussions followed by an afternoon session of open breakout discussions on specific subtopics. The workshop attempted to address a range of topics related to AI/ML in the context of optical communication systems. These included general approaches of ML and application to optical transport systems, possible training scenarios, types of data, and use cases. For a more a detailed summary of the workshop outcomes we refer the reader to the workshop White Paper [1] and workshop website at [2].

2. Talk Summary

Workshop talk topics spanned general ML approaches such as linear regression and neural networks as well as training scenarios. The topic of data for use in ML algorithms was also broached in the context of what data is important and the limiting cases of an abundance of data as well as too small of data sets. Several use cases were discussed ranging in domain from the device level to the end-to-end network.

The vast amounts of data generated by optical network management and control shows much promise as a mechanism to make use of AI/ML for the purpose of improving the optical network in several ways from management to improved transmission. In particular quality of transmission (QoT) estimation and failure management became a focus of discussions at the workshop [3],[4]. ML was discussed as a means of improving fault identification and traffic management within the network layer and the function of components in the physical

Gordon, Josh; Battou, Abdella; Kilper, Dan. "Workshop on Machine Learning for Optical Communication Systems: a summary." Paper presented at The Optical Networking and Communication Conference & Exhibition OFC 2020, San Diego, CA, US. March 08, 2020 - March 12, 2020.

layer. Control of amplifiers, mitigation of system nonlinearities, modulation format adaptation and QoT estimation could be addressed with ML. As in most ML approaches these use cases require training data sets, a topic of which was discussed at length during the workshop and deemed a topic requiring ongoing discussion.

Many models were discussed including those for individual devices, network behavior, physical layer impairments, and traffic prediction. Models based either on analytical methods, numerical methods and live monitoring all were considered. Each with advantages and disadvantages, with a tradeoff of accuracy, speed and reliability (e.g. an analytical model may be faster but not as accurate as a complex numerical model, etc.). The use case of nonlinear impairment compensation was a focus of discussion as it is difficult to compute analytically and is a critical factor in many networks, and thus is a scenario wherein ML may prove useful.

Considering the vast amount of data that could be acquired from optical networks the question arises as to “what data matters?”. This is an ongoing question [5],[6],[7],[8] and is use case dependent. Non-linearities in the physical layer poses some of the more challenging scenarios for ML with use cases ranging from nonlinearity mitigation, optical performance monitoring and modulation format recognition. Waveforms show promise as input data sets across use cases whereas on the output what data is useful depends on the use case under consideration. Standardization of waveforms could possibly provide a means for determining the effectiveness of ML algorithms and approaches.

One consideration discussed during the workshop was the data starved scenario, wherein there is a limited set of data available for training. Although the amounts of data could potentially be vast, constraints on data availability whether due to technical or non-technical reasons often severely limit the size of training sets. For example, network operators often cannot share data due to customer privacy considerations. This situation suggests that understanding the case where there is possibly too little data as a result of use case dependent data accessibility is also important. The use of ML and AI spans across many disciplines, where lessons learned, and approaches appear unique to one discipline may in fact inform new approaches and open doors in another. On this topic, work was presented at the workshop on the use of data sets that are “too small” in the context of deep learning for application to computer vision when limited annotated data are available. In particular, two common approaches widely used were discussed: 1) data augmentation and 2) transfer learning. The use of label preserving transformations for data augmentation is an efficient process for expanding a data set that is too small. Furthermore, it also allows one to specify what invariance should be present in the trained model. In the practice of model definition, transfer learning could be used to further refine a model that was first trained on large data sets then refined further on smaller sets of domain or application data.

3. Breakout Session Discussion

Three subtopics were addressed during breakout sessions. As there is a multitude of possible subtopics possible these were judiciously chosen in particular because they provided coverage of several main areas relevant to ML in optical communication systems and overarching architectures. Furthermore, these subtopics contain use cases that range in complexity from individual devices such as coherent transponders, to core networks, to multi-layer networking. More specifically, breakout session topics examined data set curation and applications related to:

- Reconfigurable optical add drop multiplexers (ROADM) and optical line system layer
- Coherent transponders
- Cross Layer End-to-end networking

With these three subtopics the optical line systems (OLS), including the ROADM nodes, fibers and amplifiers were considered as well as transponders and networking. Potential focus areas related to OLS wherein ML could make an impact were quality of transmission (QoT) estimation, fault identification, and failure prediction. QoT estimation was identified as the most promising for obtaining data sets that would provide widespread use across the community. Three network use cases wherein ML applied to the OLS could be an enabler were disaggregation, network defragmentation, and faster dynamic operation. All three of these use cases entail a more “dynamic” network either through the network accommodating variability due to changes and variations in hardware (disaggregation) or through the requirement of more dynamic control (faster add/drop and switching of optical signals). Optical parameters generated by coherent modems were discussed as a potential source of data that may prove difficult to obtain in real time otherwise. Data available from coherent modems was explored in the context of both directly measured as well as computed parameters and the possible applications of such data. In particular, applications range from predictive assessment of network health, fiber health, network performance estimation, to remote assessment of fiber integrity. The complexity of the network as a whole poses challenges to cross-domain core/metro/cloud/access and cross-layer IP/Optical performance and coordination. ML could play an important role in assessing performance based on metrics from such cross-domain/layer interactions. For example, using ML for error correlation, probability, and prediction and impact of errors based on such interactions between domains and layers. Executing ML in such a scenario also highlights the needs for more extensive training data sets.

ABSTRACT

We make use of the intrinsic aberrations of an optical microscope to track single particles in three dimensions, and we combine information from multiple particles on a rigid body of a microelectromechanical system to measure its motion in six degrees of freedom. Our tracking method provides an extraordinary amount of information from an ordinary imaging system, revealing unintentional motion of the microsystem due to fabrication tolerance and nanoscale clearance between parts in sliding contact. Our work facilitates quantification and study of the actuation performance and reliability of complex microsystems.

KEYWORDS

3D, 6DOF, MEMS, metrology, microscopy, motion

INTRODUCTION

Mechanical systems are fundamentally important to many modern technologies and have great potential for future development. Complex mechanical systems often use rigid-link mechanisms to transduce an input into an output of forces and motion to reliably perform useful work. Such transduction can involve the transfer of motion, with multiple degrees of freedom, through parts of the system in sliding contact. However, practical limitations of transduction result in an imperfect output of forces and motion, limiting performance and reliability. In particular, coupling interactions between parts in sliding contact such as play, feedback, friction, and wear can affect the system kinematics. Play and feedback can not only reduce the precision of the intentional motion of the system but can also result in unintentional and unpredictable motion of microsystems [1]. Moreover, friction and wear can become problematic at the microscale and nanoscale, due to high surface to volume ratios and lack of lubricating liquid films, motivating efforts to elucidate and mitigate these effects [2-5]. In the case that coupling interactions result in nondeterministic motion at small scales, it is necessary to measure single motion with cycles of the system to understand the true kinematics. In any case, single motion cycles are essential in a variety of applications in which the motion of the system is fundamentally aperiodic, such as positioning, switching, and gripping. However, methods to measure the single motion cycles of mechanical systems – often occurring at length scales much smaller than the parts of the system, ranging from the millimeter scale down to the atomic scale, and occurring in six degrees of freedom – have lagged behind microsystem technologies.

Methods for measuring micromechanical motion are often optical due to compatibility with the operation of the systems. Imaging methods can resolve single cycles of in-plane motion at the nanometer scale but have limits of the magnitude or mode of motion that is measurable [6, 7], specific requirements for system design [8], or the need to fabricate test structures for imaging [9]. Interferometry methods for measuring out-of-plane motion can be precise but have only recently measured in-plane motion [10] and require scanning, impeding characterization of systems with multiple moving parts. These various limitations leave a measurement gap, presenting both opportunities and challenges for the development of complex microsystems.

To bridge this gap, we advance our method of particle tracking [1, 11-14] to provide a new capability to measure microsystem motion. We exploit the intrinsic aberrations of an optical microscope to track single particles in three dimensions on a complex microsystem [15, 16], which moves through a deep and ultrawide field. We introduce an algorithm for position estimation in three dimensions, using light-weighting [17] to robustly fit Gaussian models to images and precisely estimate image shape throughout the focal volume. Linear combinations of Zernike polynomials extend this localization analysis to a widefield calibration. A rigid transform combines information from multiple particles to measure the output motion of the microsystem in six degrees of freedom, enabling tracking of the system as it rotates through a repetitive orbit with nanoscale deviations from coupling interactions. Our new method is broadly applicable, and our measurement results provide new insight into the actuation performance and reliability of complex microsystems.

RESULTS AND DISCUSSION

Materials and methods

Our microscope system has an objective lens with a nominal magnification of 50× and a numerical aperture of 0.55. A piezoelectric actuator translates the lens in the z direction with a resolution of 10 nm, providing reference values of z that we assume are accurate. A light-emitting diode illuminates the sample at a peak wavelength of approximately 625 nm. A complementary metal-oxide-semiconductor camera operating with a global shutter records fluorescence micrographs at a peak wavelength of approximately 645 nm. We calibrate the mean value of image pixel size as 127.34 nm ± 0.03 nm [17]. We report all uncertainties in this study as standard deviations, or we note otherwise. We will present further details and calibration of our microscope system in a future study.

Our test microsystem features a rotational electrostatic actuator coupling through a ratchet mechanism to a ring gear, forming a drive motor that operates in an open loop [15, 16]. The ring gear has 200 teeth that couple to a load gear with 80 teeth and a nominal diameter of 328 µm, as Figure 1a shows. A constellation of fluorescent particles with nominal diameters of 1 µm rides on the load gear, as Figure 1b-c shows. A square wave voltage with an

Paper presented at 2020 IEEE 33rd International Conference on Micro Electro Mechanical Systems (MEMS), Vancouver, CA. January 18, 2020 - January 22, 2020.

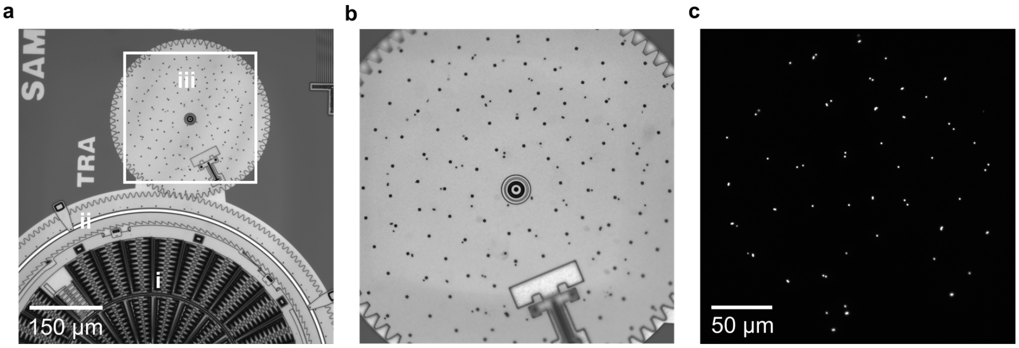

*Figure 1. Experimental overview. (**a**) Brightfield micrograph at inspection magnification showing the drive motor, with (i) a rotational actuator, (ii) a ring gear, and (iii) the load gear. (**b**) Brightfield micrograph at experimental magnification showing the load gear. The smaller dots with random spacing are fluorescent particles and the larger dots in a radial pattern are etch holes for sacrificial release of the structures. (**c**) Fluorescence micrograph at experimental magnification showing a constellation of fluorescent particles on the surface of the load gear.*

amplitude and offset of approximately 7.5 V and a frequency of approximately 90 Hz actuates the motor. Each period incrementally rotates the load gear, which we define as a single motion cycle. After each motion cycle, the microscope system records a fluorescence micrograph of the particles on the quasi-static gear, as Figure 1c shows.

We fit models to data by the method of damped least-squares with uniform weighting, or we note otherwise.

Particle tracking in three dimensions

Intrinsic aberrations of our optical microscope affect the peak amplitudes and shapes of particle images, as Figure 2a shows, enabling localization in three spatial dimensions. We fit a bivariate Gaussian model to the image data by the light-weighting algorithm [17], exploiting the information content of multiple parameters,

$$G_{biv}(x_p, y_p) =$$
$$A \cdot \exp\left(\frac{-1}{2(1-\rho^2)}\left[\frac{(x_p-x)^2}{\sigma_x^2} - 2\rho\frac{(x_p-x)(y_p-y)}{\sigma_x\sigma_y} + \frac{(y_p-y)^2}{\sigma_y^2}\right]\right) + B$$

where (x_p, y_p) is the position of a pixel in a micrograph, (x, y) is the position of the Gaussian peak, A is the peak amplitude, σ_x is the standard deviation in the x direction, σ_y is the standard deviation in the y direction, ρ is the correlation coefficient between the x and y directions, and B is a constant background. Division of ρ by the amplitude parameter A, $\rho_{amp}=\rho/A_n$, where $A_n= A/A_{\rho=\rho^*}$ is the amplitude parameter after normalization to its value in the particular image for which $\rho = \rho^*$, provides a useful z dependence, as Figure 2b shows. This normalization ensures that any differences in fluorescence intensity between the particles for calibration and for experiment do not affect the calibration of z dependence. We set ρ^* to the minimum value of $|\rho|$. The statistical uncertainty of axial localization from empirical polynomial models of z(ρ_{amp}), such as Figure 2b shows, is approximately 50 nm and is due primariliy to the random noise in ρ_{amp}. To accurately calibrate the lateral dependence of the relationship in Figure 2b, we deposit a random array of calibration particles onto a silicon substrate and image the particles through focus, sampling the field to obtain a set of local calibration functions $[z(\rho_{amp})]_{cal}$. The z positions from this set of calibration functions vary significantly across the lateral extent of the field of 260 µm by 260 µm, as Figure 2c shows for a representative value of ρ_{amp} = -0.1.

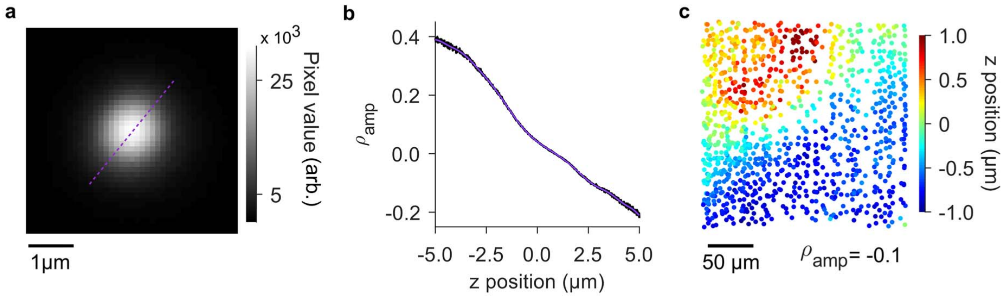

Figure 2: Axial localization. (a) Optical micrograph showing an image of a fluorescent particle with a diameter of approximately 1 µm at a z position of 2 µm above best focus. The dash violet line indicates the major axis. (b) Plot showing a representative dependence of the shape parameter $\rho_{amp}=\rho/A_n$ on z position, where ρ is the correlation coefficient and A_n is the normalized amplitude of a bivariate Gaussian model. The solid violet line shows a polynomial of order 16, which empirically models the z dependence for axial localization. (c) Plot showing the lateral dependence of z position for a common value of the shape parameter ρ_{amp} = -0.1 from a random array of calibration particles that sample the imaging field. Uncertainties in (c) are smaller than the data markers.

Copeland, Craig R.; McGray, Craig; Ilic, Robert; Geist, Jon; Stavis, Samuel M. "Particle Tracking of a Complex Microsystem in Three Dimensions and Six Degrees of Freedom." Paper presented at 2020 IEEE 33rd International Conference on Micro Electro Mechanical Systems (MEMS), Vancouver, CA. January 18, 2020 - January 22, 2020.

To develop our widefield calibration, we model this lateral dependence by linear combinations of Zernike polynomials. The residuals of this model fit to data such as in Figure 2c define systematic errors of axial localization, which have root-mean-square values of approximately 70 nm. These errors are due primarily to variation of image shape at lateral scales of a few micrometers, as Figure 2c shows. We perform analogous calibrations for the axial and lateral dependence of apparent lateral motion. We will elucidate these results, as well as the precision and accuracy of our method, in a future study.

Microsystem tracking in six degrees of freedom

A rigid transform maps particle positions between subsequent micrographs by the iterative closest-point algorithm, yielding the motion of the gear for each cycle. The center of rotation is a natural origin of our extrinsic coordinate system, which we determine as the mean value of all particle positions in each dimension over multiple revolutions of the gear. The residuals of the rigid transforms confirm the accuracy of tracking single particles to within root-mean-square errors of approximately 2 nm in x and y and approximately 80 nm in z. The rigid transform determines three translations Δx, Δy, and Δz, and three rotations in as many degrees of freedom, the intrinsic rotation of the gear γ about the axis of rotation, the nutation β of the axis of rotation with respect to the extrinsic z axis, and the precession α of the axis of rotation about the extrinsic z axis, as Figure 3 shows. Uncertainties of these six degrees of freedom depend on the particular particle constellation and the extrinsic coordinate system [13, 18], as we will describe in a future study.

Our measurements show significant variation in four of the six degrees of freedom due to play in the couplings between the parts of the microsystem, as Figure 3 shows. These results provide new insight into how the parts of complex microsystems move during operation, including both intentional and unintentional motion at nanometer and milliradian scales. Clearance between the meshing teeth of the ring and load gears, as well as variability of the rotational actuator [12], cause variability of the intrinsic rotation γ in Figure 3a. Clearance between the gear and the hub causes variability of the translations Δx and Δy that Figure 3d,e shows. Clearance between the gear and the underlying substrate allows for nutation β of the axis of rotation relative to the extrinsic z axis, as Figure 3c shows. The gear does not exhibit significant translation in the z direction Δz, as Figure 3f shows, which validates the measurement uncertainty for translations in this direction. While the precession of the axis of rotation α varies over a wide range, as Figure 3c shows, the small nutation β that Figure 3b shows causes the rigid transform to be relatively insensitive to this degree of freedom, so that nearly all of the variability is within measurement uncertainty. A different selection of reference frame could improve some of these uncertainties while degrading others. We will analyze these results in more detail in a future study.

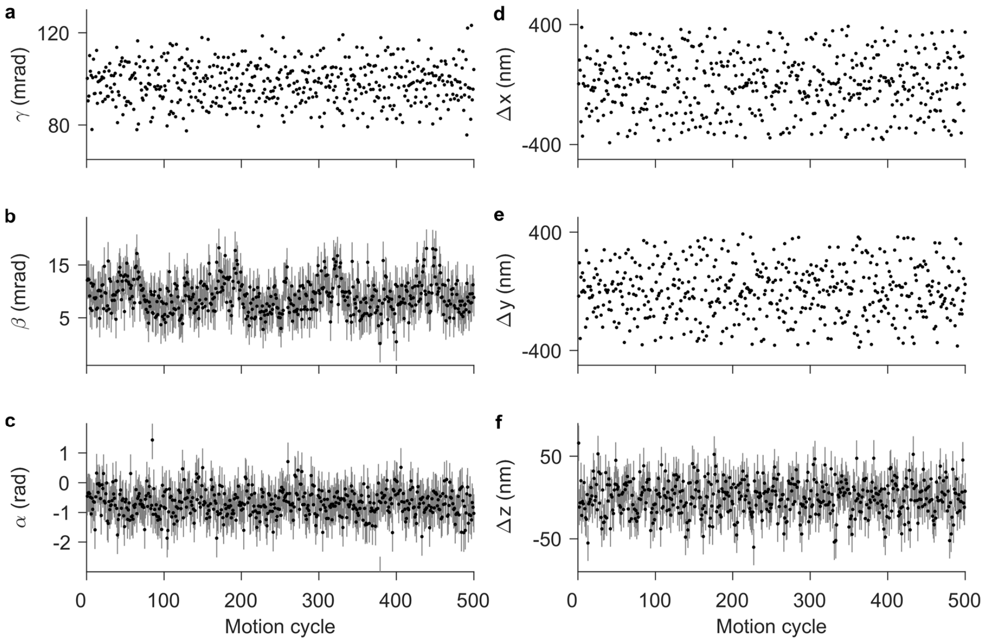

Figure 3: Microsystem tracking. (a-c) Plots showing (a) intrinsic rotations of the gear in three-dimensional space γ , (b) the angle between the axis of rotation and the extrinsic z axis, or nutation β, and (c) the angle between the axis of rotation and the extrinsic x-z plane, or precession α. Variability in (a-c) is due to rotational play in three dimensions. (d-f) Plots showing translation of the gear in the (d) x, (e) y, and (f) z directions. Variability in (d) and (e) indicates translational play, with effective ranges of 394 nm and 387 nm, respectively, while variability in (f) is due to measurement uncertainty. Uncertainties in (a, d, e) are smaller than data markers.

CONCLUSIONS

We introduce a method of particle tracking in three dimensions to measure the motion of a microscale rigid body with six degrees of freedom. Rigid transforms allow the combination of localization data to improve centroid and orientation precision through the central limit theorem [13], now in three dimensions. While such analysis is common in motion tracking of macroscale objects, this is the first such application in particle tracking by optical microscopy. Our new method enables study of a complex microsystem. We find that microfabrication tolerance and nanoscale clearance between parts in sliding contact not only degrade the precision of the intentional motion of the test system, but also result in unintentional motion that is orthogonal to the primary plane of the test system and occurs in all six degrees of freedom. These results provide insight into actuation performance and reliability. While our test system dates back two decades and is commercially available, its ultraplanar fabrication process remains near the state of the art, and we are unaware of any previous measurement that reveals the complex kinematics resulting from nanoscale clearances within such a system. Moreover, commercial microsystems still do not make full use of the complexity that such processes enable, and indeed most microsystems have simpler kinematics than our test system. Advancing practical methods to quantify and specify the motion of complex microsystems will help to fulfill their potential for many exciting applications.

Abstract

Silicon defect centers are promising candidates for waveguide-integrated silicon light sources. We demonstrate microresonator- and waveguide-coupled photoluminescence from silicon W centers. Microphotoluminescence measurements indicate wavelengths on-resonance with resonator modes are preferentially coupled to an adjacent waveguide. Quality factors of at least 5,300 are measured, and free spectral ranges closely match expectation. The W center phonon sideband can be used as a spectral diagnostic for a broader range of waveguide-based devices on cryogenic silicon photonic platforms.

1. Introduction

The rapid growth of the silicon photonics industry has the potential to bring photonic manufacturing economies comparable to those of the silicon microelectronics industry. In addition to potentials for large-volume production, silicon photonics opens possibilities for large-scale photonic processing architectures that could not be conceived of in fiber or III-V platforms [1–3]. In all photonic systems, light sources are required. Silicon does not readily emit light at room temperature due to its indirect bandgap. Therefore, most efforts in silicon photonics use external light sources coupled to chip with fiber. The use of external light sources presents critical burdens of fiber packaging, resulting in severe scaling limitations.

Substantial research has been dedicated to developing integrated light sources for silicon photonics [4, 5]. Each approach has advantages and drawbacks. These include rare earth element doping (low brightness), wafer bonding of III-V quantum wells [6] (challenging and expensive processing), epitaxial growth of III-V quantum dots [7] (specialized epitaxy steps), and strain engineering of germanium [8] (fragility and low yield). All of these approaches with the exception of germanium involve the introduction of materials that are incompatible with typical silicon foundries.

Silicon emitters can be realized by creating specific defects in the silicon crystal. Emissive defect centers in silicon have been studied for seven decades, reviewed in [9, 10], but they have not demonstrated utility as sources for silicon photonic circuits in key applications of interest. Their application domains are limited by a requirement of low-temperature operation; however, this is a limitation of little consequence when cryogenic operation is acceptable or required. Defect centers possess several important advantages, most crucial of which is their ease of fabrication: local modifications to the native crystal as opposed to the introduction of new materials and/or structures. If monolithically integrated with waveguides, defect center light sources could provide a compact, inexpensive, scalable solution for superconducting optoelectronic neural networks [2] and optical quantum information systems. In optical quantum information systems, the complex photonic circuitry can operate at room temperature, but then off-chip cryogenic single-photon detectors are needed anyways [11, 12]. The prospect of monolithic sources and single-photon detectors could potentially justify the overhead of cooling the entire quantum system.

In this work, we explore the coupling of W-center photoluminescence to silicon-on-insulator waveguides and microring resonators, a platform shown in figure 1. W centers are trigonal defects that have a

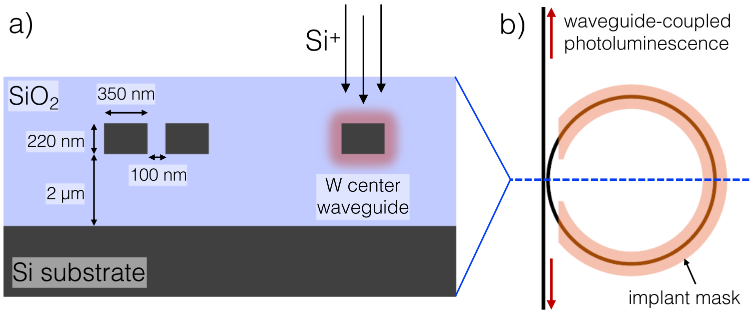

Figure 1. Illustration of platform and devices. (a) Waveguide cross-sections. All waveguides are designed to be 220 nm thick and 350 nm wide such that they are single mode at 1218 nm. As fabricated, waveguide widths were 390 nm. W-center emitters are created by implanting a waveguide with silicon ions and annealing. Evanescent couplers between microrings and the bus waveguide have 100 nm gaps in this work. (b) Top view of microring resonator coupled to a waveguide. Black is silicon; red is the pattern of ion implants defined lithographically; blue, dashed line is the cross-section slice. Implant regions are widened to relax alignment tolerance. Ions that miss the silicon become embedded in the buried oxide and have no effect on the studied devices.

zero-phonon line at 1218 nm and phonon sideband over 1225 nm–1275 nm [13]. They are created by implanting silicon crystal with silicon ions. We report that photoluminescence emitted into resonator modes preferentially couples to a bus waveguide, resulting in spectra with periodic resonances that are characteristic of microrings. The free spectral ranges of different devices closely match with theoretical models, thus allowing extraction of the group velocity parameter with a $R^2 = 0.991$ coefficient of determination. We record resonances with quality factors up to 5,300. Infrared camera and polarization measurements are used to confirm correct operation of the experimental technique for differentiating waveguide-coupled from free-space-coupled photoluminescence.

In prior work, W center waveguide coupling has been achieved in an electrically pumped device whose total power output was measured by an on-chip detector [14]. While the current work aims to support development of electrically pumped devices, micro-photoluminescence (PL) measurements offer additional research opportunities and richer information than electrical devices alone, such as pumping an array of devices or resolving emission spectra. In prior micro-PL measurements of defect centers in silicon-on-insulator, waveguides were not investigated, although several of these devices were on silicon-on-insulator of dimensions that could potentially support waveguides [15–17]. Other studies have shown coupling of various defect centers to suspended microdisk [18] and photonic crystal [19, 20] cavities; however, PL collection has always occurred directly above the structure being pumped, i.e. normal to the surface of the sample.

We monitor waveguide-coupled luminescence unambiguously by collecting from a grating coupler that is spatially offset from the microring being pumped. This circuit is shown in figure 2. The experimental apparatus for collecting offset photoluminescence is similar to those used in prior research on quantum dots and photonic crystals [21–23]. In contrast to those works, both the resonator under study and the offsetting circuitry itself are based on oxide-clad, single-mode silicon rib waveguides of the same type that form the basis of mainstream silicon photonic platforms. Results imply a potential to integrate W centers in more complex photonic integrated circuits and an ability to generalize the experimental technique to the study of a wide range of more complex photonic circuits with embedded emissive defect centers.

2. Layout and fabrication

The substrate used for this study was a 76 mm silicon-on-insulator (SOI) wafer with a 220 nm silicon device layer on a 2 μm buried oxide. Implants were masked by 600 nm thick positive-tone resist patterned by electron-beam lithography. The wafer was then implanted with Si ions at a commercial facility. The silicon etch pattern was masked by an electron-beam-patterned oxide hard mask. The 220 nm thick device layer was fully etched to the buried oxide with a reactive ion etch based on SF_6 and C_4F_8. Finally, the wafer was encapsulated by a 1.5 μm oxide. The wafer was diced into 1 cm × 1 cm die, which were then annealed. Implant and anneal conditions were chosen to yield the optimum W-center brightness as determined in reference [17].

Waveguides were designed to be 350 nm wide such that they are single-mode at 1220 nm. Scanning electron micrographs of the waveguides showed an actual width of 390 nm. Comparisons of insertion loss in single-mode waveguides of different lengths indicated a waveguide loss of 18 dB cm^{-1}, which is significantly

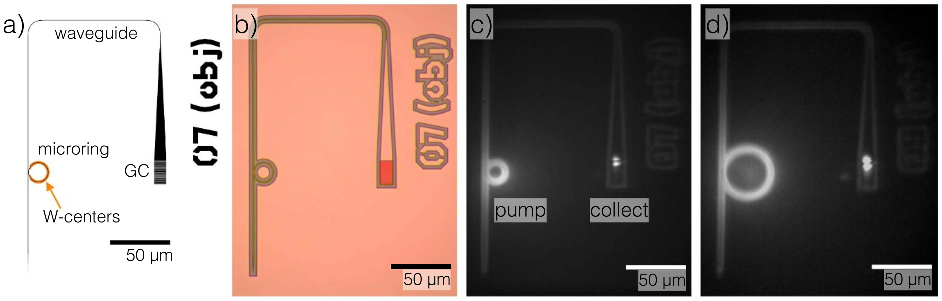

Figure 2. Different views of the circuit for offset collection from a microring resonator (MRR) with radius $r = 8$ μm. (a) Design layout. Silicon is black and the location of W-center implants is orange. GC: grating coupler. (b) Visible microscope image of the fabricated circuit. (c) Infrared image of the circuit when the MRR is optically pumped. Photoluminescence is observed directly from the MRR (free-space-coupled) and also from the offset grating coupler (waveguide-coupled). (d) Infrared image of a different device with larger radius, $r = 20$ μm.

higher than expected due to a non-optimized etch recipe. The peak brightness of the W-center zero phonon line (ZPL) in an unpatterned SOI region was measured to give 4,400 ± 220 counts/s with a 300 μW pump, which agrees with different cooldowns of different samples on the same setup. Microrings were designed with coupling gaps of 100 nm and radii of $r(\mu\text{m}) = [2, 4, 8, 10, 20, 30]$.

We employ a waveguide-based offset collection technique that allows for observation of waveguide-coupled PL, which was introduced in our recent conference proceeding [24]. The silicon photonic circuit, shown in figure 2, spatially separates waveguide-coupled PL from free-space-coupled PL, and the optical apparatus isolates these two collection points. In the circuit, an MRR implanted with W centers is evanescently coupled to a bus waveguide. When the MRR is pumped, some component of the PL is emitted upward into free-space. Another component of the PL is emitted into the resonator modes. Light in the resonator modes couples to the bus waveguide and is then routed to the spatially offset grating coupler (GC). The GC is designed to emit normal to the surface and is located 100 μm away from the center of the MRR.

3. Experimental Apparatus

A simplified experimental setup is shown in figures 3(a) and (b) and in more detail in the Supplementary Information. The primary components are a pump, cryostat, objective, and infrared (IR) spectrometer. The 11 mW laser pump at 635 nm (red) is focused onto the device in the cryostat. Excited electrons undergo an optical transition in the W centers, emitting IR photoluminescence in the infrared (depicted as blue). This PL is directed to a spectrometer and InGaAs camera. PL is emitted from two locations: the device itself and the offset GC. When the PL is imaged with a lens, the two emission sources are spatially separated. These distinct emission sources are seen in figure 3(c).

The objective performs both roles of focusing the pump to a spot and collecting the PL through a window in the cryostat. The infinity corrected, long working distance objective has 10× magnification and a numerical aperture of 0.42. The sample was fixed, and the objective was mounted on XYZ translation stages. Three mirrors were mounted to the stages in a periscope configuration that maintains a consistent relationship between beams on the optical table and the objective, despite the movement of the objective. A visible camera was used to navigate the sample and position the pump spot. More detail on visible microscopy, motion control, spot size control, and IR imaging can be found in the Supplementary Information section.

The procedure for discerning waveguide-coupled PL with this setup is as follows. Initially, the setup was aligned by collecting the free-space-coupled PL from an unpatterned, implanted region. The pump was positioned over an implanted MRR and fine adjusted such as to maximize the free-space-coupled emission signal from the MRR. Then, a razor blade in an image plane is moved to block the center of the field of view, seen in figure 3(d). The blade is translated by a further 500 μm corresponding to 50 μm on chip. Figure 3(b) shows the beams when in the blocking configuration, and figure 3(e) shows the corresponding IR image. Once the center is blocked, mirrors before the spectrometer are adjusted to optimize the offset signal. In this blocking configuration, only the offset PL from the grating coupler is observed.

The optical cryostat is based on a modified cryopump. The top flange of the cryopump chamber was removed, and a machined brass post and brass sample holder were attached to the 15 K stage of the cold

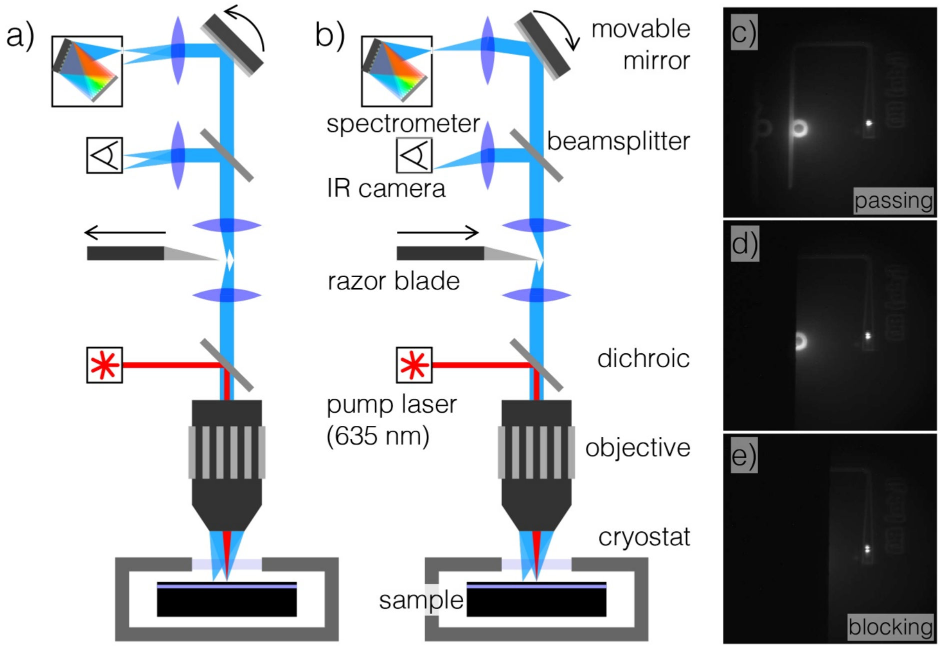

Figure 3. Simplified experimental diagram and visualization of the center PL blocking technique. The configuration can be non-blocking (a) or blocking (b). A pump laser (red) is focused onto a W-center device. Infrared (IR) PL is collected by the same objective. The returning PL transmits through a dichroic mirror and a razor blade assembly. Then the PL is split to an IR camera and spectrometer. When the central PL is blocked, the mirrors preceding the spectrometer are adjusted such that the offset component enters the slit of the spectrometer. (c-e) Verification of the razor blade technique for isolating offset PL. (c) Razor non-blocking corresponding to (a); (d) razor halfway across MRR; (e) razor fully blocking, corresponding to (b). Data is collected in the blocking state.

head. A radiation shield canister with a window was attached to the 80 K stage. Lastly, a new top flange with a window was put in place to seal the vacuum chamber. The cold head is driven by a closed-cycle helium compressor. A silicon diode thermometer is attached to the bottom of the sample holder and read a minimum temperature of 19.8 K. The cryopump motor causes substantial vibration, meaning that optical measurements of small devices cannot be taken while it is running. We estimated a sample vibration displacement between 50 and 100 μm. We addressed this vibration problem by turning the compressor off during fine alignment and measurement. While it is off, the temperature begins to increase, reaching 40 K in approximately 12 minutes. W-center brightness drops by 12% between 28 K and 40 K and then drops off precipitously above 45 K [13, 17]. All measurements in this work were taken between 28 K and 40 K.

4. Results

Waveguide-coupled spectra from MRRs with six different radii are shown in figure 4. These spectra (red) are compared to that of the control region (blue), which was an unpatterned, implanted SOI region. Emission at the zero phonon line (ZPL) at 1218 nm is 21-times brighter than the peak of the sideband; however, the sideband emission integrated over 1225 nm–1275 nm accounted for 55% of the total emission. In this measurement, the sideband was 20 dB above background noise, allowing us to spectrally resolve emission and transmission spectra over a broad, 50 nm wavelength range. It therefore can be used as a diagnostic technique for a wide range of cryogenic silicon photonic devices.

The collected PL is brighter at wavelengths that resonate with the microresonator and nearly undetectable off-resonance. This result indicates that only the PL emitted into the resonant modes couples to the bus waveguide. Preferential waveguide coupling does not necessarily mean preferential emission into the resonant modes, as in the sense of stimulated emission or Purcell enhancement, of which we did not observe conclusive evidence. The shape of the envelope of the peaks closely follows that of the W-center sideband from the control region. This indicates that the wavelength dependence of evanescent couplers and GC are relatively flat over the window. The data are not normalized, and it is coincidental that the amplitudes (dependent on multiple unmeasured factors, discussed below) also match. In figure 4(f), the peak

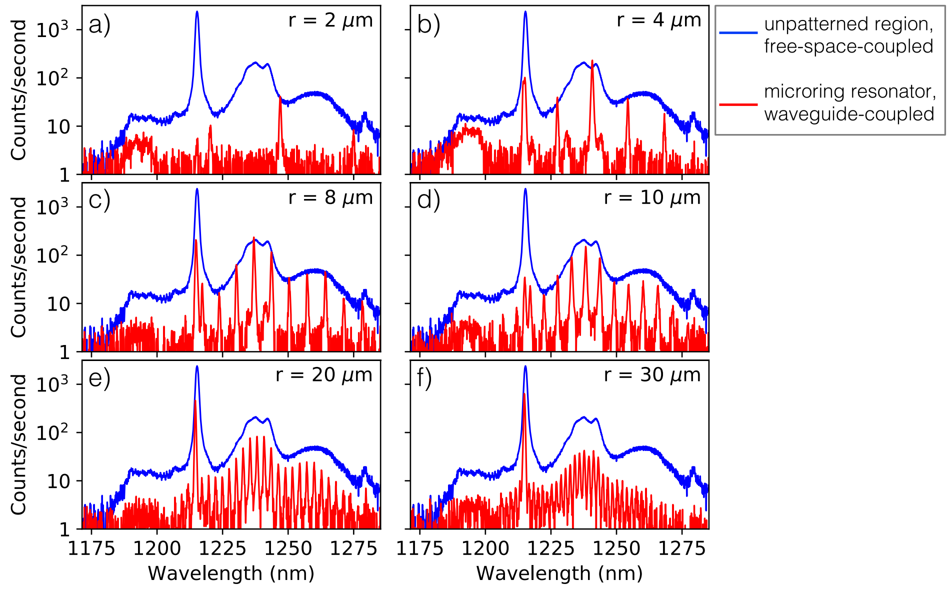

Figure 4. Comparison of free-space-coupled PL from an unpatterned control region (blue curves) to waveguide-coupled PL from the GCs connected to MRRs of different radii (red curves). Multiple peaks at evenly spaced frequencies are indicative of multiple MRR resonances. As MRR radius increases, the free spectral range decreases. The zero phonon line amplitude depends on where its wavelength falls relative to a resonator mode.

amplitudes are significantly weaker because the MRR diameter was much larger than the focused pump spot. The pump was defocused so that more of it reaches the MRR waveguide; however, most of the pump power still passed through the unimplanted center of the largest MRRs.

The zero phonon line was visible in every sample, but its amplitude varied considerably. Its amplitude depends on how close a MRR resonance falls to 1218 nm. As a result of resonance sensitivity to fabrication variation, it is difficult to control the absolute resonant wavelengths [25]. On the other hand, the relative spacing between resonances, i.e. free spectral range (FSR), is precisely determined by MRR radius according to the formula

$$\text{FSR} = \frac{\lambda^2}{2\pi r \cdot n_g}, \tag{1}$$

where n_g is the group index, and λ is wavelength. The best fit of the measured FSRs from figure 4 in the 1225 nm–1250 nm range yields $n_g = 4.51$ with a fit residual of $R^2 = 0.991$, meaning that there is close agreement between this model and the data. Previous measurements of similar MRRs, taken using a transmission spectrum analyzer and fiber alignment setup, yielded a group index of 4.33 ± 0.03; however, that measurement was at room temperature and without W centers.

Figure 5(a) shows a high resolution waveguide-coupled spectrum of the $r = 8$ μm MRR. A spectrometer grating with 1,200 grooves mm^{-1} was used for this measurement compared to the spectrometer grating used for figure 4 with 300 grooves mm^{-1}. The full-width half-maximum (FWHM) of the center peak was measured to be $\Delta\lambda = 0.23$ nm, which is near the resolution limit of the detector array. The quality factor of this feature is 5,300. Since any kind of misalignment or defocus can affect the actual resolution limit, it is possible that this Q factor is underestimated. The intrinsic Q of this MRR was at most 55,000 due to waveguide propagation loss. The extrinsic Q is determined by the combined round trip propagation loss plus ring-to-waveguide coupling coefficient, which was simulated to be $\kappa^2 = 0.121$. The extrinsic Q is therefore expected to be at most 7,700. Measurement and simulation place relatively tight bounds on the actual extrinsic Q between 5,300–7,700. In [24], measurements of a microdisk on the same setup and sample found resonances with Q factors up to 7,160. The higher Q in that work can be explained because higher-radial-order microdisk modes couple more weakly to the bus waveguide and interact less with any etched sidewalls. From the Q factors, we can estimate the coupling efficiency from the optical modes to the grating coupler. Resonator coupling efficiency is $1 - Q_e/Q_i$, where Q_e is extrinsic (5,300: measured directly), and Q_i is intrinsic (55k: estimated from loss measurements). Half of the viable PL propagates

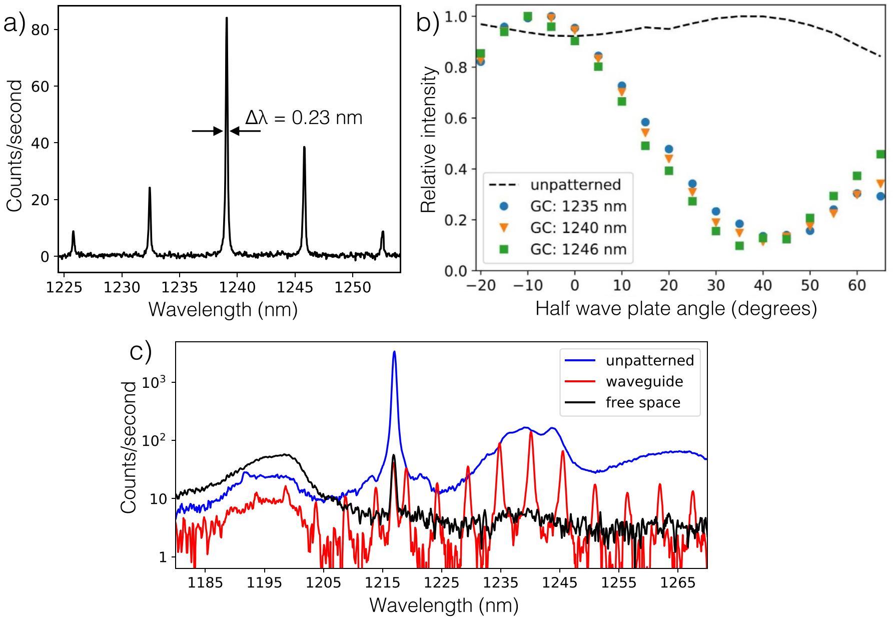

Figure 5. (a) High resolution spectrum of the sideband of the MRR with $r = 8\mu$m (figure 4(c)). The Q-factor of the central peak is at least 5,300. (b) Polarization dependence of light collected from the grating coupler (GC) compared to unpatterned control region. The GC curves are derived from three peaks of the $r = 10$ μm microring (figure 4(d)). Each curve is normalized to its maximum, and the values collected from the GC are first normalized by the corresponding unpatterned value. Note that (a) and (b) are different devices. (c) Comparison of waveguide-coupled and free-space-coupled PL from the $r = 10$ μm microring. The ZPL is visible in the free-space emission, but resonance features are not.

counter-clockwise and travels away from the GC to a waveguide taper. The waveguide from MRR and GC is 200 μm long, resulting in 0.36 dB of loss. The net efficiency between light in a cavity mode and the front of the GC is thus estimated to be 43%.

Figure 5(b) shows the PL polarization. To measure polarization, a half wave plate and polarizer were placed before the razor blade assembly. The allowed polarization angle is twice the half wave plate angle. Values labeled ‘GC’ refer to the amplitudes of different peaks in the waveguide-coupled sideband of the $r = 10$ μm MRR (figure 4(d)). Unpatterned values refer to the ZPL amplitude of an unpatterned control region. The degree of polarization of the GC emission was substantially stronger (88% depth) than that of the control (7.8% depth), which is corroborative because the GC is designed to direct only TE light vertically towards the objective. A half wave plate angle of zero corresponds to S-polarization (E-field perpendicular to the dichroic surface is nonzero). The sample was mounted roughly parallel to the setup such that TE polarized light in its waveguides ended up as S-polarized in the setup. The maximum of GC traces actually occurred at $-10° \pm 5°$. Most likely, this means that the sample was rotated by this amount away from parallel.

Figure 5(c) compares waveguide-coupled and free-space-coupled emission for the $r = 10$ μm MRR. In the sideband, there was no periodic resonance structure in the free-space-coupled component. This confirms that PL was not preferentially emitted into resonator modes, rather, that PL which was emitted into the modes preferentially coupled to the bus waveguide. For this radius and above, most of the pump power missed the MRR waveguide implanted with W centers and instead went through the ring center. As a result, the free-space-coupled ZPL was dimmer than the unpatterned ZPL. This contrasts with similar measurements of a microdisk in [24] wherein the microdisk was implanted throughout, and free-space emission was slightly brighter than the control.

A broad emission band appeared at 1186–1202 nm, which we believe to originate from unimplanted silicon. In this sample, the silicon slab more than 3 μm from waveguides was not etched in order to reduce electron beam write times (see figure 2(b)), which means, as an artifact of fabrication, there was an unetched, unimplanted silicon disk in the center of the MRR that was, for the large MRRs, illuminated with the majority of the pump power. This band was visible in all three traces, but its brightness relative to the ZPL increased by two orders-of-magnitude when comparing the free-space spectra between the MRR and unpatterned control. This feature was strongly non-linear and sensitive to pump power and spot size, explaining why it is prominent here (21 mW pump) but not in most measurements above (11 mW pump). In both control and waveguide-coupled traces, it was about one order-of-magnitude dimmer than the W-center sideband; nevertheless, we can observe that this component was waveguided as evidenced by the resonances here visible at 1194 nm, 1198 nm, and 1202 nm. Luminescence features at these wavelengths have been observed from other silicon samples [10, 26] and likely originate from a diversity of broadened phonon-assisted transitions and/or other defect states [9].

5. Discussion

Previous work on waveguide-coupled W-center emission used electrical pumping and on-chip detection [14] whereas this work used free-space optical pumping and collection techniques. The integrated and free-space approaches present complementary advantages for research. As a consequence of optical pumping, a whole array of devices can be probed in a single cooldown. Luminescence properties can be studied independent of electrical properties such as ohmic heating. Finally, fabrication is two-step (Si rib etch, Si ion implant) instead of seven-step needed for electrical injection (Si rib etch, Si partial etch, Si ion implant, heavy/light boron, heavy/light phosphorus) [14]. In addition to these optical pumping advantages, optical collection provides other complementary advantages. Superconducting detectors are not required, meaning that operating temperature can be 40 K instead of 1 K. Free-space collection allows use of commercial detection instruments (e.g. spectrometers, high-speed diodes, cameras) without a need for fibers in the cryostat. The presented techniques could thus play a central role in the characterization of cryogenic silicon photonic platforms. As an example, we have observed the FSRs of various MRRs and precisely determined their group velocity by examining the sideband spectrum, while any sort of on-chip detection approach would require an on-chip spectrometer to provide similar information.

In several cases, it would be desirable to make a resonance align with the bright ZPL. This alignment presents a challenge because both the resonances and the ZPL are narrow, and the resonant wavelengths are sensitive to fabrication variability. One approach to resonance alignment are cavities designed with FSRs smaller than the ZPL linewidth, which would ensure that at least one resonance would fall within the ZPL. In this work, the $r = 30$ μm MRR has an FSR that meets the condition; however, this device is much larger than the pump spot size, so nearly all of the pump power passes through the center of the ring, missing the implanted waveguide. We fabricated a $r = 40$ μm device, but it was not measurable for this reason. Next steps could include modifying the ring shape or increasing pump power further. In general, the approach of using small-FSR cavities has the issue that they must be physically large, meaning that they have undesirably large footprint and capacitance. Additionally, without a means of tuning, parasitic index changes (e.g. from electrical pumping) cannot be countered.

Refractive index tuning is a more favorable approach for static and dynamic resonance alignment. Tuning is typically implemented with heaters at room temperature. Below 4 K, however, thermooptic tuning is likely not viable because $\mathrm{d}n/dT$ approaches zero [27]. There are other candidate approaches to refractive index tuning at low temperature, including carrier depletion modulation [28], electromechanical tuning [29], and localizing heating to raise the device temperature to between 4 K and 40 K. Static adjustment of MRR resonances could be realized with defect-mediated or other postfabrication trimming [30–32], although these techniques are not capable of dynamic adjustment.

Investigations into a W-center laser would be of particular interest for further work. We did not observe conclusive evidence of lasing in this study primarily due to the resonance alignment challenge. A silicon laser would have a variety of applications for on-chip optical measurement and non-linear optics, for example, photon pair generation through degenerate four wave mixing [33, 34]. Stimulated emission has been observed from G-center defects in nanopatterned silicon [35]. It remains to be shown whether population inversion—let alone amplification—can be achieved in a waveguide that is implanted with W centers.

Substantial research has been dedicated to study of PL in photonic crystal cavities, which differ significantly from MRR cavities [36–38]. Photonic crystal cavity designs often have a goal of minimizing mode volume, while MRRs make use of their small FSRs to more easily align a cavity resonance to the emitter wavelength. Their FSRs are inversely proportional to their mode volumes, which are the product of circumference and modal cross-section. MRRs are essentially bent waveguides that can be oxide-clad. As compared to air-clad photonic crystals, MRRs integrate more readily with traditional silicon photonic platforms, metal layers for index tuning, and other waveguide-based photonic integrated circuits.

The data in this manuscript might be improved by characterizing the GC response spectrum, but likely only slightly. As seen in figure 2(c) and (d), emission appeared to originate entirely from the front of the GC, and sometimes the emission pattern was bifurcated into two lobes, which indicates that this GC is not optimal. Despite the GC being non-optimal, its response is flat over the phonon sideband of interest, which can be inferred by comparing the shape of the control spectrum to the envelope of GC peaks in figure 4. The current setup would be ideal for GC characterization and optimization in further work: using an array of identical sources coupled to varying GCs, the GC that is optimal for objective-coupled normal emission at 1218 nm at 20 K could be found in a single cooldown.

This work presents several other directions for further study. Optical cavities provide a degree of control over emitter lifetime, as in reference [20]. Source lifetime is a critical parameter for superconducting optoelectronic neural networks [39]. Other silicon defect centers can be induced by lithium, carbon, or copper implants [9]. We find that, in practice, W centers produced by silicon ion implant have been more reliable in terms of brightness uniformity. These other centers possess complementary advantages, and further work could apply the current techniques to their investigation. Another prospective direction would be using the broad sideband for wavelength-division multiplexed (WDM) sources. Although the ZPL peak is 21-times brighter than the peak of the sideband, the sideband contains 55% of total emission power when integrated from 1230 nm to 1275 nm. This power may prove sufficient to implement multiwavelength neuromorphic silicon photonic architectures [40] with monolithically integrated light sources. Finally, engineering W-center density to be on the order of λ^{-3} (one emitter per wavelength volume) could be a route to silicon single-photon sources; however, at this time, the density of W centers has not been measured, let alone as a function of implant parameters.

In conclusion, we have used micro-PL measurements with a spatial-filtering technique to unambiguously measure microcavity- and waveguide-coupled luminescence from silicon light sources. These all-silicon sources were locally created with lithographic patterning and integrated with photonic circuits. We found that light emitted into resonant modes is preferentially coupled to an adjacent waveguide. We have illustrated how this setup can employ the phonon sideband as a tool to characterize cryogenic silicon photonic circuits, extracting device values for FSR, group velocity, quality factor, and polarization. These results and methods open numerous directions for further research of fundamental defect center properties, all-silicon active devices, and large-scale photonic information processing.

We thank R. Boutelle and K. Silverman for helpful discussions on the experimental setup. We thank S.-P. Yu and N. Sanford for editorial input. This is a contribution of NIST, an agency of the U.S. Government, not subject to copyright.

Abstract—In this work, we report on an ultrafast direct measurement on the transient ferroelectric polarization switching in hafnium zirconium oxide with a crossbar metal-insulator-metal (MIM) structure. A record low sub-nanosecond characteristic switching time of 925 ps was achieved, supported by the nucleation limited switching model. The impact of electric field, film thickness and device area on the polarization switching speed is systematically studied.

I. Introduction

Due to the fast speed [1-7], high retention/endurance [8, 9] and CMOS compatible process, ferroelectric (FE) hafnium oxide (HfO_2), such as hafnium zirconium oxide (HZO) [10], has been the promising material for various ferroelectric device applications such as ferroelectric memory (FeRAM), ferroelectric field-effect transistors (Fe-FETs) [1,2,4] and negative-capacitance FETs (NC-FETs) [11-13]. In all these devices, ferroelectric polarization switching speed is a critical factor, which directly determines the working speed of the device. The reported ferroelectric polarization switching times in literatures broadly scatter from few ns to µs [1-7]. Recently, it was studied that the RC time constant in the measurement system can be one of the key problems to under-estimate the intrinsic fast switch speed of ferroelectric hafnium oxide, leading to a broad distribution of polarization switching time [7]. By excluding the impact of RC, 10 ns full polarization switching or few ns characteristics switching time (t_0) were achieved [7]. The fast, scalable in dimension and non-volatile properties enable HfO_2 based Fe-FET to be a strong energy-efficient candidate for non-volatile memory applications and even for the faster volatile memories [14]. However, to replace volatile memories like dynamic RAM (DRAM) or even static RAM (SRAM), sub-ns or GHz operational speed is required and has not been demonstrated in FE HfO_2 system directly.

In this work, the transient ferroelectric polarization switching dynamics in HZO is directly measured by an ultrafast pulse measurement setup. A record low characteristic switching time down to 925 ps is achieved for the first time in sub-ns range, extracted by a nucleation limited switching (NLS) model [15]. A W/HZO/W crossbar capacitor structure and fabrication process are developed to scale down the device area to few µm^2. RC time constants are carefully measured by both capacitance and resistance measurements directly. It is demonstrated that the capacitor area has a significant impact on polarization switching time not because of the RC time constant but due to the intrinsic area dependence. The intrinsic area dependence is ascribed to the multi-grain polycrystalline nature of the FE HZO thin film. The electric field dependence and film thickness dependence are also systematically studied.

II. Experiments

A photo image of the fabricated W/HZO/W crossbar MIM structure is shown in Fig. 1. W is used for both top and bottom electrodes. Ti/Au pad is used on top of bottom W electrode to prevent HZO thin film formation during the atomic layer deposition (ALD) process and also reduce the probe contact resistance. An insulating sapphire substrate is employed to reduce the parasitic effects and signal reflection. The device fabrication process is described in Fig. 2(a). The starting point is an insulating sapphire substrate. W sputtering followed by CF_4/Ar dry etch was used to pattern the bottom W electrodes. Ti/Au contact pads were then defined by photo lithography, e-beam evaporation and a lift-off process. HZO (Hf:Zr=1:1) was deposited by ALD at 200 °C using TDMAHf ($[(CH_3)_2N]_4Hf$), TDMAZr ($[(CH_3)_2N]_4Zr$) and H_2O as Hf, Zr and O precursors. The top W electrodes were defined by sputtering and a lift-off process. A 500 °C rapid thermal annealing was then performed in N_2 for 60 s. Fig. 2(b) and 2(c) shows the cross-sectional schematic of fabricated capacitor and the TEM image on FE HZO. Fig. 3 shows the polarization versus electric field (P-E) hysteresis loop of a crossbar MIM capacitor with 8 nm HZO, showing well-behaved ferroelectric properties. Fig. 4 shows the capacitance-voltage (C-V) characteristics of a crossbar MIM capacitor with 15 nm HZO, with a typical butterfly-shape ferroelectric hysteresis. Fig. 5 is a circuit diagram of the ultrafast pulse measurement setup. A high speed pulse generator along with high speed and high power amplifier (leading to maximum of ~9 V and 300 ps rise time in this work) and a 80 GS/s oscilloscope were used to generate the voltage pulses and monitor the transient switching current. Impedance matched probes and pick-off tee were used to minimize the signal reflections. A positive-up-negative-down (PUND) pulse sequence was applied to directly measure the polarization switching current [7, 16], as shown in Fig. 6, highlighting the preset pulse, switching pulse and non-switching pulse, as also pointed out in Fig. 3. Fig. 7 shows the resistances and the corresponding RC time constant versus different areas, among which the smallest RC constant is below 200 ps. The RC time constants are calculated using experimentally measured resistances and capacitances.

III. Results and Discussion

The voltage pulses with 300 ps rise-time and the corresponding transient current responses are shown in Fig. 8 for both switching (pulse 1) and non-switching (pulse 2) pulses in the PUND measurement. The current response to switching pulse

Shrestha, Pragya; Lyu, xiao; Si, Mengwei; Cheung, Kin (Charles); Ye, Pei. "First Direct Measurement of Sub-Nanosecond Polarization Switching in Ferroelectric Hafnium Zirconium Oxide." Paper presented at IEEE International Electron Devices Meeting (IEDM), SAn Francisco, CA, US. December 07, 2019 - December 11, 2019.

(I_{pulse1}) is wider compared to the current response to non-switching pulse (I_{pulse2}) due to the extra polarization switching current. Fig. 9 plots the transient current I_{pulse1}, I_{pulse2} and I_{FE} in the same time scale. The net polarization switching current I_{FE} is calculated by $I_{FE}=I_{pulse1}-I_{pulse2}$. The transient polarization charge density is calculated by the integration of I_{FE} ($P = \int I_{FE}\, dt$), as shown in Fig. 10. A nucleation limited switching model was applied for the multi-grain polycrystalline HZO to extract the characteristic switching time constant. In NLS model for a single grain element, the polarization switching dynamics follow the equation as $P = P_S(1-\exp(-\left(\frac{t}{t_0}\right)^{\beta}))$, where β is an exponential parameter and t_0 is a voltage-dependent characteristic switching time [5,15]. β=2 is used in this work due to 2-dimentional nature of thin film. Sub-ns polarization switching was achieved in 15 nm HZO at 9 V and with a device area of 8.4 μm^2, where the extracted characteristic switching time is 925 ps, as shown in Fig. 10.

The transient FE switching currents for 15 nm HZO capacitors with different areas (Voltage=9 V, E=0.6 V/nm) are plotted in Fig. 11 and the corresponding transient polarization charge densities are shown in Fig. 12. There is a clear area-dependent switching speed as indicated in Fig. 13. The RC time constants for these devices (as shown in Fig. 7) are about 5 times smaller than the characteristic switching times, suggesting the measured switching speed is not limited by the RC effect. Therefore, the ferroelectric polarization switching has an intrinsic area dependence. It is understood that the polarization switching process in polycrystalline FE thin film is a sequential switching process of each elemental grain, according to the nucleation limited switching model, as shown in Fig. 14. At scaled device size, the grain number is significantly reduced so that the polarization switching speed is improved.

Measurements of I_{FE} on 10 nm HZO capacitors under different electric fields are shown in Fig. 15, showing a clear electric field dependence. The corresponding transient polarization charge densities are shown in Fig. 16. Fig. 17 shows the extracted characteristic switching time versus electric field for 10 nm HZO, showing faster polarization switching under higher electric field. Fig. 18 and Fig. 19 show the thickness-dependent transient polarization switching current and transient polarization charge density. The HZO capacitors of each thickness are measured at maximum voltage allowed. The corresponding extracted characteristic time constants versus HZO thickness is shown in Fig. 20, from which the trend of thickness dependence is clear that thicker films are faster. Fig. 21 is a summary of the thickness-dependent remnant polarization (P_r).

The ferroelectric polarization switching time of the FE HZO crossbar capacitor is benchmarked with the reported fastest polarization switching times on FE HfO_2 in literatures, as shown in Table. I. The experimental devices have different structures including capacitor structure (MIM) and FeFET structure, different FE HfO_2, different electrode materials including W, WN, TiN and Ni, different thicknesses from 8 nm to 15 nm and different applied voltage so that under different electric fields. Fig. 22 shows the switching time versus electric field from the benchmark Table I. In this work, a sub-ns (925 ps) record low full polarization switching time is achieved for the first time.

IV. CONCLUSION

In summary, we report on a record low sub-ns characteristic switching time of 925 ps on FE HZO, by a direct ultrafast measurement of transient polarization switching current. The impact of electric field, film thickness and device area on polarization switching speed is systematically studied. The ferroelectric switching speed is significantly improved compared to previous reports and more importantly is approaching GHz regime, suggesting FE HZO to be a promising and competitive high-speed non-volatile memory technology and has the potential even to replace the DRAM and SRAM for high-density, high-speed, and both on-chip and off-chip memories.

Abstract

Due to its tremendous potential, Augmented Reality (AR) has experienced a recent surge in adoption and integration within the manufacturing enterprise. While industrial AR has been successfully implemented and shown to have significant benefits in a variety of applications, proper use case development, application-specific evaluation, and data interoperability remain open research challenges. In this work, we demonstrate an AR-enabled use case that allows for remote monitoring and inspection of manufacturing systems by overlaying contextual information, such as machine execution data, over the video feed of the manufacturing floor. Additionally, we discuss challenges related to our prototype's implementation and potential opportunities to mitigate such issues through standard indoor geospatial representations.

1 Introduction

In recent years, Augmented Reality (AR) has proven to be a versatile technology that has been leveraged in a multitude of domains including many industrial applications, such as manufacturing planning [5], assembly guidance [14] and maintenance and repair [6] among many others [11]. In this paper, we discuss a new use case for industrial AR that demonstrates remote inspection and monitoring of manufacturing systems by streaming and contextually representing real-time machine process information over the video stream of an Internet Protocol (IP) camera that can be controlled over the network. In doing so, our prototype system provides users, e.g., foremen, operators, and shop managers, with additional capabilities that leverage existing data structures already deployed within smart manufacturing systems. Moreover, by displaying manufacturing information in AR rather than in a strictly digital environment, dynamic elements common to a workshop floor that are much more difficult or even infeasible to track or model are included, such as humans or tools. Our presented prototype also accepts Computer-Aided Design (CAD) models and other virtual 3D objects as inputs that can be layered onto the video feed for a better representation and correlation between the digital (or *as-designed*) models and their physical (or *as-realized*) instances.

During prototyping, we encountered a number of design challenges related to object tracking and camera pose estimation due to the scale of the scene and the rather large distance between the camera and target. These issues are common across other crowded, complex environments akin to busy production floors. This means that traditional tracking methods, such as marker-based tracking, implemented in existing frameworks are not immediately applicable to this scale or are simply infeasible. In other words, popular marker-based recognition methods used in *large target, small field* situations seem to fail when applied to *small target, large field* scenarios.

2 Background

Over the years, numerous different AR tracking and registration techniques have been proposed with various benefits and drawbacks depending on the application context [1, 13].

Fiducial markers have been used in AR applications for decades with diverse designs and implementations [15]. The maturity of marker detection and tracking techniques allows for efficient and reliable pose estimation of the camera that can be computed leveraging the four corners of a marker. In spite of their simplicity and robustness, fiducials have the disadvantage of requiring setup and could cause aesthetic issues, making them inappropriate for certain application environments. In this sense, feature-based markers offer an alternative that trades simplicity for aesthetics, enabled by popular frameworks such as Vuforia[1] and Wikitude[2]. Koch et al. [9] demonstrate how *natural markers* within a building, such as exit signs, can be used for tracking while being seamlessly immersed in the environment.

While both *artificial* and *natural* markers are well-suited for most AR applications, where the markers are relatively close to the camera, success of marker detection and the precision of pose estimation generally decreases with distance. This challenge is evident when applying techniques to wider, more complex environments such as manufacturing floors (often to the point where markers become undetectable). *Artificial* markers seem to perform better than the *natural* markers in such conditions, being more robust to far-field detection and bad camera focus conditions due to their purposeful design.

Even so, most markers were not designed with far-field detection in mind, as most of them report detection ranges of around 3 m for a 20 x 20 cm marker [10]. Cho and Neumann [3] acknowledge this range limitation and present a multiring fiducial design that is able to smoothly zoom-out from near-field to room-sized detection, promising a detection range of up to 4.5 m using a 4 cm diameter circular fiducial. However, at least four of them are required to be in view to calculate the camera's pose. Claus and Fitzgibbon [4] propose a machine learning approach to marker detection, using a marker comprised of four circles on a white background, that shows a significant decrease in error rates compared to square marker detection systems for challenging environment conditions, e.g., bad lighting and far-field detection.

Recently, marker-less methods, such as Simultaneous Localization and Mapping (SLAM) [12], have gained popularity as an alternative to marker-based tracking. Such techniques aim to dynamically build a 3D map of the environment using the already existing natural features without the need of a former setup. This approach is particularly useful for unknown environments or when careful marker placement in the environment is impossible or impractical. Researchers have extended SLAM-based methods to deal with large, complex and dynamic environments. To this extent, Castle et al. [2] present a technique for wide-area tracking by creating multiple distinct maps of different scales that can be used in unison by transitioning from one map to another appropriately. This modular approach has the advantage of only needing to rebuild a subsection of the maps when a change occurs in the target room's configuration. While marker-less tracking techniques can be valuable for tracking the position and orientation of the camera within the environment without the limitation of needing a marker in view at all times, additional work can be required to correctly and automatically register the digital objects in the tracked scene.

Despite its limitations and advances in marker-less tracking methods, marker-based tracking is still effective and commonly used for prototyping purposes due to its robustness and the effortless implementation afforded by frameworks. These limitations can be alleviated in

[1] For more information, visit http://www.ptc.com/en/products/augmented-reality.
[2] For more information, visit https://www.wikitude.com.

combination with marker-less techniques but ultimately there are still challenges when applying these to large, busy environments. These issues were made apparent during the development of our room scale prototypes, which means that they would only be amplified on a larger scale and would require alternative solutions.

3 Camera-Supported Monitoring of Production Systems

To explore opportunities for far-field tracking in the context of industrial AR, we developed a prototype to interface with the National Institute of Standards and Technology (NIST) Smart Manufacturing Systems (SMS) Test Bed[3]. Streaming near-real-time data via a web portal, the SMS Test Bed is representative of a contract manufacturer with a good mix of machine tools. Such an environment offers appropriate testing conditions, e.g., occlusion due to crowded spaces. Our initial testing described here was conducted in the Data Information Visualization and Exploration (DIVE) Lab, recently deployed at NIST.

Our prototype makes use of an off-the-shelf Pan-Tilt-Zoom (PTZ) Internet Protocol (IP) Camera that can stream the video feed and be controlled via the Hypertext Transfer Protocol (HTTP) protocol. A *Unity* desktop application receives the video stream and allows the user to send PTZ commands to the camera, via the keyboard, over the network. Simultaneously, *MTConnect* data generated by computer numerical control (CNC) machines is continuously fetched from the SMS Test Bed, as shown in Figure 1. Quick Response (QR) Codes are used to represent different CNC machines and encode their *MTConnect* Universally Unique IDentifier (UUID). *ZXing*, a barcode processing library, is used for QR Code detection and decoding, while *OpenCV* is used for drawing the detection information on the processed frames. When a QR Code is detected and successfully decoded, the current *MTConnect* data for the respective machine is shown on screen, as shown in Figure 2. In this case, two QR Codes are detected in the frame, representing two different machines: *GFAgie01* and *Mazak01*. Timestamped data corresponding to the two machines is pulled from the SMS Test Bed and displayed on the side-panels next to the video feed as long as they are in view. In doing so, an operator is able to remotely identify which machines are currently producing value or are experiencing downtime.

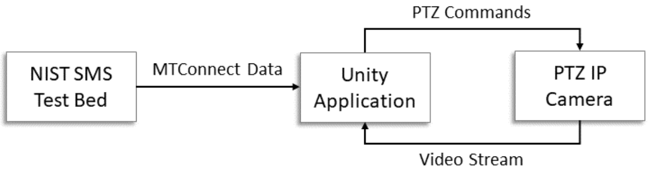

Figure 1: Prototype process diagram.

3.1 Approach Limitations

While our prototype serves as a proof of concept designed to make use of simple ubiquitous technologies, e.g., IP cameras and QR codes, there are some obvious limitations to this approach.

First of all, even more so than AR markers, QR codes are not designed for far-field use, being difficult to detect and especially decode across large distances, unless scaled appropriately, which in itself is often infeasible or impractical. Secondly, there are scalability issues concerning

[3] Access to data generated by the SMS Test Bed can be found here: http://smstestbed.nist.gov/.

the number of QR codes in view at any given time, which in turn affects how well users can access data for which they are interested. In other words, the simultaneous detection of multiple machines would also increase the amount of unwanted data on the screen. Additionally, each machine needs to be physically tagged and the markers need to be in the camera's line of sight. Our design allows users to manipulate the line of sight of the camera by accessing its PTZ capabilities. However, detectable markers still (a) need to be oriented orthogonal (or nearly orthogonal) to the camera and (b) cannot be obstructed by other physical objects. This suggests that multiple cameras would be needed to ensure that no machine is obstructed from view. Lastly, while not necessarily a drawback for some use cases, this approach is limited to displaying 2D data over the video feed, given a lack of 3D spacial understanding of the scene.

3.2 Augmenting the Video Feed with Digital 3D Data

Building on the previously described prototype, we present an additional use case showcasing the potential of replacing QR Codes with AR-ready fiducial markers that are more easily tracked by design. Given that the markers can be used to compute the camera pose, 3D objects can be overlaid onto the video stream with an accurate perspective, in addition to the 2D data of the previous use case. This offers the potential of digital models of machines being superimposed over their physical counterparts or displaying any other spatial information in the scene, perhaps in different layers depending on the use context. This is illustrated in Fig. 3, where three CAD models of CNC machines are overlaid on the video feed using the MAXST AR software development kit[4]. A model of the DIVE Lab was created, where three points of interest (the three tables) were mapped. Using this model, the points of interest can be accurately tracked while moving the camera by having a single AR marker in view, thus mitigating some of the issues highlighted by the previous use case such as individual machine tagging.

Note that these prototypes have been implemented and tested in a typical room scale laboratory setting. As described in Section 2, while the prototypes work at this scale, they might not immediately scale appropriately for the desired use case, i.e., a large, crowded, and complex

physical environment. Further work and experimentation is required to implement prototype iterations at a larger scale to better understand the full scope of challenges.

4 Future Directions & Opportunities

In this paper, we presented two deployed prototypes that leverage the NIST SMS Test Bed and the DIVE Lab to explore issues related to far-field object tracking in the context of production systems. Based on our preliminary findings, we discuss research directions, including opportunities for standards development.

AR framework developers are pushing towards markerless detection, yet for prototyping and testing purposes, marker-based tracking is still very prevalent throughout industrial implementations. In the case of production systems, where the primary manufacturing assets, such as cranes, industrial robots, and CNC machines, are affixed to a particular location, geospatial definitions can offer more precise data to anchor critical objects in a scene. In other words, rather than relying on techniques such as SLAM to build a feature-map of large area such as a factory floor, we believe that building an as-planned indoor representation might provide additional benefits, such as the ability to include semantics related to the tracked elements and incorporate domain-specific information akin to our MTConnect data streams. Additionally, this approach would alleviate some of the challenges discussed earlier related to far-field marker tracking by removing the need of individual machine tagging and minimizing the number of markers required for the whole scene. This would have the potential for reducing burdens, in terms of both cost, time, and equipment, for testing industrial AR-based prototyping iterations. Furthermore, opportunities exist for the development of measurements methods for the efficiency and appropriateness of as-planned indoor representations.

Moving forward, we plan to explore how richer, pre-defined geospatial representations can influence industrial AR implementation. Based on our early findings, a geospatial representation of a room simplifies the implementation of far-field tracking systems for indoor use. In our prototype, we plan to leverage IndoorGML [8], a standard data format from the Open Geospatial Consortium (OGC)[5]. Specifically designed for formally describing scenarios that require positional data of physical entities inside buildings, IndoorGML[6] provides a framework for geospatial information that relates properties and features of indoor spaces within a flexible framework. We chose IndoorGML for implementation due to existing available tools built around the technology, including an editor for generating IndoorGML documents [7] and

[5] For more information, refer to https://www.opengeospatial.org.
[6] For more information, refer to http://www.indoorgml.net.

an existing link to scene generation in Unity[7], a 3D development platform. Leveraging such geospatial definitions, we hypothesize that (1) less markers would be required for tracking a set of objects, (2) the burden of introducing additional spatially-aware sensors into the predefined environment would be lessened, and (3) such representations coupled with vision-based tracking, like SLAM, would provide more robust object tracking solutions.

Similar to other visualization-driven technologies, industrial AR must overcome a divergence of two traditionally separated standards development communities: (i) the primarily gaming-driven AR frameworks contributed by standards developments organizations (SDOs) such as the Khronos Group and OGC and (ii) data interoperability solutions from SDOs focused on smart manufacturing systems such as the MTConnect Institute[8] and the Open Platform Communications (OPC) Foundation[9]. We believe that our work will provide more guidance and direction for the revision or extension of existing standards and/or opportunities for new standards development. For example, we plan to test how data elements standards by the AR-focused SDOs for affixed and mobile objects (e.g., load-bearing columns and furniture, respectively) relate to analogous manufacturing assets, such as CNC machining centers (affixed) and tooling carts (mobile). We believe that such exploratory tasks will pave the way for the conformance mappings between the two standards communities.

*Author e-mail address: (*sumit.bhushan@nist.gov, †lijun.ma@nist.gov)*

Abstract: We outline a proposal to realize Electromagnetically Induced Transparency (EIT) with the potential to store Terahertz (THz) optical pulses in Cesium atoms. Such a system, when experimentally realized, has a potential to make Quantum Communication possible with THz signals.

1. Introduction

Terahertz (THz) (0.1 – 10 THz) signals suffer less attenuation and scintillation effects caused by fog, dust, and airborne particles in comparison to Infrared (IR) signals [1, 2]. At the same time, the high level of directionality associated with THz signals reduces the vulnerability to eavesdropping [2]. Additionally, THz signals are compatible with superconducting based quantum computers. Taken together, these factors make THz frequencies an attractive regime for communication purposes and there are several groups conducting research in this field. However, THz quantum communication has not been fully investigated [3, 4]. Here, we present a study in which an ensemble of Cesium atoms is shown to have the potential to store THz signals via Electromagnetically Induced Transparency (EIT). In this scheme, the Cesium atoms are excited to the Rydberg energy levels and EIT occurs within the Rydberg manifold. These energy levels have been chosen because the transition frequencies between the Rydberg levels are of the order of THz and this suggests it is possible to realize EIT based quantum memory for THz signals. We present the theoretical model and simulation results of this scheme.

2. Theoretical Model

The energy level diagram of our model is shown in Fig.1. The ground level (represented as $|g\rangle$) atoms are excited to the Rydberg level $30P_{1/2}$ (represented as $|1\rangle$) by a very strong pulsed Ultraviolet (UV) light at 320 nm and with a repetition rate of GHz order [5]. $|1\rangle$ - $|3\rangle$ and $|2\rangle$ - $|3\rangle$ are the probe and control transitions respectively. The decay from the energy levels $|1\rangle$, $|2\rangle$, and $|3\rangle$ and all other intermediate levels to $|g\rangle$ is compensated by a very strong 320 nm laser which pumps almost all the atoms to $|1\rangle$. Therefore, the four-level system effectively becomes the three-level system shown in Fig.1, which can be used for EIT.

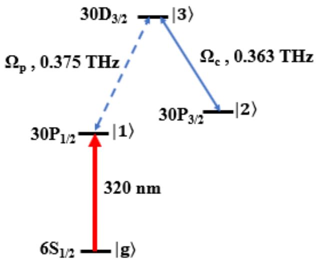

Fig.1 Simplified Cs energy level diagram for our model. Ω_p and Ω_c are the Rabi frequencies of probe and control fields respectively.

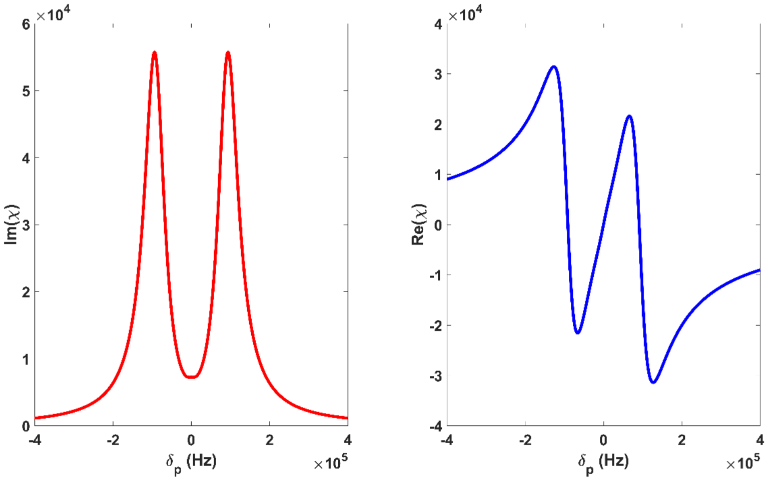
The susceptibility of the three-level light-matter system can be written as [6]

$$\chi = i\frac{Nd^2}{\varepsilon_0 \hbar}\frac{1}{\left[\frac{(\Omega_c/2)^2}{\gamma_d - i(\delta_p - \delta_c)} + (\gamma_p - i\delta_p)\right]}$$

Bhushan, Sumit; Slattery, Oliver T.; Tang, Xiao; Ma, Lijun. "Terahertz Electromagnetically Induced Transparency in Cesium Atoms." Paper presented at Frontier in Optics (FIO). September 14, 2020 - September 17, 2020.

where N is the atomic number density, d is the dipole moment associated with probe transition, γ_d is the decoherence rate between $|1\rangle$ and $|2\rangle$, γ_p is the probe decay rate, δ_p (δ_c) is the detuning of probe (control) from its corresponding transition, ε_0 is the permittivity of free space, and ħ is $h/2\pi$ where h is the Planck's constant. The real and imaginary parts of the above equation have been plotted as a function of δ_p as shown in Fig. 2



(a) (b)

Fig.2 (a) The imaginary part of the susceptibility and (b) the real part of susceptibility both plotted as a function of δ_p. The values of the other equation parameters are: $N = 10^{15}$ atoms/m^3, $d = 5.69 \times 10^{-26}$ C.m, $\gamma_p = 0.046$ MHz, $\gamma_d = 0.018$ MHz, $\delta_c = 0$, and $\Omega_c = 4\gamma_p$. The typical EIT features are clearly visible.

The values of various parameters written in the caption of Fig.2 have been either taken from or calculated from the relevant formula given in Ref. [7, 8]. The signal pulse can be spatially compressed inside the atomic ensemble due to the reduction of the probe's group velocity. Note that this reduction in the group velocity is evident from the steep slope around $\delta_p = 0$ in Fig. 2(b). After the signal enters the medium, one can adiabatically turn off the control field and the quantum state of the signals will be mapped on the atomic spin wave. When needed, the signal can be retrieved by turning on the control field. As mentioned above, this system is effectively three levels, hence the readout of the stored pulse will be the same as in a usual three level lambda type EIT based quantum memory. Such a scheme would be useful for quantum memory using THz signals.

Abstract

We developed a measurement system that combines on-wafer metrology and high-frequency network analysis to characterize the response of transmission-line integrated Er-GaAs and InGaAs photomixers up to 1 THz to support the telecommunication and electronics industry.

Radio frequency (RF) test equipment is used in the electronics and telecommunications industry to characterize electronic devices from DC to above 1 THz. Commercial semiconductor foundries need proper high-frequency diagnostic signals to reduce the time-intensive and costly trial-and-error process during development of next-generation wireless communication, computer processing, and other high-speed electronics [1–3]. Complex modulated-signal tests use arbitrary waveforms that are generated by discrete digital steps to construct analog signals, but are fundamentally limited in frequency based on the operating frequency of the digital circuit. Drawbacks to the current RF approach include frequency-banded rectangular waveguides, amplification of phase noise, and poor stability caused by multiplying the RF source to the desired frequency. While interleaving multiple digital sources is one way to overcome the issue, amplitude fluctuation, timing jitter, and noisy signals above 40 GHz remain an issue [4].

Here, we present a broadband optoelectronic source for linear and non-linear network analysis of wafer-based devices and the first steps toward a terahertz synthesizer. We first separate individual frequencies of an optical comb and pass them through a phase-and-amplitude control array that steers the optical frequencies to a fiber. The modulated signals in the fiber are converted into an electrical signal by dividing the frequency down with a photomixers that operate to a terahertz. As a part of this new signal generation paradigm we grew erbium doped GaAs and InGaAs photomixers via molecular beam epitaxy on semi-insulating InP substrates and defined electrodes and co-planar waveguide structures using traditional and electron-beam lithography techniques. We leveraged recent advances in the photomixer field to simulate and incorporate plasmonic electrode structures to enhance terahertz conversion efficiency. Figure 1a shows SEM images of the fabricated devices as well as a multiphysics simulation of the plasmonic enhancement of the optical absorption. Two teeth of an optical frequency comb source excited the photomixers, and a WR1 wafer probe and extender head connected to a vector network analyzer measured the output signal up to 1 THz. Fig. 1b shows the measurement setup and initial data.

Smith, Kassi; Bosworth, Bryan; Jungwirth, Nick; Cheron, Jerome; Orloff, Nate; Long, Chris; Williams, Dylan; Chamberlin, Richard; Quinlan, Franklyn; Fortier, Tara; Feldman, Ari. "On-Wafer Metrology of a Transmission Line Integrated Terahertz Source." Paper presented at CLEO: Laser Science to Photonic Applications, San Jose, CA, US. May 10, 2020 - May 15, 2020.

There are a large number of industries that rely on electronic devices that operate over a terahertz and currently no way to measure or calibrate devices that operate within that frequency regime. Continuous-wave (CW) terahertz photomixing devices have emerged along side a number of advances to photoconductive materials, electrode design, operating frequency, and conversion efficiency [5]. $In_{0.53}Ga_{0.47}As$ grown on semi-insulating InP substrates allow utilization of low-cost and readily available Er-doped fiber lasers that operate at 1550 nm. While InGaAs is a promising material, there is room to reduce dark current and increase optoelectronic conversion efficiency [6]. InGaAs offers much higher mobilities than the more commonly utilized LT-GaAs, but suffers from lower conversion efficiency at typical bias voltages [7–9]. Implementing advanced growth techniques such as incorporated nanostructures and Bragg reflectors are ways to improve bandwidth, increase signal output, improve resistivity, and add the ability to tune photocarrier lifetimes.

Historically, high-frequency photomixer devices have been intended for terahertz radiation. They are operated by pumping an ultra-fast mode-locked laser onto the electrode contact and measuring the radiated power as a function of bias voltage and optical pump power. Alternatively, fabrication of co-planar transmission-line integrated photomixers with terahertz output represents an innovative advancement for on-wafer metrology. When the photomixer is excited by the heterodyned beat of two tones from an optical frequency comb a high fidelity terahertz signal is generated and can be used as a convenient on-wafer source. Dividing down from the optical regime reduces phase noise at these frequencies, as opposed to traditional multiplication which increases phase noise. Through on-wafer metrology techniques, the propagation constant and dispersion effects of the transmission line can be solved for, which allows the reference plane to be rolled to a plane of interest. For example, when using a photomixer as a source, it will need to be coupled to or embedded within a device or material of interest and the reference plane can be rolled to that interface [10]. Furthermore, when a device is fabricated on an electro-optic substrate, optical network analysis techniques can be used to examine the outgoing and reflected waves of devices under test [11]. The ability to generate pure sine waves up to 1 THz and optically measure outgoing waves and their reflection off a device or material-under-test is a useful measurement tool that will enable development of next-generation technologies with first-pass design success [12].

***Abstract*—Industrial Internet of Things (IIoT) is predicted to drive the fourth industrial revolution through massive interconnection of industrial devices, such as sensors, controllers and actuators, integrating advances in smart machinery and data analytics driven by computing, networking and artificial intelligence techniques. The massive interconnections between industrial devices increase not only information exchange, productivity, and resource efficiency, but also cybersecurity risks and their impact to the IIoT system. In this paper, we investigate the evolutionary process, which captures the natural interactions and evolutions of attackers and defenders, as well as their strategies to launch data integrity attacks and protect the IIoT system, respectively. We leverage the wireless cyber-physical simulator (WCPS) as a realistic IIoT testbed to implement and evaluate strategies at different levels of evolution. The experimental results indicate the effectiveness of defensive strategies in guarding against various forms of data integrity attacks with increase in time and knowledge throughout the evolutionary process.**

***Index Terms*—Industrial Internet of Things, Data Integrity Attacks, Evolutionary Process, and Cyber-Physical System**

I. Introduction

INDUSTRIAL Internet of Things (IIoT), also known as Industry 4.0, is the integration of Internet of Things (IoT) technologies with industrial manufacturing and production. Benefitting from the massive interconnections of IoT, the IIoT is anticipated to improve the productivity, efficiency, and reliability of manufacturing and production processes. From the viewpoint of a cyber-physical system (CPS), the networking, computing, and control subsystems in IIoT are the cyber components, which connect and coordinate physical industrial entities (sensors, controllers, actuators, etc.). Specifically, the networking system enables real-time information transmission to interconnect the physical devices of factories and plants. The computing system brings intelligence to cover all stages of manufacturing and industrial processes through data analytics. The control system controls industrial devices through control loops to ensure reliable system operations.

Despite the great potential for transforming traditional industrial factories to smart factories in Industry 4.0, the integration of IoT will also face cybersecurity risks. The cybersecurity risks are introduced by the massive interconnections among IIoT systems and the attraction of valuable information inherent to industrial critical infrastructures. In addition, the cybersecurity risks could eventually impact the reliable and safe operations of the industrial devices, as well as the manufacturing and production processes. In other words, cybersecurity risks could affect not only the information integrity, but also the safety operations of IIoT systems. To study cybersecurity issues from a CPS perspective, Liu *et al.* [1] investigated the impacts of cyberattacks on cutting-edge smart-world systems, including smart manufacturing, smart grid, and smart transportation. The smart manufacturing system has shown great vulnerabilities to disruption, such as via the Stuxnet worm to gain control of programmable logic controllers (PLCs) [2]. Likewise, the smart grid system has also been shown to be vulnerable to data integrity attacks that could result in disturbance of state estimation, a critical component in the energy management system of the smart grid [3]–[5].

In addition, there remain significant gaps between the understanding of cybersecurity risks in traditional cyber systems and risks to industrial cyber-physical systems. To bridge the gap, in this paper we study data integrity attacks (i.e., false data injection (FDI) attack) on IIoT systems as a case study. Note that the FDI attack has been a pernicious cybersecurity threat to a number of smart-world systems, such as the smart grid [3], [6], [7], smart manufacturing [8]. To be specific, we first study the FDI attack on the Kalman filter, which is a key component in carrying out state estimation in realistic testbeds (i.e., wireless cyber-physical simulator (WCPS)) for IIoT systems[1]. We then propose and study the evolutionary process of the interactions between the attacker and defender, and their changing strategies with the increase of time and knowledge. We use the WCPS testbed to conduct extensive experiments to emulate the evolutionary process and validate the performance of defensive strategies (e.g., k-nearest neighbors (KNN), 1NN-dynamic time warping (1NN-DTW), and recurrent neural networks (RNNs) with long short-term memory (LSTM) units) against attacks in different stages of evolution. A continuous stirred-tank reactor (CSTR) system as the physical system is modeled in our evaluation.

To study the interactions between the attacker and defender, we leverage the kinetic warfare principles from Sun Tzu in the

[1] Certain commercial equipment, instruments, or materials are identified in this paper in order to specify the experimental procedure adequately. Such identification is not intended to imply recommendation or endorsement by the National Institute of Standards and Technology, nor is it intended to imply that the materials or equipment identified are necessarily the best available for the purpose.

Art of War and Carl von Clausewitz in the *Principle of War*, apply them to the design of cyber warfare tactics at a strategic level [9], [10]. We apply the principle to design a set of defense strategies by considering the different combinations of three basic elements (i.e., strength, space, and time) that attack and defense strategies can manipulate, all in the context of CPS.

Fig. 1. Overview on the Evolutionary Processes of Attack and Defense Strategies in IIoT

From Fig. 1, the Baseline Attack strategy at the early time stage is a data tampering attack, in which the attacker can modify and inject malicious measurements to affect state estimation and system operations. At the early stage, the attacker launches the data tampering attack by manipulating the strength feature of the system. Accordingly, from the aspect of a defense strategy, the Baseline Defense strategy detects the data tampering attack by investigating the strength feature of the system. In particular, the Baseline Defense strategy can be the x^2 bad data detector (BDD), which ensures the residual of the received measurement and estimated measurement of Kalman filter below a certain threshold [11]. Note that the Kalman filter estimates the system state through the analysis of received measurement data and the system model.

Nonetheless, with an increase in knowledge and time, the attacker can leverage the vulnerability of x^2 BDD to design Attack Evolution A (Knowledge-based FDI (Re-attack)) to bypass the detection [12]. In Attack Evolution A, the attacker manipulates the strength feature of the system with the assistance of system knowledge. Thus, the defense strategy has to evolve to Defense Evolution A (Cyber-Physical Integrated Detection (Reload)), which monitors the behavior of both the physical system and the measurement data. Note that Defense Evolution A conducts detections relying on both the strength (i.e., system residual) and space (i.e., cyberspace and physical space) features of the system.

Moreover, the attacker continues to leverage the vulnerabilities of Defense Evolution A to evolve that attack into Attack Evolution B (Temporal-based Stealthy FDI (Re-attack)), which manipulates not only the strength feature, but also the time feature of the system. In detail, Attack Evolution B is designed to cause limited system deviations that are similar to the system deviations introduced by harsh wireless communication conditions (i.e., heavy noise) intermittently. Eventually, the defensive strategy evolves to Defense Evolution B (Temporal-based Cyber-physical Integrated Detection (Reload)) to defend against Attack Evolution B so that the safety of operations in industrial systems can be ensured. Note that the Defense Evolution B conducts anomaly detections by leveraging both strength, space, and time characteristics of the system.

In short, the attack strategy can evolve rapidly into various forms by combining different system characteristics (i.e., strength, space and time). This makes the design of a solid defense challenging. By following the aforementioned principle, the above defense strategies that we designed, considering the diverse evolutions of an attacker, make the IIoT system unassailable.

To summarize, our contributions are two-fold:

- First, we design the evolutionary process model to capture the natural interactions and evolutions between the attacker and the defender. Particularly, the strategies that either the attacker or defender use to attack or defend the IIoT system evolve as time and knowledge increase.
- Second, we use a realistic IIoT testbed to carry out the investigation of the cybersecurity threats to the IIoT systems. The IIoT testbed collects real data from both the control system and wireless network to be applicable in real-world factories and facilities. We also carry out extensive experiments to validate the effectiveness of the defense strategies in protecting the IIoT system against data integrity attacks.

The remainder of this paper is organized as follows. We review existing research efforts regarding IIoT and cybersecurity in Section II. In Section III, we describe the system model and threat model. In Section IV, we introduce the evolutionary process in detail, which captures the interactions between the attack and defense strategies. In Section V, we present the system implementation and experimental results. We conclude the paper in Section VI.

II. Related Work

Envisioned by Industry 4.0, IIoT has been developed to transform the manufacturing industry from traditional factories to automated smart factories with the integration of advanced information technologies, such as IoT, 5G, machine learning, and others [13]–[15]. Specifically, IIoT is aimed to improve productivity, resource efficiency, and intelligence, and at the same time reduce safety risks, operational overhead and so on through massive interconnections between machinery, sensors, and actuators [16], [17].

There have been a number of research efforts investigating IIoT from a variety of perspectives, including 5G for IIoT [18], data analytics in IIoT [19], and cyberattacks on IIoT [20], among others. For example, Xu *et al.* [15] investigated IIoT from the perspective of a CPS, which integrates the control [21], networking [22], and computing [23] systems as the cyber components of IIoT. Moreover, there have been some research efforts on the co-design of cyber systems, which captures the fundamental relationships of cyber entities to satisfy diverse requirements (e.g., low latency and high reliability), such as in networking and control co-design [24], [25].

Despite the communication advantages gained from massive interconnections, the cybersecurity threats are also raised that could endanger not only the cyber systems, but also the physical critical-infrastructures [1], [8], [26], [27]. There have been several research efforts on the investigation of the cybersecurity issues in IIoT, including the security risks of industrial control systems (ICS) [28], cyberattack paths against critical infrastructures [20], and securing IoT-based critical infrastructures [1].

Uniquely, in this paper, we study data integrity attacks against IIoT from the perspective of the evolutionary process, which naturally captures the interactions between the attacker and the defender. We leverage a realistic testbed for IIoT, which consists of plant, sensors, network, state estimator, and controller, to investigate the interactions between attack and defense strategies. In addition, we collect real data from a temperature control plant (i.e., CSTR) model to conduct analysis. Moreover, we investigate two evolved attack scenarios, i.e., Attack Evolution A and Attack Evolution B, and two evolved defense strategies, i.e., cyber-physical integrated detection (Defense Evolution A) and temporal-based cyber-physical integrated detection (Defense Evolution B). Finally, we carry out extensive experiments to evaluate the performance of the proposed detection strategies in defending against different attack scenarios.

III. System and Threat Model

In this section, we first introduce the system model of the IIoT system, including the key components in the system. We then describe the threat model of FDI attacks, including attack goals and objectives.

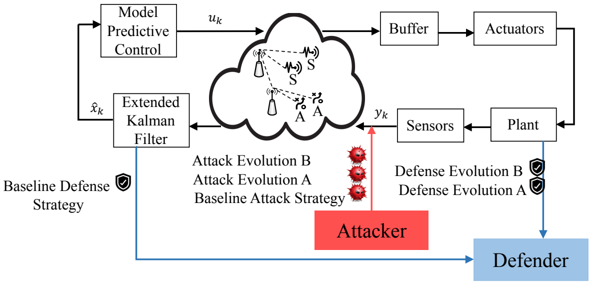

Fig. 2. System Architecture of IIoT with the Integration of Attack and Defense Strategies

We use a linear time-invariant (LTI) system and a wireless network, which transmits sensing data and control commands to form a networked control system. Specifically, we use Fig. 2 to illustrate the IIoT system, which consists of several key components, including the extended Kalman filter (EKF), model predictive control (MPC) controllers, buffer, and wireless networks. As shown in the figure, the attacker injects malicious data into network packets transmitted from sensors and the defender carries out anomaly detection from both cyber and physical aspects.

In particular, the EKF conducts state estimation based on the system model and sensing data received through the wireless networks. Note that, compared to the basic Kalman filter, the EKF conducts state estimation based on not only on the received sensing data, but also on the output of the EKF for prediction. Thus, the EKF is robust to dropped packets of sensing data in wireless networks. We assume the wireless network to be the wireless sensor and actuator network (WSAN) utilizing the WirelessHART protocol, which is a standard communication architecture in IIoT [29].

The MPC controller is the controller for the LTI system. The buffer is used to store the actuation commands to improve the actuation performance to deal with packet drops. Specifically, the MPC controller will generate multiple consecutive control commands and store them in the buffer. In the case of transmission failure of a sensing packet to the controller due to communication noise, the system can use the previously generated actuation commands in the buffer to conduct sub-optimal control.

In this study, we use a classic continuous stirred-tank reactor (CSTR) model as the physical plant in the IIoT system [30]. The CSTR has one main tank for chemical reaction, which requires a certain reaction temperature (i.e., setpoint temperature). This main tank has one inflow to input product, one outflow to output effluent, and a stirrer to mix the products. An additional stream pipe is installed to conduct heat exchange and ensure the main tank has a given setpoint temperature. A valve is equipped on the stream pipe so that the MPC can control the stream rate to adjust the temperature to the desired value. A sensor is equipped on the main tank to measure the tank temperature.

The LTI system, which describes the linearized CSTR, is represented by

$$\begin{aligned} x_{k+1} &= Ax_k + Bu_k + w_k, \\ y_{k+1} &= Cx_{k+1}, \end{aligned} \tag{1}$$

where x_k represents the state variables at time k, u_k is the control input (e.g., stream rate), w_k represents the system disturbance, y_{k+1} is the system output (e.g., water tank temperature), A and B are Jacobian matrices, and C is the output matrix.

The goal of attack is to mislead the controller to generate wrong control commands and cause deviations to the system without being detected. For example, the attacker can deviate the tank temperature from the setpoint temperature to produce bad chemical products in the CSTR system. We assume that the attacker has full knowledge of the target system and can control some sensors (e.g., the temperature sensor in the CSTR main tank) to inject malicious data to be transmitted to the controller.

To do so, the knowledge-based FDI attack (Attack Evolution A) can carefully design an attack sequence and inject it into network packets, which are distributed by sensors and bypasses the detector (i.e., BDD), as shown in Fig. 2. The attacker has full control over the compromised sensors, in which he or she can inject attack sequences and change the sensing value. The EKF receives the sensing value y_k (containing malicious data) through the wireless network and conducts state estimation as $\hat{x}_k$. Then, the controller generates a sequence of control commands u_k based on the received false sensing data, which could lead to deviation of the system from the setpoint. Note that the evolutionary process of attack strategies (from Attack Evolution A to Attack Evolution B) and defense strategies (from Baseline Defense strategy to Defense Evolution A and further to Defense Evolution B) will be detailed in Section IV.

IV. Evolutionary Process

In this section, we present the evolutionary process of attack and defense strategies.

A. Rationale

The Baseline Attack strategy injects malicious data to tamper with measurement data and impact the system performance. The Baseline Defense strategy computes the square of the errors between the estimated measurement and the received measurement, such that measurements above a threshold will be considered as incorrect measurements and will be removed. The Baseline Defense strategy can identify some arbitrary and intentional bad measurements injected by the attacker effectively. Nonetheless, a sophisticated attack strategy (i.e., Attack Evolution A), which leverages the vulnerability of the Baseline Defense strategy, implements an attack sequence with knowledge of the current system configuration (i.e., CSTR system) to bypass the Baseline Defense strategy [11].

From the defender's perspective, the defense must evolve to Defense Evolution A, checking not only the measurement value, but also the system behaviors. Recall that the attack goal is to cause deviations to the system. The system trajectory captures the system behaviors in a long time window. By comparing normal and malicious system behaviors, Defense Evolution A can identify the existence of malicious data injected by Attack Evolution A.

With the increase in time and knowledge, the attacker will further evolve their strategy to leverage the harsh wireless condition inherent to the industrial environment. The harsh wireless condition, which results in packet drops, will cause system instability and deviations. Thus, Attack Evolution B launches an FDI attack intermittently and in a short time (i.e., 5 to 10 seconds) to mimic the actual harsh wireless condition, causing limited system deviations (similar to the system deviations in harsh wireless condition) repeatedly to bypass the Defense Evolution A.

Furthermore, to defend against Attack Evolution B, the Defense Evolution B (Temporal-based Cyber-physical Integrated Detection), which leverages the memory capability of RNN-LSTM, can identify the existence of Attack Evolution B by leveraging the sequential relationship of system behaviors under attack or harsh wireless conditions.

B. Baseline Attack and Defense Strategies

Recall that the Baseline Attack strategy is to inject malicious measurements to disrupt the system control and achieve malicious goals. It is conceivable that an attacker can compromise the industrial sensors, networking devices, and so on, in the IIoT system to intercept and modify the measurement data. The modified measurement data could produce incorrect state estimations and malicious control commands to the system. In this way, the system could eventually perform poorly, achieving the attacker's goal.

To defend against the Baseline Attack strategy, the Baseline Defense strategy is the x^2 BDD, which detects the error between the estimated sensor measurement and the actual sensor measurement caused by meter failures or malicious attacks. The Baseline Defense strategy will compare the error of the estimated measurement and the actual measurement to a predefined threshold (τ). If the deviation is larger than the threshold, it will infer the presence of bad measurement data. The selection of threshold (τ) is usually based on the hypothesis test with a significant level of (a). This means that the error^2 is larger than threshold^2, inferring the presence of bad measurement data with (a) false alarm rate.

We use Algorithm 1 to carry out the bad data detection. The initialization values are system output y_k, estimated system output $\widehat{y}_k$, as shown in Equation (3)), threshold τ, *DetectionRate*, *Runtime* and *TotalError*. The *DetectionRate* indicates the number of samples that the BDD collected per unit time. The *Runtime* is the time window in which the BDD conducts the detection. The *TotalError* is the threshold determined by the hypothesis test. Then, Algorithm 1 compares z_k to τ in line 6 to determines the existence of bad data in a given set of data samples. The total time complexity of Algorithm 1 is $O(N)$, consisting of $O(N)$ for the while loop and $O(1)$ for the if-else statement. Here, N equals the size of *DetectionRate* × *Runtime*.

Note that we define the residue, which measures the error between the estimated system output $\widehat{y}_k$ and actual measurement y_k as

$$z_k = y_k - \widehat{y}_k, \tag{2}$$

and

$$\widehat{y}_{k+1} = C(A\widehat{x}_k + Bu_k). \tag{3}$$

The state estimation $\widehat{x}_k$ is conducted by the Kalman filter as shown in Equation (4).

Algorithm 1: Detecting Bad Data using x^2 Failure Detector

```
   Result: Alarm Triggered
1  Initialization: $y_k$, $\widehat{y}_k$, $\tau$, DetectionRate, Runtime and TotalError;
2  while $k \leq$ DetectionRate $\times$ Runtime do
3      $z_k = (y_k - \widehat{y}_k)^2$ ;
4  end
5  TotalError $= sum(z_k)$;
6  if TotalError $\leq \tau^2$ then
7      Do nothing;
8  else
9      Trigger False Data Alarm with possibility $P($TotalError $\leq \tau^2)$;
10 end
```

C. Attack Evolution A: Knowledge-based FDI (Re-Attack)

To bypass the Baseline Defense strategy, the attacker can design an attack sequence carefully with the increased system knowledge and inject it into the compromised sensors. We now illustrate how to compute the FDI attack sequence and analyze the FDI attack under the different wireless conditions in the IIoT environment. We assume that the adversary knows the system parameters in Equation (1), as the adversary can be an insider.

The wireless network plays the role of transmitting information between the sensors, actuators, and controllers, such as transmitting the sensed temperature to the state estimator and MPC in CSTR. The wireless network performs differently in a harsh industrial environment, due to channel noise, moving obstacles, etc. [29]. To collect realistic measurements in the industrial environment, Li *et al.* [31] collected the noise traces under wide-range wireless conditions from industrial WSAN testbed and injected them into TOSSIM (a TinyOS simulator) in the WCPS testbed to measure the network performance under different noise levels. The noise levels in the industrial environment ranged from -82 dBm to -72 dBm. The impact on the network performance, measured by link failure rate ranges from 15 % to 98 %, accordingly. Note that the high-level noise usually results from extreme conditions, such as weather or jamming attacks. The results from [31] demonstrate that the EKF and Buffered actuation have very good performance in handling up to 60 % packet drops. Thus, we assume that, under the weak noise levels (e.g., -82 dBm to -75 dBm), the IIoT system operates normally.

We now present the FDI attack on the Kalman filter in the IIoT system under weak wireless conditions. The Kalman filter conducts state estimation based on the received system output. The state estimation is represented in Equation (4) under the assumption that Kalman filter gains K will converge quickly if the system is detectable, as shown in [12]. The state estimation of the Kalman filter is represented as

$$\widehat{x}_{k+1} = A\widehat{x}_k + Bu_k + K(y_k - C(A\widehat{x}_k + Bu_k)), \quad (4)$$

where the $\widehat{x}_{k+1}$ is the estimated state at time $k+1$, and the K represents the Kalman filter gain.

Thus, the system under attack can be represented by

$$y'_k = Cx'_k + v_k + \Gamma R^a_k, \quad (5)$$

where y' and x' are the system output and system state under attack, Γ represents a diagonal matrix to select sensors to manipulate, and R^a_k is the malicious data.

To conduct a "successful" attack, we can leverage Theorem 2 in [12] to compute an attack sequence R^a_k. Specifically, to compute an attack sequence recursively, we have

$$R^a_{k+1} = R^a_k - \frac{\lambda^{i+1}}{M} y^*, \quad (6)$$

where $M = max\,\|\Delta z_k\|$ and $|\lambda| \geq 1$. Note that z_k is the residue defined in Equation (2). Mo *et al.* [12] proved that the system in Equation (1) is "perfectly attackable" if and only if v is the reachable state of the dynamic system (an unstable eigenvector of A) and $Cv \in span(\Gamma)$, in which $span(\Gamma)$ is the column space of Γ. Thus, there exists y^* such that $\Gamma y^* = Cv$.

In addition, heavy noise levels (e.g., -75 dBm to -73 dBm) will cause a link failure rate to above 60 %. Under the heavy noise levels, the control system becomes significantly unstable, experiencing abrupt deviations, as shown in Fig. 5. Note that the EKF and Buffered actuation equipped in the IIoT testbed can eventually bring the control objective of the system to the setpoint. The system deviations under heavy noise levels are significant compared to the system deviations caused by the FDI attack. Thus, the FDI attack becomes ineffective in terms of causing system deviations.

Under extreme wireless conditions (noise levels ranging from -73 dBm to -72 dBm), the packet drop rate will exceed 90 %, which indicates consecutive packet drops. The Kalman filter will receive consecutive zeros in a long time window. The consecutively receiving zeros will make the Kalman filter dysfunctional. Thus, the entire system will go to the fail-safe state to prevent further damage. Moreover, under extreme wireless conditions, the FDI attack is not effective.

To implement Attack Evolution A, we propose Algorithm 2, which computes the malicious system output y'_k and sends it to the EKF via wireless network. Recall that we assume the attacker knows the system configurations. Thus, to launch an FDI attack, the attacker first collects the initial values of system output y_k, estimated system state x_k (follows Equation (4)), residue z_k, M (follows $M = max\,\|\Delta z_k\|$), $\lambda = 1$, v (eigenvectors of A), Kalman filter gain K, y^* (follows $\Gamma y^* = Cv$).

Then, the attacker computes the attack sequence R^a_k (line 3) and injects it into the system (line 4) when the packet drop rate (*PacketDrop*) is below 60 %. Note that the *PacketDrop*, which represents the current wireless conditions statistically, can be computed during a time window. The *AttackLength* determines the duration of the attack. The time complexity of Algorithm 2 is $O(N)$ due to the while loop in the if-else statement, where N equals the size of *AttackLength*.

Algorithm 2: Implementation of Attack Evolution A

```
   Result: malicious system output: $y'_k$
1  Initialization: $y_k$, $x_k$, $M$, $v$, $K$ and $y^*$, $\lambda$, PacketDrop and
     AttackLength;
2  if PacketDrop $\leq 60\%$ then
3      while $k \leq$ AttackLength do
4          $R^a_{k+1} = R^a_k - \frac{\lambda^{i+1}}{M} y^*$;
5          $y'_k = Cx'_k + v_k + \Gamma R^a_k$;
6      end
7  else
8      Do Nothing;
9  end
```

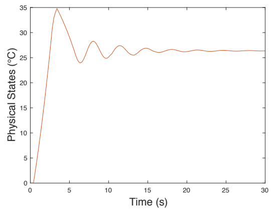

Fig. 3. System Output of a Control System under Normal Conditions

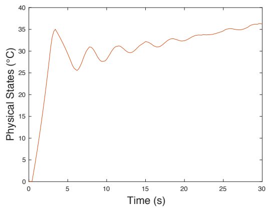

Fig. 4. System Output of a Control System under FDI Attack

As a result, Fig. 3 illustrates the attack-free control system performance, where the MPC controller quickly drives the system to the setpoint (i.e., 27°C for the CSTR system). Fig. 4 shows the system under a continues FDI attack, which leads to significant deviation (i.e., from 27°C to 35°C). Note that both cases do not trigger the alarm of BDD.

D. Defense Evolution A: Cyber-physical Integrated Detection (Reload)

To defend against the knowledge-based FDI (Attack Evolution A), the defender seeks to leverage both the strength and the space characteristics of the system. The detection strategy is implemented in the physical system to collect not only the measurement data, but also the system behaviors. This is because the attack objective of the FDI attack is to disrupt the control system and cause deviations to the physical system. Thus, the Defense Evolution A can leverage a distance-based classifier on the plant (e.g., CSTR water tank) to monitor the output of the LTI system. In addition, to mitigate the deviations caused by the FDI attack on the LTI system, the design goal for the classifier is not only the accurate detection of attacks, but also the rapid detection of attacks (using a small number of data points).

From Fig. 4, the deviations caused by the FDI attack is one significant feature that can be leveraged to design a classifier. This is because the distance of the system behaviors between normal conditions and attack conditions is significant. In this case, we can leverage the K-nearest neighbor (KNN) algorithm as one of the representative classifiers to conduct supervised learning. Specifically, the KNN computes the Euclidean distance of the given input to all training samples and classifies the input as the majority category of the κ nearest samples.

We use Algorithm 3 to conduct the detection of the FDI Attack using the distance-based classifier. The first step is to prepare the data for training and testing, such as data samples under normal conditions *xNormal* and their label *yNormal*, and data samples under FDI attack *xAttack* and their label *yAttack*. Then, for initialization, we separate the data into 70 % training samples (Normal and Attack) and 30 % testing samples: *XTrain* and its label *YTrain*, and *XTest* and its label *YTest*. We also determine the optimal number of κ neighbors by testing the performance of κ from 1 to 10. The total time complexity of Algorithm 3 is $O(N^2)$ due to the two nested loops.

Nonetheless, due to the time-series nature of the LTI signals, when two LTI signals are not aligned, the Euclidean distance will increase, which could interfere with the classification results. To deal with this problem, we use dynamic time warping (DTW) to find the optimal alignment between two time-series signals. Specifically, 1NN-DTW, which classifies the input based on the DTW distance of one nearest neighbor, can achieve state-of-the-art classification performance on time-series classification tasks [32].

Algorithm 3: Detecting FDI Attack using Distance-based Classifier (KNN)

```
  Result: $Results$
1 Data Preparation: xNormal, yNormal, xAttack and
    yAttack;
2 Initialization: XTrain, YTrain, XTest, YTest, $\kappa$;
3 for $i = 1 : length(XTest)$ do
4     for $j = 1 : length(XTrain)$ do
5         Compute EuclideanDistance(XTest(i),
            XTrain(j));
6     end
7     Compute $I(i)$ containing indices for $\kappa$ smallest
        Euclidean distance EuclideanDistance(XTest(i),
        XTrain(j));
8     Assign majority labels: $Results = YTrain(I(i))$
9 end
```

To compute the FDI attack detection using 1NN-DTW, we use Algorithm 3 and update the *EuclideanDistance*(*XTest*(i), *XTrain*(j)) in line 5 with *DTWDistance*(*XTest*(i), *XTrain*(j)). The *DTWDistance* is computed following

$$\textit{DTWDistance}(i,j) = \|x(i) - y(j)\| + \\ min\begin{cases} \textit{DTWDistance}(i, j-1) \\ \textit{DTWDistance}(i-1, j) \\ \textit{DTWDistance}(i-1, j-1) \end{cases}$$

, which combines Euclidean distance $\|x(i) - y(j)\|$ and the cumulative distance of nearest neighbors. In this way, the 1NN-DTW can measure the similarity of two time-series signals more accurately.

E. Attack Evolution B: Temporal-based Stealthy FDI (Re-Attack)

To design a better attack strategy to bypass the cyber-physical integrated detection, the attacker leverages not only the strength characteristic, but also the time characteristic. In other words, the attacker reduces the strength of the FDI attack and diffuses the FDI attack in the time domain.

Specifically, recall that cyber systems, such as networking and control systems, are highly interrelated in the IIoT environment. The communication noise in the networking system also impacts the stability of the control system. Thus, an intelligent attacker could leverage the imperfection nature of the networking system to disrupt the distance-based classifiers. In particular, the attacker can launch the FDI attack intermittently and periodically and only cause deviations that are similar to the deviations caused by packet drops in heavy noise. In this way, the performance of a distance-based classifier will decrease significantly as the classifier would fail to distinguish between system deviations caused by FDI attacks from packet drops under harsh wireless conditions.

We use Fig. 5 to visualize the comparison of the system behaviors under FDI attacks, heavy noise, and attack-free scenarios. Observe that, if the attacker launches periodic FDI attacks of short duration (e.g., 1-10 seconds), the Euclidean distance will no longer be capable of discriminating between malicious and benign signals. This is equivalent to the scenarios that a detector can only use small observation windows to

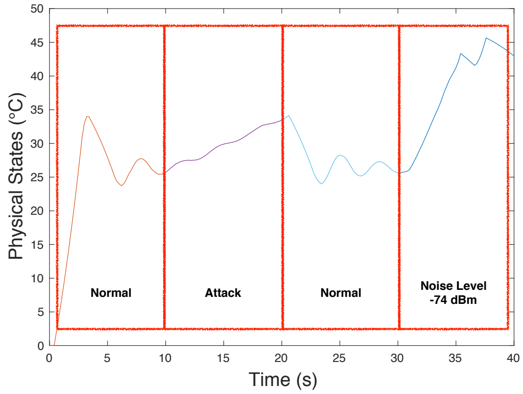

Fig. 5. System Behaviors under Normal, Attack and Heavy Noise Levels

conduct classification. This type of attack over a long duration can cause system deviations that are harmful to industrial systems.

We use Algorithm 4 to implement Attack Evolution B. The initial values are the Attack Evolution B period (AEBP), hiding period (HP), sampling rate (SR) and the initial values in Algorithm 2, such as y_k, x_k, M, v, K and y^*, λ and *PacketDrop*. Specifically, the algorithm repeatedly computes malicious system output y'_k, containing the y'_k with false data R^a_k injected during AEBP and unchanged system output $y'_k = Cx'_k + v_k$ during HP. Note that the SR determines the number of data points per unit time(s). The total time complexity for Algorithm 4 is $O(N)$, consisting of $O(N)$ for the first loop and $O(N)$ for the second loop. Here, N equals to the size of $AEBP \times SR$.

Algorithm 4: Implementation of Attack Evolution B

```
Result: malicious system output: $y'_k$
Initialization: AEBP, HP, SR, $y_k$, $x_k$, $M$, $v$, $K$ and $y^*$,
  $\lambda$ and PacketDrop;
repeat
    for $k = 1 : (AEBP \times SR)$ do
        if PacketDrop $\leq 60\%$ then
            $R^a_{k+1} = R^a_k - \frac{\lambda^{i+1}}{M} y^*$;
            $y'_k = Cx'_k + v_k + \Gamma R^a_k$;
        else
            Do Nothing;
        end
    end
    for $k = (AEBP \times SR) :$
      $(AEBP \times SR + HP \times SR)$ do
        $R^a_k$ = 0 ;
        $y'_k = Cx'_k + v_k + \Gamma R^a_k$;
    end
until STOP;
```

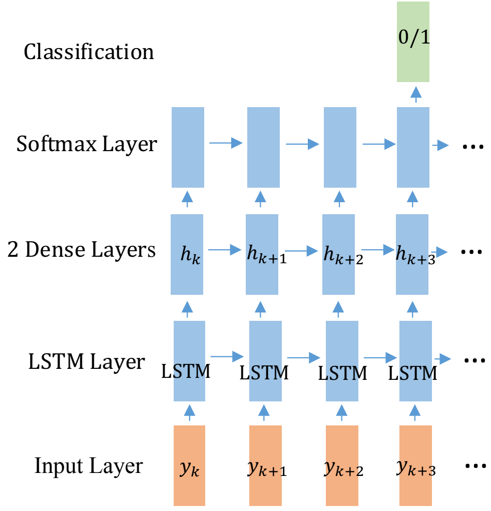

Fig. 6. RNN Architecture

F. Defense Evolution B: Temporal-based Cyber-Physical Integrated Detection (Reload)

Defense Evolution A fails to distinguish between system behaviors under Attack Evolution B and heavy noise levels in the wireless network. This is because the distance between the system deviations under heavy noise and Attack Evolution B declines. Thus, the classification accuracy of distance-based classifiers decreases and at the same time, more data points are necessary to conduct classification accurately. To overcome the issue, we design the temporal-based cyber-physical integrated detection, which leverages not only the strength characteristic, but space and time characteristics to conduct anomaly detection.

In detail, we leverage the recurrent neural network, which has proven effective on natural language processing (NLP) tasks, such as voice recognition, in addition to many others [33], [34]. Due to its memorization capability, the RNN-LSTM can be used to solve sequence classification problems. This is because the RNN-LSTM accumulates information extracted from previous observations and adjusts the next decision based on the historical observations. Thus, RNN-LSTM can provide better classification accuracy in terms of sequential data classification. In particular, we use the many-to-one architecture, as shown in Fig. 6, which takes the sequential control signal as input, examines this sequence sample-by-sample, and gives a decision at the last sample. The RNN-LSTM follows a standard sequence-to-label classification design, which contains a sequence input layer, an LSTM layer, a dense (fully connected) layer, a softmax layer, and a classification output layer.

V. Experimental Results

We have implemented the attack and defense strategies outlined above in an IIoT testbed and have conducted extensive experiments to study the evolutionary process. We used the classic CSTR in MATLAB as our physical system [30]. The network settings followed the WirelessHART network topology to simulate a WSAN. The testbed adopted TOSSIM to simulate the WSAN with adjustable noise levels.

We implemented the 1NN-DTW and KNN (Defense Evolution A) in MATLAB, which takes the LTI system as input and outputs the classification result (benign or malicious). We collected 1,000 samples of attack-free LTI signals and 1,000 samples of LTI signals under attack. Additionally, we used 70 % of the samples to train the 1NN-DTW and KNN, and the remaining 30 % of samples were used for testing. We also implemented the RNN-LSTM based classifier of Defense Evolution B in MATLAB. The RNN-LSTM architecture consists of an input layer, an LSTM layer, a fully connected layer, a softmax layer, and an output layer. We used the back-propagation through time (BPTT) as the gradient descent algorithm. Similarly, we used a 70 %/30 % sample split for training/testing the RNN-LSTM.

The classification performance is quantized from the aspect of both accuracy and timeliness. The accuracy is measured by the percentage of correctly identified time-series data samples over the total number of testing samples. The timeliness means how many data points have been used to obtain the classification accuracy. The larger the number of data points used, the longer it took to conduct classification, assuming that the sampling rate is fixed.

A. *Performance of Defense Evolution A in Defending Attack Evolution A*

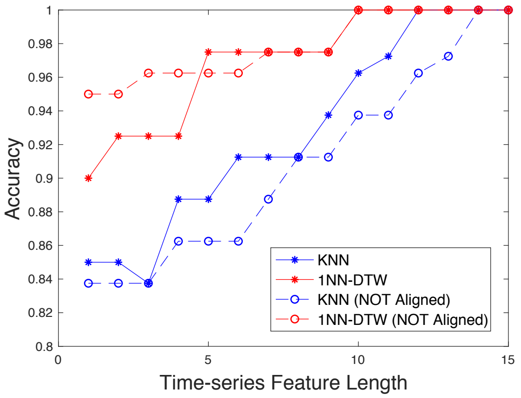

Fig. 7. Classification Performance of KNN vs 1NN-DTW

We now illustrate the experimental performance of the Defense Evolution A (i.e., distance-based anomaly detection (reload)) vs. the Attack Evolution A (i.e., knowledge-based FDI (re-attack)). Observe from Fig. 7 that the 1NN-DTW can obtain nearly 97.5 % in classification accuracy at a single control loop (5 data points per second at a sampling rate equal to 5 HZ) and 100 % classification accuracy at two control loops (10 data points in 2 seconds). The KNN can obtain 88.8 % classification accuracy at a single control loop, 96.3 % classification accuracy at two control loops, and 100 % classification accuracy at three control loops (15 data points in 3 seconds). Note that the ’NOT Aligned’ signifier indicates the signals have not been manually aligned. The red lines show the performance of 1NN-DTW and KNN without aligning the signals manually. Benefitting from the DTW technique, the 1NN-DTW performs better when the signals are not manually aligned.

B. *Performance of Defense Evolution A and Defense Evolution B in Defending against Attack Evolution B*

We further illustrate the experimental performance of Defense Evolution A and Defense Evolution B vs. Attack Evolution B under different wireless conditions.

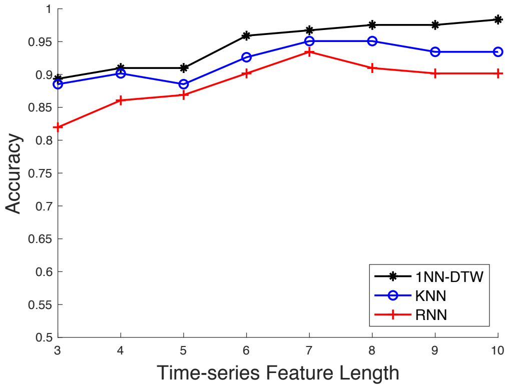

Fig. 8. Detect Attack Evolution B under Weak Noise Levels

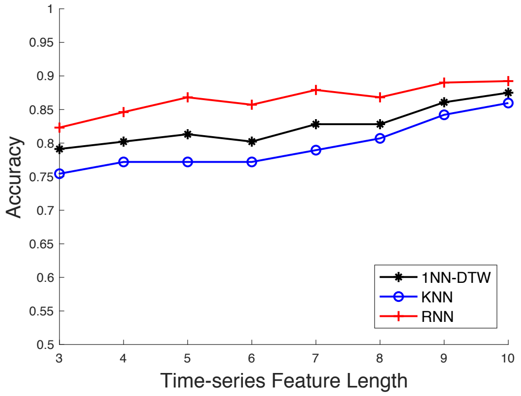

Fig. 9. Detect Attack Evolution B under Weak and Heavy Noise Levels

Observing from Fig. 8, we can see that both 1NN-DTW and KNN outperform RNN-LSTM under a weak communication noise environment (Defense Evolution A defend against Attack Evolution A). Specifically, the detection accuracy of 1NN-DTW increases from nearly 89.3 % with only three data points to 98.4 % with 10 data points. In addition, the detection accuracy of 1NN-DTW increases faster than the others when the number of data points used increases. This is due to the signal alignment capability of the DTW.

The RNN-LSTM shows the lowest classification accuracy in comparison to the distance-based classifiers. This is because the time-domain sequential feature is not significant compared to the distance feature. In contrast, Fig. 9 shows the inadequacy of Defense Evolution A in defending against Attack Evolution B, where the distance feature used by Defense Evolution A has been disrupted by the heavy noise. The system deviations caused by the packet drops under weak and heavy noise levels misleads the distance-based classifiers. Thus, the detection accuracy of KNN and 1NN-DTW drop to 75.4 % and 79.1 % with 3 data points, respectively. With 10 data points, the accuracies are 85.9 % and 87.5 %. In comparison, the RNN obtains a higher classification accuracy, which increases from 82.3 % with 3 data points to 89.2 % with 10 data points.

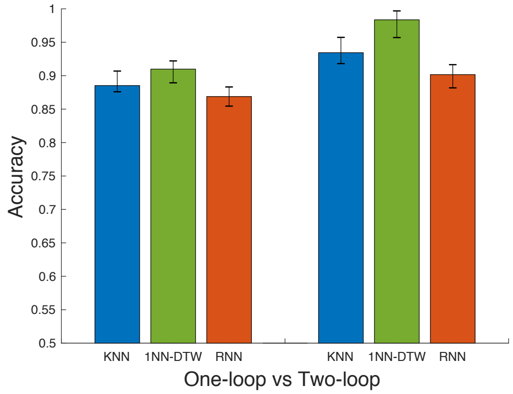

Fig. 10. Classification Performance per Control-Loops under Weak Noise Levels

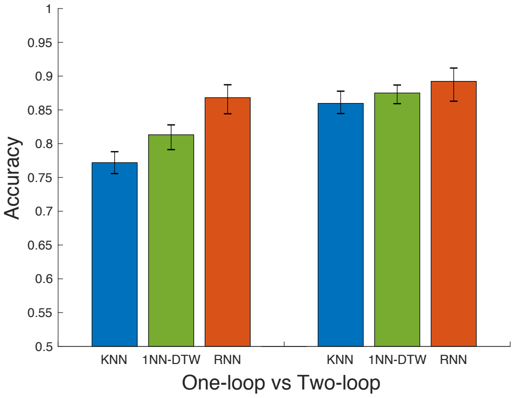

Fig. 11. Classification Performance per Control-Loops under Weak and Heavy Noise Levels

Recall that, as the goal of the defender is to detect the FDI accurately and rapidly, we compare the classification accuracy with regard to detection speed, as shown in Fig. 10 and Fig. 11. Observing from Fig. 10, we can see that the 1NN-DTW outperforms KNN and RNN-LSTM and achieves an average classification accuracy of 90.9 % and 98.3 % at one-loop and two-loop under the weak noise scenario. In contrast, from Fig. 11, the RNN-LSTM outperforms 1NN-DTW and KNN and obtains a classification accuracy of 86.8 % and 89.2 % at one-loop and two-loop under weak and heavy noise levels.

In addition, we use the receiver operating characteristic (ROC) curve to measure the performance of classifiers in Fig. 12 and Fig. 13 with the false positive rate and true positive rate on the x-axis and y-axis, respectively. Note that we use the area under the curve (AUC) to quantitatively measure the separability of classifiers between 0.5 to 1 (the higher the better). Notably, the 1NN-DTW obtains 0.98 of AUC in weak noise levels, the highest when compared to other methods. Additionally, the RNN-LSTM obtains 0.90 of AUC in weak and heavy noise levels, the highest compared to the other classifiers.

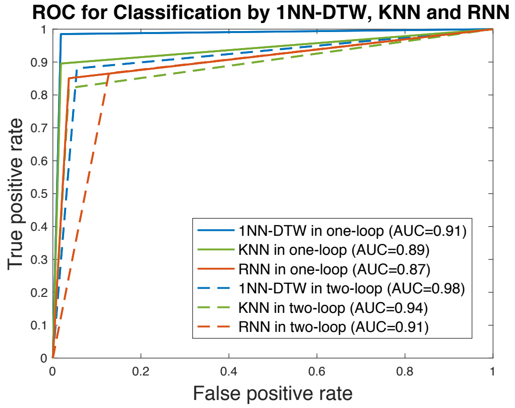

Fig. 12. ROC Curve for Classifiers under Weak Noise Levels

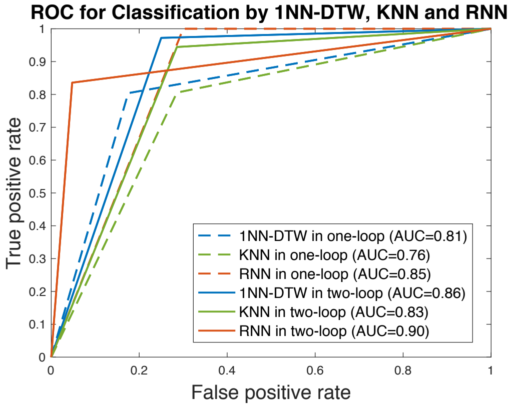

Fig. 13. ROC Curve for Classifiers under Weak and Heavy Noise Levels

VI. Final Remark

In this paper, we have studied the evolutionary process of the strategies that an attacker uses to launch data integrity attacks against IIoT and the strategies that a defender uses to detect such attacks, as knowledge and time increase. We have leveraged a realistic IIoT testbed to implement multiple attack and defensive strategies, and have evaluated their interactions. We have also conducted extensive experiments to validate the effectiveness of the defensive strategies against increasingly complex data integrity attacks under different levels communication noise. The experimental results demonstrate strong classification accuracy for 1NN-DTW under weak communication noise and RNN-LSTM under weak and heavy communication noise in wireless communication.

Abstract

Segmentation of additive manufacturing (AM) defects in X-ray Computed Tomography (XCT) images is challenging, due to the poor contrast, small sizes and variation in appearance of defects. Automatic segmentation can, however, provide quality control for additive manufacturing. Over recent years, three-dimensional convolutional neural networks (3D CNNs) have performed well in the volumetric segmentation of medical images. In this work, we leverage techniques from the medical imaging domain and propose training a 3D U-Net model to automatically segment defects in XCT images of AM samples. This work not only contributes to the use of machine learning for AM defect detection but also demonstrates for the first time 3D volumetric segmentation in AM. We train and test with three variants of the 3D U-Net on an AM dataset, achieving a mean intersection of union (IOU) value of 88.4%.

1 Introduction

Additive manufacturing (AM), also known as three-dimensional (3D) printing, is experiencing rapid adoption in the manufacturing domain. AM introduces several advantages such as the fabrication of models with complex geometries, quick prototyping, customization of materials and flexibility in design (Ngo et al., 2018). During an AM fabrication process, consecutive layers are printed (Gross et al., 2014). Internal defects can be created due to reasons such as print error, residual stress, or cyber-attack (Holzmond and Li, 2017). The presence of defects leads to flaws, such as insufficient material properties, in the printed object (Reese, Bheda and Mondesir, 2016). An automatic defect segmentation system to identify interior defects can therefore aid AM quality control.

Some current non-destructive defect segmentation techniques include infrared radiation monitoring and X-ray computed tomography (XCT). The former monitors radiation given off by melt pools during the printing process. The monitoring process requires a complex laser setup and only works for the powder bed fusion (PBF) process (Holzmond and Li, 2017). XCT can be used to visualize internal structures, including porosity, in three dimensions (Buffiere et al., 2001; Masad et al., 2002). While XCT can be used to obtain images and segmentation labels, it requires manual thresholding, which can be tedious given many samples. Other approaches including analyzing an array of sensor signals to monitor the process (Rao et al., 2015), but such approaches require the installment of multiple sensors and analysis of multiple signal types. Automatically identifying small defects inside an object therefore remains a challenging task in manufacturing.

Defect segmentation can be treated as an image segmentation problem in computer vision. In defect segmentation, each 2D pixel or 3D voxel is classified as either defect or background. Image segmentation is a difficult task, and many methods have been proposed to solve the problem, especially in the medical imaging domain, which requires localization of objects (Ronneberger, Fischer and Brox, 2015). State of the art 2D and 3D segmentation methods that perform best in various segmentation tasks are based on deep learning and use convolutional neural networks (CNN) (Guo et al., 2018). The benefits and the drawbacks of some of the current segmentation methods are further discussed in Section 2.

Despite their drawbacks, 3D CNNs have demonstrated potential in 3D medical image segmentation tasks (Cicek et al., 2016; Milletari, Navab and Ahmadi, 2016; Lee et al., 2017; Yu et al., 2017; Zhou et al., 2018; Ghavami et al., 2019). AM images share similar characteristics with medical images such as their volumetric nature and similar level of contrast. Therefore, it is thought that certain deep learning approaches from the biomedical domain might be of similar benefit in the AM domain. However, processing XCT data from AM parts poses certain difficulties that are less prevalent in the biomedical domain, such as small and highly irregular defect geometries. In addition, the sparsity

Wong, Vivian; Ferguson, Max; Law, Kincho; Lee, Yung-Tsun; Witherell, Paul. "Automatic Volumetric Segmentation of Additive Manufacturing Defects with 3D U-Net." Paper presented at SSS20 (VIRTUAL) AAAI Spring Symposium on AI in Manufacturing, Palo Alto, CA, US. March 23, 2020 - March 25, 2020.

of defects in AM varies dramatically, as exemplified by the dataset used in this paper which contains samples that range from 0.37% to 19.38% porosity. Furthermore, AM datasets are both difficult and costly to produce and hence there are very few publicly available datasets large enough to employ machine-learning approaches. Despite these challenges, developing fast and reliable quality control procedures is essential to the mainstream adoption of additive manufacturing processes.

The need for automatic manufacturing defect detection and the promising performance of CNN in the volumetric segmentation of medical images thus motivates our work. We propose to train a 3D U-Net model with existing defect labels and use the trained model to automate the segmentation process on XCT or 3D images of unknown additive manufacturing samples. To demonstrate the effectiveness of our method, an experiment is conducted using an AM defect dataset constructed with XCT images. We train and evaluate 3 variants of the 3D U-Net model and obtain a mean intersection of union (IOU) value of 0.863 to 0.884. Although no previous work has been done in AM defect segmentation to compare this accuracy with, our mean IOU is comparable with the accuracy of 3D U-Net segmentation of kidney embryos, which achieves a mean IOU of 0.704 (Cicek et al., 2016).

The rest of the paper is organized as follows. Section 2 provides an overview of related works. Section 3 briefly introduces 3D CNNs and presents the network architecture of our 3D U-Net models. Section 4 discusses our implementation and experimental results. Finally, Section 5 briefly concludes our work.

2 Related Works

This section reviews current advancements in 3D image segmentation using deep learning approaches, as well as related works in automatic AM defect identification.

Segmentation of 3D objects are often framed as a 2D segmentation task with post processing (Zhou et al., 2016; Milletari, Navab and Ahmadi, 2016). The most commonly used CNN architectures used for 2D segmentation problem are region-based and fully-convolutional-network-based (FCN-based) (Guo et al., 2018).

Region-based segmentation methods first extract regions and describe them, then classify the region (Caesar, Uijlings and Ferrari, 2016). Region-based CNN (R-CNN) is a representative method using this approach (Guo et al., 2018). The Mask R-CNN architecture is an example of R-CNN that performs object detection and segmentation simultaneously (He et al., 2017). Mask R-CNN has proven to be effective in segmenting everyday objects (He et al., 2017), medical images (Johnson, 2018) and metal casting defects in manufacturing (Ferguson et al., 2018).

On the other hand, FCN-based methods perform segmentation by directly learning a mapping from input to output pixels, without proposing regions (Long, Shelhamer and Darrell, 2015). U-Net is a CNN model that extends the FCN architecture, achieving excellent performance in the segmentation of ventral nerve chord (Ronneberger, Fischer and Brox, 2015). U-Net is less computationally expensive than Mask R-CNN, since it does not require the generation of region proposals.

Despite the success of the above-mentioned methods, AM specimens are 3D, and therefore predicting one 2D slice at a time loses information on the correlation between slices (Yu et al., 2019). A similar problem exists in the medical imaging domain, where most images are 3D volumes. To that end, 3D CNN models have been developed to make predictions on volumetric medical images (Cicek et al., 2016; Milletari, Navab and Ahmadi, 2016).

While 3D CNN models can leverage information between slices, they lack pre-trained models, leading to less stable training (Yu et al., 2019). Patch-wise predictions are also more time-consuming to generate compared to 2D predictions. V-Net (Milletari, Navab and Ahmadi, 2016) and 3D U-Net (Cicek et al., 2016) are examples of end-to-end architectures for 3D segmentation. In this work, we adopt 3D U-Net and two of its variants in our experiments with AM defect data.

A few related works have been done to automatically detect AM defects using CNN. Scime and Beuth (2018) and Zhang, Liu and Shin (2019) perform 2D detection and classification on defects using slices of camera images in their work. Shevchik et al. (2018) use CNN to analyze acoustic emissions during AM processes.

As discussed in this section, the use of 3D CNN to segment AM defects represents a new and novel approach, and will be the subject of discussion in the rest of this paper.

3 3D Convolutional Neural Networks

In this section, we present some background knowledge on 3D CNNs. As discussed in the previous section, 2D CNNs and 3D CNNs each have their own drawbacks and advantages. 3D CNNs extend upon 2D CNNs by using the same technique of convoluting a kernel spatially through the input of a convolutional layer with two important distinctions:

1) The kernel of a 2D convolutional layer is two dimensional (2D) with width and height (W × H), and the kernel of a 3D convolutional layer is three dimensional (3D) with width, height and depth (W × H × D).
2) A 2D kernel moves in 2 directions, along the axis corresponding to W and H dimensions. A 3D kernel moves in 3 directions, with an additional axis along the D dimension.

3D U-Net

The 3D U-Net is an extension upon the standard (2D) U-Net architecture proposed by Ronneberger, Fischer and Brox,

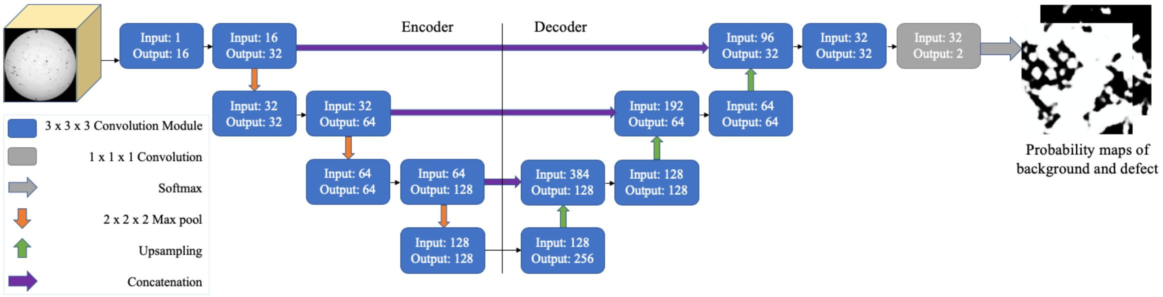

Figure 1: 3D U-Net architecture implemented in this study. The numbers on the convolutional blocks indicate the number of input and output channels (Cicek et al., 2016).

Table 1: Details of the AM defect data

Specimen	Distance between 2D slices [pixel]	Total number of voxels	Porosity (%)	Dataset
Sample 1	0.00245	6.57×10^8	1.01	Validation
Sample 2	0.00277	6.61×10^8	19.28	Training
Sample 3	0.00243	6.55×10^8	0.37	Training
Sample 4	0.00252	5.50×10^8	11.01	Training

(2015). The 3D U-Net can be implemented using a modular architecture, as shown in Figure 1. The architecture consists of two types of modules, encoder modules shown on the left and decoder modules on the right. The encoder modules perform max pool operations and the number of feature maps produced increases as the number of layers increases. On the other hand, the decoder modules perform upsampling and the number of feature maps produced decreases as the number of layers increases. This overall encoder-decoder design is preserved for all 3D U-Net models, but the design of each module can be altered. Each 3 x 3 x 3 convolution module consists of a convolutional layer as well as group normalization (GN) or batch normalization (BN) layer, and a rectified linear unit (ReLU) layer (Cicek et al., 2016).

Both GN and BN are techniques to improve the speed and stability of training neural networks (Ioffe and Szegedy, 2015). Wu and He (2018) propose GN, which is more robust than BN, and does not suffer the limitation of BN that smaller batch size leads to larger errors. The 3D U-Net in the work by Cicek et al. (2016) uses BN and reports outstanding results. To conduct the experiments on the AM defects, the 3D U-Net implementation by Cicek et al. (2016) is employed. However, we modify the convolutional modules to replace BN with GN, as well as rearranging the layer structures, allowing us to achieve a higher accuracy on the AM defects, as discussed in the next section.

Residual Symmetric 3D U-Net is an improved variant of 3D U-Net, proposed by Lee et al. (2017). Several changes are made compared to the 3D U-Net architecture, including the addition of a layer by redesigning convolutional modules to include residual skip connections and symmetricity, as well as modifying the downsampling and upsampling techniques. Lee et al. (2017) report that their model exceeds human accuracy in an experiment segmenting neurites in electron microscopic (EM) brain images.

As discussed in the next section, we modify the convolution module of the 3D U-Net architecture to analyze their impact on the model's performance on the AM defect segmentation task. We also compare Residual Symmetric 3D U-Net against the two designs.

4 Implementation Details and Experimental Results

This section describes the implementation and results of the experiments conducted using a dataset of AM defect images.

4.1 Data

The dataset consists of four cylindrical AM specimens, shown in Table 1. The datasets were introduced and analyzed by Kim et al. (2017), and the data are publicly available (Kim et al., 2019). The artificial defects were produced by changing AM processing parameters. The sample contains AM defects due to unoptimized AM processing parameters. Each specimen consists of 8-bit grayscale images of 2D slices. These images are 16-bit raw images obtained using XCT reconstruction processed by adding a median 3D filter and a non-local means filter (Buades, Coll and Morel,

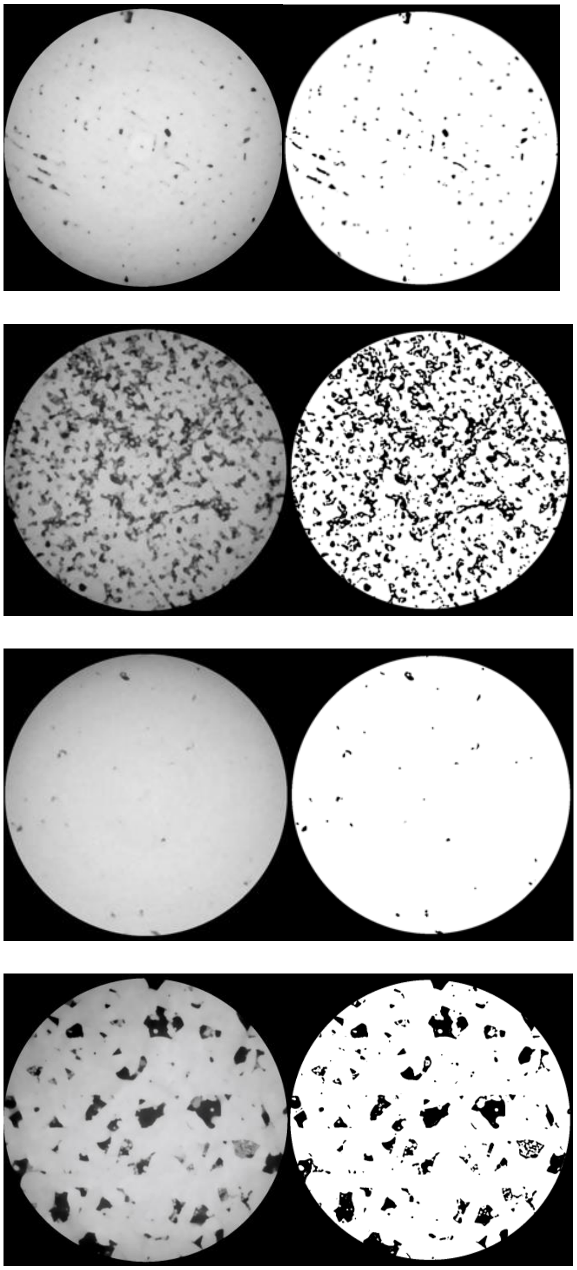

Figure 2: Examples of images from the AM defect dataset. Processed XCT images are on the left and segmentation masks are on the right.

2011; Sun, Brown and Leach, 2012). To obtain the segmentation mask, the 8-bit images are processed with Bernsen local thresholding (Bernsen, 1986). The local contrast threshold parameters of the thresholding process are set by relating average noise value to local contrast threshold as explained by Kim et al. (2017). Examples of some images and corresponding masks are shown in Figure 2.

Table 2: Mean IOU and average training time

Model	Training Time on GPU [hours]	Validation Mean IOU
3D U-Net with Conv+BN+ReLU	**6.58**	0.863
3D U-Net with Conv+ReLU+GN	14.00	0.881
Residual Symmetric 3D U-Net	19.97	**0.884**

In the experimental study, Sample 1 is used for validation. Samples 2, 3 and 4 are used for training. This choice is due to the fact that Sample 1, among all samples, does not have an extreme value of porosity.

4.2 Training and Inference

To analyze the effect of 3D U-Net convolutional modules on performance and convergence, three 3D U-Net models are trained and evaluated in this study. The three models vary in the layers of the basic convolutional modules. The first model, hereby referred to as 3D U-Net with Conv+BN+ReLU, follows the implementation by Cicek et al. (2016). The model uses a 3D convolutional layer, a BN layer and a ReLU nonlinearity layer in its basic convolutional module. The second model, 3D U-Net with Conv+ReLU+GN, is a variant that uses a 3D convolutional layer, a ReLU nonlinearity layer, followed by a GN layer. The third model, Residual Symmetric 3D U-Net, follows the implementation by Lee et al. (2017).

Network inputs are 3D images of dimensions Depth × Width × Height, constructed by stacking the 2D slices, as shown in Figure 3. The inputs are normalized, randomly flipped and rotated prior to training. Network outputs and targets are compared using the softmax function with cross-entropy loss. The models are trained end-to-end and without pretraining for 2000 iterations using a NVIDIA Tesla T4 GPU, which fits patches of size 128 × 128 × 128.

The models are fine-tuned on the AM defect dataset. Each model is trained with an initial learning rate of 0.0002 that decays at a rate of 0.5 at the 600th, 1000th, and 1400th iteration. The networks are trained via the Adam optimizer (Kingma and Ba, 2014). A weight decay factor of 0.0001 is used. We set the batch size and the group size of one in BN and GN, respectively. Stride sizes are 32 × 32 × 32 to overlap the patches and to capture the fine details in the images. All modifications and fine-tuning to the models are conducted using a publicly available implementation of the 3D U-Net architecture (Wolny, 2019).

The models are evaluated with the same GPU. The prediction accuracy of each model is evaluated using the mean intersection over union (IOU) metric.

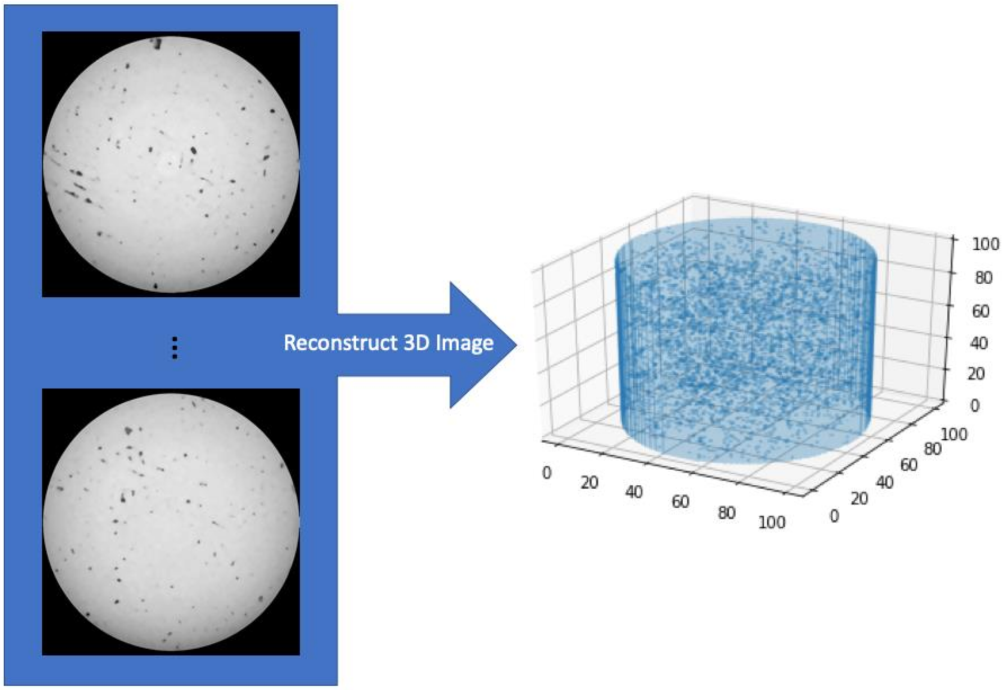

Figure 3: Reconstruction of a 3D image. Note that the voxels on the right are downsized for display purpose.

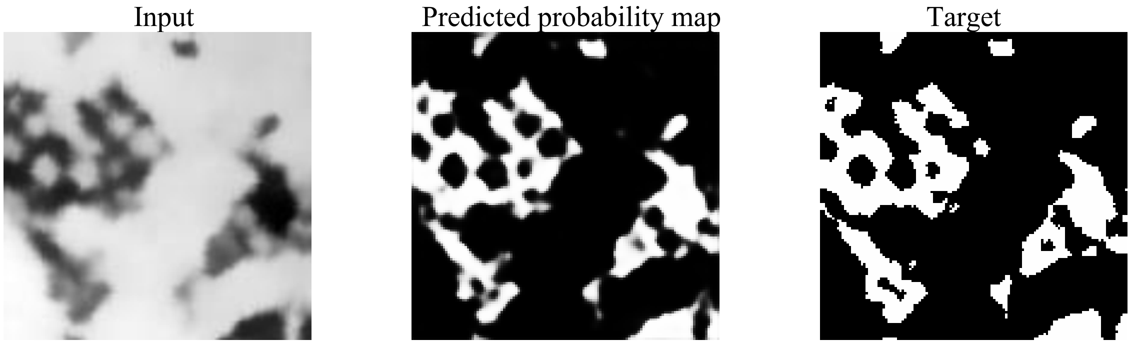

Figure 4: An example slice of a defect and its segmentation probability map outputted by Residual Symmetric 3D U-Net.

4.3 Results and Discussion

The performance of the three different 3D U-Net models are compared in Table 2. Each model's validation accuracy and the amount of time taken to achieve that are reported in the table. The Residual Symmetric 3D U-Net model, with a mean IOU of 0.884, exceeds the other models slightly in performance, but requires the longest training time. With the 3D U-Net model, GN improves the result with respect to BN, but is slower in the training iterations. In general, we observe a trade-off between training time and accuracy. In practice, an appropriate model should be selected taking into consideration the time and accuracy trade-off.

Figure 4 shows an example of a slice segmented using the Residual Symmetric 3D U-Net model. It can be seen that the segmentation probability map compares well with the target (labelled) sample. One observation is that the voxels corresponding to sharp geometries of the defects are often misclassified. Due to the size of the defects and poor contrasts at the edges, these sharp geometries appear to be small and light in color, and their true label is often ambiguous, hence posing difficulties for segmentation.

5 Summary and Discussion

This paper has presented a method for automatic volumetric segmentation of AM specimens using 3D U-Net, a CNN model previously developed for medical image segmentation. Three variants of the model are compared using an AM defect dataset, and the highest mean IOU achieved is 0.884, which is a good accuracy considering the various challenges in segmenting small defects. The proposed method is able to automatically segment defects in AM samples with a reliable amount of accuracy, and can be of assistance to quality control for the additive manufacturing process.

Future work could focus on tuning the network to handle the misclassification of areas with very few voxels. One improvement might involve using focal loss, which puts less penalty on well classified samples and focuses on misclassified samples (Lin et al., 2017). Dilation could be used to pre-process the training images to add voxels to the boundaries of the defects (Jackway and Deriche, 1996). The proposed models could also be trained to segment defects in AM specimens with different geometries, materials and additive manufacturing approaches. Furthermore, the effect of transfer learning on the performance and training speed of the CNN models could be explored. It would also be interesting to develop CNN models to focus on studying other important characteristics of AM defects, such as defect pattern classification.

The ability to segment defects with high accuracy could be beneficial in a number of situations in practice. A trained CNN model could be used to evaluate fabricated AM specimen for quality assurance. Furthermore, images of a specimen could be captured in the middle of fabrication to identify warning signs early on during the printing process, thereby saving materials from a failed printing process. However, to deploy this method in practice would require more training data and ensure that the model generalizes to other types of AM defects.

ABSTRACT

Unscheduled downtime in manufacturing systems can be a major source of lost productivity, profits, and, ultimately, reduced process quality and reliability. However, the incorporation of asset condition management (ACM) into manufacturing systems offers an approach to improve equipment and plant operations by providing real-time condition awareness, system diagnostics, and estimates of future health to enable predictive maintenance. ACM is a framework for assessing the current and future state of health of a manufacturing system and integrating that knowledge with enterprise applications to meet the demand of production operations. In manufacturing systems, successful operations rely on the ability to maintain production assets at their optimal working levels to optimize operations and system performance. Some large corporations have made great strides in incorporating smart technologies to enhance their asset management strategy; however, small- and medium-sized enterprises (SMEs) face distinct challenges. One of the key challenges is that most SMEs do not have the wherewithal to invest in new machines nor is there standard guidance on how older machines can be integrated into an ACM solution, so that their end-to-end manufacturing process can be optimized from a health management point of view. This research presents a framework for ACM to facilitate its introduction into manufacturing systems based on their "health-ready" capabilities. Specifically, an ACM system architecture is defined for manufacturing systems, the health-ready principles and capability levels from the aerospace and automotive industries are adapted to the manufacturing domain, and the results from outreach efforts to the manufacturing community are discussed.

Keywords: Health-Ready Capability Levels, Health State; Smart Manufacturing; Diagnostics; Prognostics; Predictive Maintenance

OUC	Operational Use Case
RCM	Reliability-Centered Maintenance
RUL	Remaining Useful Life
SCADA	Supervisory Control and Data Acquisition
SME	Small- to Medium-Sized Enterprise

1. INTRODUCTION

Many machines are still reactively maintained or are operated in run-to-failure modes of operation [1]. Such an approach can result in the waste of time, cost, and resources. More advanced maintenance strategies include condition-based maintenance (CBM), reliability-centered maintenance (RCM), and the combination thereof, CBM-Plus. Continuous monitoring of an asset's condition to facilitate CBM, can help reduce unscheduled downtime and allow maintenance to be scheduled

Diaz-Elsayed, Nancy; Hernandez, Luis; Rajamani, Ravi; Weiss, Brian A. "Asset Condition Management: A Framework for Smart, Health-Ready Manufacturing Systems." Paper presented at ASME 2020 15th International Manufacturing Science and Engineering Conference (MSEC2020), Cincinnati, OH, US. June 22, 2020 - June 26, 2020.

during a financially-opportune time with minimal impact on production operations [2]. CBM has been found to be a sustainable alternative to reactive and preventive maintenance practices [3]. At the very basic level, RCM leverages the detailed study of failure and degradation mechanisms for critical systems to appropriately schedule maintenance actions to enable the reliable operation of these systems and meet user needs. While CBM is a laudable goal, a deeper understanding of the RCM principles has done much to improve maintenance practices across many industries. One notable industry is the aerospace sector where RCM is used to determine maintenance requirements based on the analysis of the likely functional failures of components, equipment, subsystems, or systems having a significant impact on safety, operations, and life cycle cost.. Combining RCM and CBM principles, also known as CBM-Plus, is gaining traction as the U.S. Department of Defense has required its suppliers to follow this strategy [4].

In recent decades, the growth of computing power, the increased use of automation, and the advanced capabilities of sensor technology has facilitated the emergence of the Industrial Internet-of-Things (IIoT) and smart manufacturing. Readily available data has also allowed researchers to apply artificial intelligence and machine learning techniques to manufacturing applications as well. With the shift towards smart manufacturing systems, decision-makers in the factory can go beyond CBM and apply prognostics and health management (PHM) to avoid failures and sizable disturbances via predictions [2,5]. However, several challenges remain in the implementation of PHM and even more so for small- to medium-sized enterprises (SMEs), which represent the vast majority of manufacturers in the United States [6]. For example, legacy equipment likely do not have the digital capabilities that are designed into newer machines to offer plug-and-play solutions for process monitoring. Additionally, SMEs may lack the in-house expertise needed to implement and sustain smart manufacturing technologies [1] and may not have the personnel or financial resources to invest in new machines. A major challenge across manufacturers, however, is that they "lack a standard process and methodology for using [PHM] technologies on the shop floor" [7].

SAE JA6268: Design & Run-Time Information Exchange for Health-Ready Components is a standard that was recently developed to help reduce existing barriers to the successful implementation of Integrated Vehicle Health Management (IVHM) technology into the mobility sector [8]. This standard introduces the concept of "health-ready components and systems (HRCS)." HRCS, in the aerospace and automotive domains, are components that monitor and report their own health (at run-time) so that the health management of the entire aircraft or vehicle can be achieved. For the system to achieve this integrated behavior, JA6268 advocates that the supplier needs to work closely with the system integrator during the design phase to provide sufficient amount of (design-time) information to accurately assess the component's health via a higher-level "reasoning" system on the vehicle. This SAE standard has two primary objectives: (1) to encourage the introduction of a much greater degree of IVHM functionality in future vehicles at a much lower cost, and (2) to address intellectual property concerns by providing recommended design-time and run-time data specification and information exchange alternatives to help unlock the potential of IVHM [8].

This paper presents a framework to facilitate the characterization of an Asset Condition Management (ACM) system based on the "health-ready" capability of the manufacturing assets. ACM has been defined as "*the unified capability of a manufacturing system (i.e., the asset) to assess its current and future state of health and integrate that knowledge of the system state of health with enterprise applications to meet production operations demand*" [9]. This unified capability takes the form of a framework whose goal is to help manufacturers introduce IIoT technologies and advanced maintenance practices into their operations to improve the awareness of a system's health state, reduce asset downtime, and improve productivity and product quality. In this way, operation and maintenance (O&M) can be optimized and the useful life of the system can be extended. The objectives of this research were as follows: 1) define an ACM system architecture for manufacturing systems, 2) adapt the SAE JA6268 principles and Capability Level definitions to the manufacturing industry, and 3) reach out to the manufacturing community to obtain feedback on the key artifacts developed for ACM.

2. ASSET CONDITION MANAGEMENT

The first objective of this research was to define a PHM architecture reference for manufacturing systems. This research effort referenced prior work done in the aerospace and automotive industries [8,10,11] and PHM research for the manufacturing industry [2,7,12]. During this research, the use of "Asset Condition Management" was proposed for the manufacturing industry, since asset management can be recognized and interpreted by the manufacturing community without prior knowledge of PHM. Moreover, the concept behind ACM was introduced to attendees of the ASME Standards Subcommittee Meeting on Advanced Monitoring, Diagnostics, and Prognostics for Manufacturing Operations, held at NIST in May 2019. Several attendees expressed their interest in ACM to better understand its potential and how it could help their manufacturing operations.

ACM has been defined as "*the unified capability of a manufacturing system (i.e., the asset) to assess its current and future state of health and integrate that knowledge of the system state of health with enterprise applications to meet production operations demand*" [9]. ACM can support an enterprise in advancing their maintenance strategies by promoting the appropriate identification of current and desired "health-ready" capabilities throughout the system and manufacturing process. In this context, *"health-ready assets" are manufacturing systems or subsystems with the capability to monitor and report their own health*.

Maintenance practices for manufacturing equipment are based on activities that attempt to extend equipment life and reduce the likelihood of equipment failure. Scheduled and other "preventive" maintenance strategies have been the norm –

achieving maintenance objectives through regular equipment inspections and scheduled maintenance at pre-determined intervals based on operational time, cycles, units, etc. [1]. ACM aims at moving maintenance more towards Condition-Based Maintenance or Predictive Maintenance (PdM) strategies, where it makes sense. In some assets, the preventive and run-to-failure strategies may be enough to meet the enterprise business objectives. CBM and PdM maintenance strategies require the monitoring and management of the condition of the manufacturing equipment to avoid disruptions in operations due to equipment downtime. The objective of ACM is to drive maintenance when it is needed to ensure safety, reliability, availability, and reduced life cycle costs. In practice, these strategies help reduce unnecessary downtime by employing "just-in-time" maintenance procedures.

2.1 A Physical Hierarchy for Manufacturing Systems

To decompose the complexity of manufacturing systems, a physical hierarchy is defined ranging from an enterprise to a component level as represented by Figure 1. Weiss et al. [13] previously described the functions of the entities at each of the levels in terms of activity diagrams, and identified the monitoring and PHM functions at each level. The operational metrics related to PHM at each level flow up to be aggregated at the top level to get an overall picture of the health of the entire system.

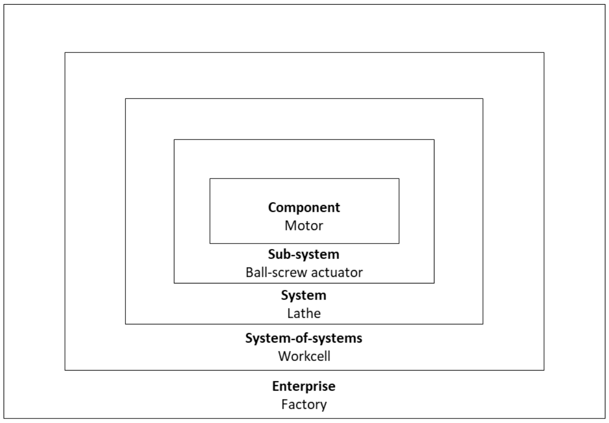

FIGURE 1: THE PHYSICAL HIERARCHY OF MANUFACTURING SYSTEMS

Examples of a physical entity are provided in Figure 1 for each category. At the highest level is the enterprise, which can represent a factory or the larger environment in which the factory operates, such as a collection of factories connected by logistic chains. Next is a workcell or a production line (a system-of-systems). In this case, the "System" is represented by a lathe, and the downstream "sub-system" is a linear actuator. The actuator consists of several components such as the ball-screw, the motor, the motor controller, the tool assembly, etc. Components can be further broken down into sub-components, but for illustrative purposes, the "Enterprise" to "Component" levels are shown in Fig. 1. Also, as has been pointed out by Weiss et al. [13], this is a relative hierarchy. If the focus is at a different level, a component might well become a system, such as what might happen for a motor original equipment manufacturer (OEM).

To understand how one key element of ACM may work in this context, consider the function of estimating the health of the ball-screw actuator. Let us assume that measuring the slew-rate of the actuator is enough to adequately assess one aspect of the actuator health (e.g., the time it takes for the actuator to slew from one position limit to the other and back is enough to determine the health of the system). As all components age, the slew rate increases for the same motor command inputs. By trending this rate, one can calculate a metric indicative of the health of the actuator.

In this example, it is assumed that the slew rate is measured in the computer by measuring the time it takes for the actuator to travel between limit switches. This means that the signals from the switches must be acquired, sampled and encoded, then transmitted to a computer where the analysis is done. Some physical elements are very clear in this implementation. The limit switches are key sensing elements, as are their companion data acquisition electronics, which includes the A/D convertors, for example. In this embodiment, it is assumed that digital data is further transmitted to another central computer for analysis. It is quite conceivable that in another embodiment, the analysis is done in the same location that data is acquired. Such distributed architectures will become more common as distributed computational systems become more feasible with advanced technology, such as higher throughput and faster communications. We present this example, because a lot of interest has been generated in recent decades on the health management of electromechanical systems such as the linear actuator in the mobility sector. This is mainly because of the increase in electrification both of automobiles and aircraft. This trend will continue, and the manufacturing sector can make full use of it to increase its ACM capabilities. To situate this example in the ACM context we compare this with what would be done traditionally in monitoring an actuator of this kind, which is next to nothing! Any estimate of the health of the actuator would be inferred from other parameters further downstream. In a highly ACM-capable manufacturing system, the parameters from the actuator itself will be monitored and its health directly measured. This would be fed to a higher system health management function that would use this lower level intelligence to assess the health of the entire system. The more integrated these capabilities are, the higher the level of health management capability we would assign the system.

2.2 ACM System Architecture Reference

Leveraging sensors and "health-ready systems" in the ACM framework calls for practitioners to focus on identifying and defining information that must be exchanged between the levels in the physical hierarchy or between lower-level components, sub-systems and the higher-level system functions. Hence, data transfer will occur between three tiers: a) Production Assets, Sensors, and Health-Ready Systems, b) Data Acquisition, Contextualization, Integration and Exchange, and c) Enterprise

FIGURE 2: AN OVERVIEW OF THE ACM SYSTEM ARCHITECTURE

Tools and Manufacturing Operational Processes (see Figure 2). The ACM system functions can be integrated with the ANSI/ISA-95 Level 0-1-2 functions (production process and manufacturing control) to enable the automation of equipment health data. Knowledge of the equipment state of health may then drive efficiencies and the effectiveness of Level 3-4 (manufacturing operations management and business planning and logistics) functional operations including Maintenance Operations, Production Operations, Quality Operations, Plant Production Scheduling, etc. The ANSI/ISA 95 series of standards address the integration of the enterprise operations with the manufacturing control system [15]; this approach aligns quite well with the concept of ACM.

The Data Acquisition, Contextualization, Integration and Exchange functions can be local (to the specific equipment or process), distributed (e.g., across the factory), or cloud-based (i.e., across the enterprise). The operational use cases (OUCs) express the specific business purpose for using the asset health state data captured by the system; they are used to convey user-specific needs and drive ACM system functional requirements. For example, from an operational perspective, the specific value-added a maintenance department expects from the capability for assessing the individual equipment health, the health of subsystems or workcells.

The objective of this “top-down” approach is to associate the value of ACM with overall equipment effectiveness (OEE) to specify and characterize manufacturing productivity based on equipment and process health. OEE is a commonly used metric across many manufacturing facilities that indicates performance based upon measured productivity, quality, and availability metrics and measures [14]. OEE can be derived at multiple levels of the manufacturing hierarchy, from the enterprise level down to the equipment level. The OUC specification also drives the communication between the business and ACM development teams and provides a way to represent user requirements that align with the operational business requirements. They should be specified in non-technical language and enable ordering, grouping, and prioritization. Also, the use case specification is the primary input for user acceptance testing as well as the development of test cases. Nevertheless, the specific architecture solution depends on the motivating factors driving the need for ACM, the existing infrastructure, and the economics of the situation.

Note that a system implementation may utilize all or a portion of the health-ready functions inherent in the production assets. The reason is that some sensor parameters and lower level diagnostic codes are representative of symptoms and are manifested in higher-level health-state indications. Specifying how each layer in the system produces or uses the data available for exchange was outside of the scope of this research, but future work should leverage existing standards and recommend how data capture, processing, and exchange within and between the architecture tiers should occur for ACM in greater detail.

3. HEALTH-READY CHARACTERIZATION

Historically, manufacturing equipment maintenance policies have been defined based on maintenance actions that attempt to extend equipment life and minimize likelihoods of equipment failure, e.g., preventive maintenance strategies relying on scheduled tasks. ACM can support an enterprise in advancing its maintenance strategies by promoting the appropriate identification of current and desired “health-ready” capabilities throughout the system and manufacturing process.

Starting with data capture, an ACM practitioner characterizes each process or function using technical specifications and interface control documents (ICD). The specific functions and processes depend on the design and implementation of the ACM capabilities considering the physical scope (e.g., the system, sub-system or component level) and the type of equipment involved (e.g., new assets with advanced monitoring capabilities or legacy equipment without them). For example, a certain component might have perfect data acquisition capability, i.e., it can reliably deliver the appropriate data to an acquisition system for a health assessment. This data capture system would buffer the data, convert it as needed and deliver it to the appropriate receivers for further processing (e.g., by a downstream SCADA system). The assessment might end at this point, or, for a more complex sub-system, data processing might be included in the health assessment as well. Such a sub-system might have built-in data normalization and parameter correction, and have the capability of providing such normalized data to the more advanced ACM functions further downstream. All diagnostic and prognostic analysis systems need to work with processed data. Accordingly, most PHM systems have built-in normalization routines to filter noise and correct for different operating conditions. This way, data under different operating conditions can be compared. In the aerospace domain, for example, this would include correction for standard day conditions, and varying loading factors. The functions or processes involving state detection, health assessment and prognostics assessment might not be very advanced. In fact, it is expected that most assets will not have prognostics capabilities (i.e., capabilities to predict future health states). But for some smarter components, there may be limited ability to assess the current state of health, especially in terms of detecting anomalies and faults. With historical data and analytics, the ability to extrapolate the estimates and to assess remaining useful life (RUL) may also be provided, which would generate the data needed for predictive maintenance. Future efforts will involve some measures of validation.

3.1 Health-Ready Capability Levels

Adapting the SAE JA6268 IVHM Capability definitions [8], a proposed approach for establishing ACM Capability Levels for smart manufacturing systems was developed. The definitions consist of a progression of ACM Capability Levels (from Level 0 to Level 5), which are based on functional aspects of the asset's inherent capabilities:

- **Capability Level 0 - Limited Failure Indicators:** Asset maintenance is prompted by either scheduled preventive maintenance or inspections, when the asset operator is alerted by failure indicator lights or gauges conveying limited awareness, or when the operator observes a performance issue.

- **Capability Level 1 - Diagnostics**: Asset is equipped with diagnostic functions. Maintenance personnel gain diagnostic insight by viewing or extracting operating parameters and/or diagnostic information from the asset. Simple (e.g., relatively high-level) fault isolation information is available.

- **Capability Level 2 - Asset Monitoring**: Asset is equipped with the ability to automatically capture data, possibly store the data, and diagnose based on intelligent algorithms. A key characteristic is that data can be used to monitor real-time performance or to capture performance history over time for subsequent analysis. More detailed fault isolation information is available.

- **Capability Level 3 - Prognostics**: Asset operator and maintenance personnel are provided with alerts of impending faults, listing severity levels, along with estimated RUL, and recommended fault remediation and maintenance actions.

- **Capability Level 4 - Comprehensive ACM**: Asset operator and maintenance personnel are provided with diagnostics and prognostics information at the enterprise level with alerts of impending faults listing severity levels, RULs, and recommended fault remediation and maintenance actions. Limited logistics recommendations may also be provided. This would include resource allocation, resource scheduling, and spare part locations, which may be used to support transportation decisions for tools and material.

- **Capability Level 5 - Self-Adaptive ACM**: ACM capability is integrated with asset control and enterprise management to automate logistics and maintenance scheduling based on available information, resources, and costs. Assets can be automatically (or manually, based on automated advice) reconfigured and repurposed to deliver acceptable performance in the presence of asset or process degradation, with detailed advice on fault remediation and system maintenance.

A key transition occurs between Level 2 and Level 3, where prognostics and predictive analytics are brought to bear to significantly enhance the ACM capability. Moreover, as the levels increase, the maintenance practices shift. For example, maintenance at Level 0 would occur after an inspection or failure. At Level 1 and 2, scheduled maintenance would be coupled with CBM (driven by diagnostic functions) but limited predictive capabilities would be available. At Levels 3 and 4, maintenance would rely on predictions of the asset's condition (i.e., predictive or CBM). Lastly, Level 5 applies CBM with logistics optimization and adaptive process control. Referring to the example of the ball-screw actuator, typical systems are at Level 0 with little or no diagnostic capability. The monitoring of the slew rate as described above would constitute a basic information source that could be used to develop capability at Level 1 or 2 depending on how the information is used. With more sophisticated algorithm that trends the slew rate over time and extrapolates it to estimate RUL, we may even be able to get Level 3 capability. To get to higher levels, the system-wide monitoring and assessment capability must be in place so that the information from the actuator can be used for more than just prediction but also automated maintenance scheduling, etc.

3.2 The Health-Ready Capability Levels in Practice

The outreach to manufacturers was conducted via a survey that was developed and deployed in Qualtrics, as well as one-on-one interviews. The guidelines presented in Sections 2 and 3 incorporate the changes made following the feedback from the outreach efforts. In all, feedback was obtained from six manufacturing entities including four SMEs, one OEM, and one manufacturing trade association.

After being introduced to the ACM definition and the health-ready capability levels (including details about the data acquired and the maintenance practices at each capability level), manufacturing entities were asked which health-ready capability level was achieved by most of their assets and the highest level achieved by their assets. While most assets operated at a Level 2, one manufacturer did operate equipment that achieved a Level 5 as shown in Figure 3. The asset that achieved a Level 5 was a CNC machine tool that had advanced monitoring and control capabilities used for precision manufacturing operations. The machine could self-calibrate based on real-time conditions and optimize the life of the ball-screw, bearings, and rails. In the case where "I don't know" was selected, the manufacturer was an OEM and was unaware of the highest capability level achieved by their suppliers.

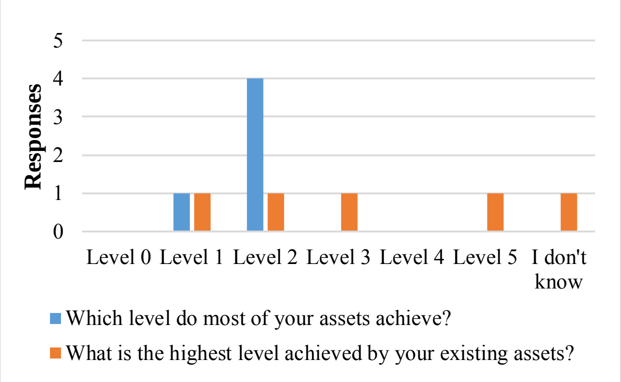

FIGURE 3: ACM CAPABILITY LEVELS OF EXISTING ASSETS; SUMMARY OF RESPONSES FROM THE MANUFACTURERS (EXCLUDES THE TRADE ASSOCIATION).

To further investigate how these assets were maintained, the manufacturers were also asked who the individual or organization was that maintained the assets at the highest level. Table 1 shows the results for all surveyed manufacturers. While routine maintenance was often performed by internal personnel, the supplier of the asset, component, or technology was also a key contributor to maintenance activities as summarized in Table 1. The latter played a key role in maintaining the asset at Level 5 where more sophisticated tasks and deeper knowledge of the asset were necessary.

TABLE 1: THE INDIVIDUAL OR ORGANIZATION THAT MAINTAINED THE ASSET(S) WITH THE HIGHEST ACM CAPABILITY LEVEL AT THEIR FACILITY.

Health-Ready Capability Level	Individual or Organization Maintaining the Asset(s)
Level 0	Not Applicable
Level 1	The supplier of the asset, component, or technology
Level 2	Internal personnel (e.g., technician)
Level 3	The supplier of the asset, component, or technology
Level 4	Not Applicable
Level 5	Internal personnel for routine maintenance and the supplier of the asset for calibration and annual checks.

4. CONCLUSION

Key challenges for SMEs to advance their maintenance strategy include not having the wherewithal to invest in new machines nor standard guidance on how older machines can be integrated into an ACM solution, so that their end-to-end manufacturing process can be optimized from a health management point of view. Legacy equipment may not have the digital capabilities that are designed into today's smart machines, but that does not mean it is impossible to extract high-quality, meaningful data from these assets. Many SMEs may not be realizing the full benefits of ACM because they have older machines and the traditional approach assumes that there is no health-ready capability within the assets. That is, it is assumed that these (legacy) machines don't have the needed sensors to track data or the necessary capabilities to easily connect the assets to a central repository. By retrofitting these systems with sensors and data acquisition units, they may be brought into higher ACM capability levels without excessive investments; the benefits derived from enhancing the capabilities can far outweigh the costs.

The ACM framework offers an opportunity to extend the useful life of manufacturing systems, such that waste and resource consumption can be reduced. It is not the intention of this research to suggest that all manufacturers should maintain their assets at a Level 5. Instead, with the framework in hand, manufacturers can benchmark which health-ready capability level their assets achieve. By comparing the capabilities achieved by alternative systems, they can optimize their decision-making based on the factors that are most critical to their factory or enterprise; for example, the value added, the resources consumed, and the ability to meet their customer's demand.

ACKNOWLEDGEMENTS

This material is based upon work supported by the National Institute of Standards and Technology (NIST) (Cooperative Agreement No. 70NANB18H260). The authors wish to acknowledge the cooperation and support of the Prognostics and Health Management for Reliable Operations in Smart Manufacturing project team at NIST for the collaborative discussions and their valuable inputs during the performance of this work. The project team would also like to acknowledge the Center for Advanced Vehicular Systems Extension (CISE) at Mississippi State University, Crevalle Boats, Custom Manufacturing & Engineering, Inc., Custom Metal Designs, Inc., Ferrera Tooling, FloridaMakes, the MTConnect Institute, and the Tampa Bay section of the Society of Women Engineers for their support of this project during the manufacturer outreach process.

ASSESSMENT OF A NOVEL POSITION VERIFICATION SENSOR TO IDENTIFY AND ISOLATE ROBOT WORKCELL HEALTH DEGRADATION

Brian A. Weiss[1], Jared Kaplan
National Institute of Standards and Technology (NIST)
Gaithersburg, Maryland, USA

ABSTRACT

Manufacturing processes have become increasingly sophisticated leading to greater usage of robotics. Sustaining successful manufacturing robotic operations requires a strategic maintenance program. Without careful planning, maintenance can be very costly. To reduce maintenance costs, manufacturers are exploring how they can assess the health of their robot workcell operations to enhance their maintenance strategies. Effective health assessment relies upon capturing appropriate data and generating intelligence from the workcell. Multiple data streams relevant to a robot workcell may be available including robot controller data, a supervisory programmable logic controller data, maintenance logs, process and part quality data, and equipment and process fault and failure data. This data can be extremely informative, yet the sheer volume and complexity of this data can be overwhelming, confusing, and sometimes paralyzing. Researchers at the National Institute of Standards and Technology have developed a test method and companion sensor to assess the health of robot workcells which will yield an additional and unique data stream. The intent is that this data stream can either serve as a surrogate for larger data volumes to reduce the data collection and analysis burden on the manufacturer; or add more intelligence to assessing robot workcell health. This article presents the most recent effort focused on verifying the companion sensor. Results of the verification test process are discussed along with preliminary results of the sensor's performance during verification testing.

Keywords: degradation, diagnostics, industrial robot systems, kinematics, manufacturing, prognostics, prognostics and health management (PHM), use cases, verification, workcell.

1. INTRODUCTION

Every product used in daily life is manufactured in some way; from the clothes that are worn, to the automobiles that are driven, and the cell phones that are used. Each of these products, and many more, are being offered with more customizable configurations and options. Coupling the concept of product customization with the evolution of manufacturing technologies has led to manufacturing processes becoming increasingly flexible and complex [1-3]. To enable greater flexibility and handle increased task complexity, manufacturers have turned to robotic technologies. Robots can offer manufacturers numerous benefits (e.g. increase accuracy, precision, repeatability, efficiency) as compared to conventional manufacturing automation or manual capabilities [4-6].

As robots have become more adept at providing a broader range of manufacturing capabilities, they are presenting more operational complexity. More complexity typically leads to greater opportunity for faults and failures in the process and equipment. In turn, this spurs more unplanned maintenance or more planned maintenance routines to lessen the potential for unexpected faults or failures [7-9]. Manufacturers, from small to large, recognize that strategic and scripted maintenance

strategies are critical to maximize process and equipment availability [10, 11].

Personnel from the National Institute of Standards and Technology (NIST) are conducting research to develop measurement science products (e.g., test methods, performance metrics, reference datasets) to promote the verification and validation of monitoring, diagnostic, and prognostic technologies within manufacturing operations as part of NIST's Smart Manufacturing programs [12-14]. These measurement science products are intended to decrease equipment and process downtime and increase reliability for smart manufacturing systems. A critical output of the effort is the dissemination and adoption of these products by the manufacturing community. A specific measurement science product being developed is a test method, along with a companion sensor to be used within the test method, to assess the degradation of the workcell's kinematic chain (i.e. the assembly of individual rigid bodies at joints) [15, 16]. When applied by industry to operational manufacturing robot workcells, the test method can identify and isolate degradations, within the workcell, that are negatively impacting the accuracy of the process. Ultimately, the test method, along with the sensor, will be made publicly-available to industry for widespread adoption and implementation. Before this can be achieved, the overall test method, including the sensor, require testing and verification.

This publication presents NIST's latest efforts to verify the performance of the companion sensor. Early work focused on manually testing the sensor. This proved overly time-consuming and prone to human error. Current efforts have focused on automating the testing process to cover more test points in a faster manner, as compared to manual testing. The remainder of this article is organized as follows. The Background section presents the motivation for this effort. The Test Method and Sensor Description section describe the test method in detail and discuss how the sensor is integrated with the test method. The Experimental Design section talks about the design and development of the automated measurement test stand. The Testing and Results section highlight the tests that were conducted. The Lessons Learned Section analyzes the preliminary results from two perspectives – how well did the automated measurement test stand perform and how well did the companion sensor perform. Lastly, the Future Efforts section describes the expected next steps of this research effort.

2. BACKGROUND

Maintenance is typically a critical factor to ensure long-term, acceptable operation for any process or piece of equipment. Although important, maintenance can at times be expensive and cumbersome [17, 18]. Without sufficient intelligence regarding the health of their manufacturing operation, which would include resident robot workcells (defined to include the robot, end-of-arm tooling, sensors, controller(s), and other supporting automation), manufacturers cannot make informed decisions about the most cost-effective and efficient maintenance strategy(ies) by which to maintain their operations. The discipline of monitoring, diagnostics, and prognostics to enhance decision-making surrounding maintenance activities is known as prognostics and health management (PHM) [19-22]. The optimal maintenance schedule includes striking a balance between preventative maintenance (PM) (performing specific maintenance activities at set intervals of time, cycles, or other measurable unit) and predictive maintenance (PdM) (performing specific maintenance activities only when the current condition of equipment predicts that maintenance is necessary) all in an effort to minimize reactive maintenance (RM) ("fix it when it breaks") [23]. Preventive maintenance can become excessive leading to wasted time and money. However, minimizing or trivializing preventive maintenance can lead to too much reactive maintenance. Unexpected shutdowns resulting from reactive maintenance can lead to lost revenue and even lost customers.

Tracking the health of robot workcells allows manufacturers to make informed decision about the type of maintenance needed and the schedule at which it should be performed. Data is required to generate intelligence regarding robot workcell health. Multiple data streams are likely to exist that are relevant to identifying the health of a robot workcell. They include:

- Robot-level data – Many robot controllers capture a range of information including robot joint and tool center positions, velocities, and accelerations; joint temperatures; joint currents; and joint voltages. This data is usually quantitative.
- Process-level data – This type of data could be captured from the overall process controller or from a supervisory Programmable Logic Controller (PLC). Time data is an example of process-level data, where time can include overall task time, sub-task time, and takt time. This data is usually quantitative.
- Quality data – As measured of the part produced once the workcell has completed its operation. This data could be quantitative or qualitative.
- Operational configuration data – Information describing the workcell's configuration and operations. This can include the make and model of equipment, technologies, and sensors critical to the workcell's function. This information can also describe the workcell's operation (e.g., *Robot Arm 01 lifts a 2 kg box, puts it down, then lifts a 5 kg box, puts it down, etc.*). This can be both quantitative and qualitative descriptive data.
- Fault and failure data – For any fault or failure that presents itself within a manufacturing operation, it is almost always documented. This documentation could be done by multiple individuals including the equipment and process operator, maintenance technician, or supervisor. Fault and failure data can be quantitative from sensor and equipment readings (e.g., the current peaked at 18 A). It can also be descriptive – e.g., smoke started rising from the motor, I then heard a loud crack, and the motor stopped running.

- Maintenance logs – Most manufacturers document their maintenance activities, whether it results from planned maintenance (predictive or preventive) or from unplanned maintenance (reactive). Maintenance records can include what specific work was performed and a descriptive of the restorative state that the equipment is now in.

Effectively turning all of this data into health intelligence is non-trivial, especially as it relates to robot workcells [24]. Multiple algorithms exist that dictate how to fuse or analyze the data to discover new intelligence. Each method comes with its advantages and disadvantages. Generating the appropriate amount of intelligence can be paramount to an organization. Too little intelligence can lead to vast uncertainty and present an excessive amount of options to maintenance decision-makers. An over-abundance of intelligence can be costly, both in the time to generate and required resources. For highly critical processes or equipment, a cost-benefit analysis could dictate the need for more, as opposed to less, intelligence. The right amount of intelligence can prevent degradations that force part quality or process productivity to unacceptable levels while still promoting cost effective operations [25, 26]. NIST has developed the *Identification and Isolation of Robot Workcell Accuracy Degradation* test method and companion Position Verification Sensor with Discrete Output (U.S. Patent Pending, Serial Number 16/572,847) to provide a new stream of direct intelligence that can localize where faults and failures are occurring in a workcell's kinematic chain; and offer additional data that can be fused with the afore-mentioned data to offer a richer understanding of the workcell's health. The following section describes the test method, position verification sensor, and the need for sensor verification.

3. TEST METHOD AND SENSOR DESCRIPTION

The *Identification and Isolation of Robot Workcell Accuracy Degradation* test method was developed in concert with a multi-robot testbed at NIST [27]. FIGURE 1 presents the NIST's PHM for Robot Systems testbed with many representative features of a manufacturing robot workcell including robots, controllers, and end-of-arm tools. The testbed features two six-degree-of-freedom (6DOF) Universal Robots, each with industrial controllers. The smaller robot, a UR3 (shown on the left in FIGURE 1), is configured to perform path planning operations including drawing several unique patterns) while the larger robot, a UR5 (shown on the right in FIGURE 1), is configured to perform a material handling operation. The UR3 is configured with a pen at its tool-center-position using a specially-designed mount. The UR5 is configured with an RG2 gripper that is controlled through the UR5's controller. Supervisory commands are issued to both the UR3 and UR5 by a single Beckhoff PLC.

The testbed's primary manufacturing-relevant use case is for the larger robot to physically place test parts on fixtures within reach of the path planning robot for this smaller robot to draw on the test part. This drawing activity is analogous to welding, adhesive application, and additive manufacturing processes performed by six-degree-of-freedom robot systems. Additional information on the testbed and use case is shown in [15, 27]

The *Identification and Isolation of Robot Workcell Accuracy Degradation* test method involves testing the positioning repeatability, and therefore the health, of different components along the robot workcell's kinematic chain. The test method uses the NIST-developed Position Verification Sensor with Discrete Output (PVS) sensor (depicted in FIGURE 2) to measure the positioning of the components in question [16]. The test method is robot agnostic; it can be integrated and executed with any 6DOF robot workcell. When different measurement points along

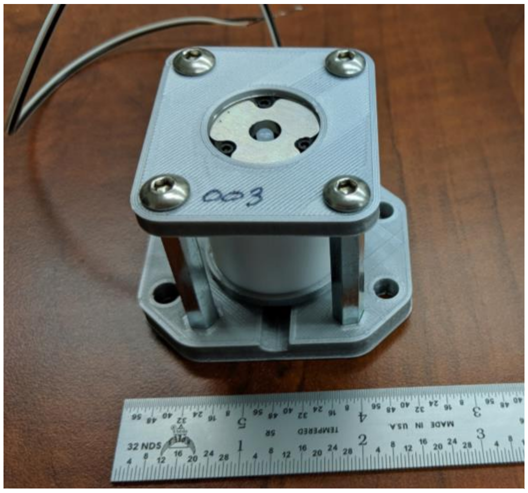

FIGURE 2: POSITION VERIFICATION SENSOR WITH DISCRETE OUTPUT

the kinematic chain are tested, the test method's results aim to isolate any source(s) of the error so the responsible component can be appropriately addressed. Implementing the test method first involves affixing mechanical keys at strategic locations along the workcell's kinematic chain that can present positional degradation. The PVS is physically installed within the workcell's work volume. The keys are commercial-off-the-shelf (COTS) items with precise geometries. The dimensions of the keys are in English units so the sensor's clearance dimension is manufactured in English units.

In the case of the NIST testbed, keys have been attached to multiple elements including the robot's tool flange, physical mount of the gripper jaws, and the movable gripper jaws, themselves (shown in FIGURE **2** 3). Once the keys are installed, the robot, along with the other movable elements in the kinematic chain (e.g., gripper), are systematically programmed to 'insert' their keys into the PVS. The PVS is designed such that the key can be successfully inserted within a specific tolerance as determined by the dimensions of the key and the opening of the PVS. If the key's position is inaccurate beyond the tolerance of the PVS' opening, then the test of that specific point will fail. Otherwise, if the movement of the key is within the tolerance of the PVS' opening, then the key will be successfully inserted into the PVS and this specific point will pass. The element to which the key is attached when a failure is observed highlights the approximate location of the degradation within the kinematic chain. More details are available in [16, 28].

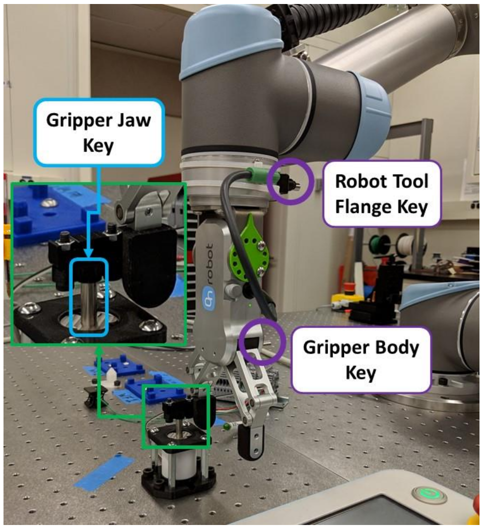

FIGURE 3: NIST TESTBED KEY MOUNTING LOCATIONS

The insertion of the key into the PVS is being verified to determine what uncertainty, if any, exists regarding the known tolerances of the fit. For example, if the clearance between the key and the PVS are designed to 25 µm, then the ideal scenario is that the key has a range of motion of 25 µm regarding its insertion into the PVS. Realistically speaking, uncertainties exist including manufacturing tolerances of the key and the PVS, the setup error of the key with respect to the PVS, etc.

As noted earlier, the PVS provides binary output, meaning that the element being tested either passes or fails its specific positioning test. If all elements can insert the key into the PVS then the workcell is considered healthy to the designed tolerance between the key and the PVS. If an element fails, then that data can be used to determine specifically where within the workcell a change or degradation has occurred. By itself, or coupled with other data from the workcell's operations, this data can be used to then efficiently respond to that change. The declaration that the workcell is healthy to the designed tolerance is only true if all uncertainties are known and quantified. If not, for example, a kinematic chain that successfully passes all tests with a tolerance of 25 µm may only be healthy to 50 µm or larger. Whatever it may be, it is critical for the manufacturer to know exactly what they are testing. The verification testing of the PVS is a core step in ultimately determining the uncertainty of the overall test method.

4. EXPERIMENTAL DESIGN

The PVS' performance needs to be verified to understand its capability and measurement uncertainties as it's used within the test method. The PVS is actively being tested to gather this information. A verification test process has been developed using an automated, linear, three-axis stage. The test stand is set up such that a standard key is mounted to the three-axis stage and a PVS is mounted directly below (as shown in FIGURE 4). The stage can then be commanded to move and insert the key into the PVS at different locations in an attempt to achieve a positive response from the PVS (i.e., the key is successfully inserted into the sensor). This test stand simulates robot movement with an attempt to insert the key into the PVS and the repeatability uncertainties that exist within them.

This test process was previously performed manually where there was a desire to automate the process because of the manual process being tedious, cumbersome, and susceptible to human

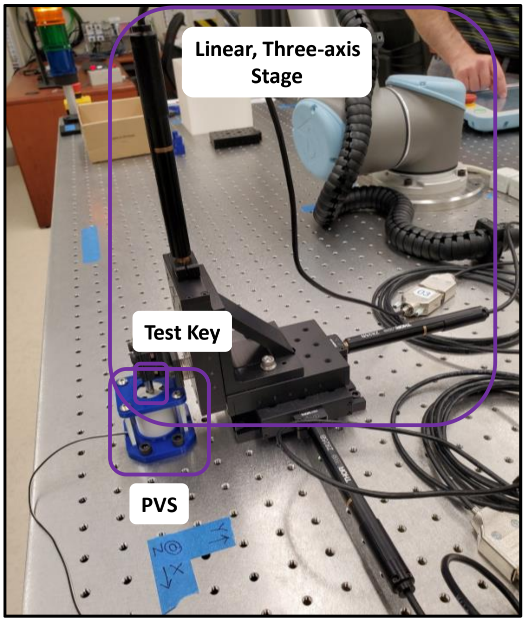

FIGURE 4: AUTOMATED TEST STAND

error. Stage movement had previously been controlled using manual micrometers, for the X and Y axis, and a lever for the Z axis (shown in FIGURE 5). The X and Y movements test different locations or points of the sensor while the Z axis movement is used to engage or disengage the key from the PVS. The chosen units enabled the user to move the stage in increments of one micrometer at a time providing very granular control of the stage's movements. To automate the movement of the stage, the micrometers and lever have been replaced with three motor controllers that are connected to three actuators (shown in FIGURE 4). This new hardware has the same range of motion and resolution as the manually-driven stage.

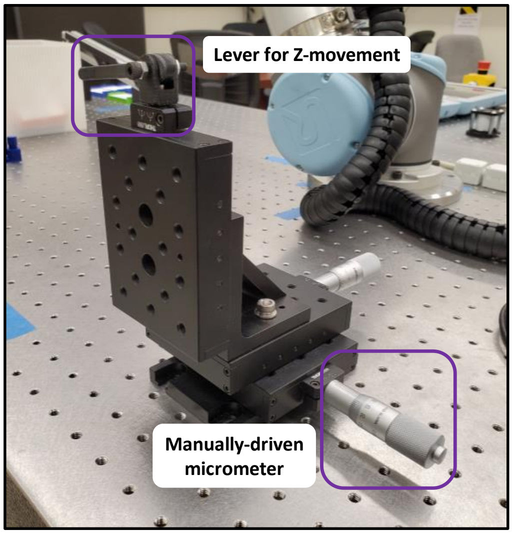

FIGURE 5: MANUAL TEST STAND

A Matlab program (running off a laptop PC that is connected via USB to the motor controllers of the linear stage) provides a test grid encompassing the top hole of the PVS. This grid consists of points to be tested, with the size and resolution of the grids (i.e., number of points to be tested and spacing between points) determined by user input. The program then selects the order for which the test points are evaluated by using one of three user-selected methods (i.e., random pattern, vertical movement testing each Y-column before moving onto the next, or horizontal movement testing each X-row before moving onto the next) and commands the stage to move the key to those points. At each point, the stage will attempt to insert the key into the PVS. The PVS' digital output is connected to an oscilloscope, which is used to determine the success of each attempted insertion. The oscilloscope measures the output voltage of the sensor at each test point, which is then input into the Matlab program. The oscilloscope is connected to the same PC laptop via USB connection. Upon receiving the signal input from the oscilloscope, the program can determine if the insertion was successful or not based on the captured voltage value (high voltage indicates success). Each test result is recorded within the program. Sample output from the Matlab is shown in FIGURE 6. Movements of the stage are programmed via Matlab in English Units given the English dimensions of the COTS key.

The results of the insertion at each point are stored, formatted into grids, and exported into MS Excel ®. Each point in the grid contains either a green "1" (indicating a successful test point) or a red "0" (indicated failed test point). These grids advance the understanding of how the sensor performs. Due to the circular shape of the mating hole on the sensor, it is expected that the results from each test will be a grid with a tight center circle of successful test points surrounded by unsuccessful test points. FIGURE 7 present results of random, horizontal, and vertical ordered tests with a 12x12 grid (for 144 total test points) and a stated key and sensor tolerance of 25 µm.

5. TESTING AND RESULTS

Preliminary sensor testing has been performed using this new automated test method. Testing was performed on two unique PVS's that differed in the material of a single internal component; one sensor's component is made from 3D printed plastic and the other sensor's component is made from machined stainless steel (SS). The PVS with the SS component was found to be of much higher precision than the PVS with the 3D printed plastic component.

Testing of the measurement test stand, along with capturing preliminary verification results of the PVS, began by conducting 55 total tests on a single PVS. These tests consisted of grid size XX and resolution YY. The order that the individual observations were collected varied across the 55 tests such that 19 tests were collected in random order, 18 tests in vertical order, and 18 tests in horizontal order. Ideally, it is expected that the successful sensor results would create a precise circular pattern, within the resolution of the test grid, with a diameter equal to the diameter of the key. All other areas of the test grid should result in

FIGURE 6. SAMPLE MATLAB OUTPUT

unsuccessful sensor results." The results of the testing done with this PVS deviated from the expected results. The circle of successful test observations encompassed most of the grid as opposed to the tight, expected center region. This led to the dissection of the first PVS revealing the internal 3D printed component. Given this material type is less precise than the machined SS, the SS PVS was then integrated into the measurement test stand. Fifteen total tests were run with the SS PVS: five random order, six vertical order, and four horizontal order; each with grid size XX and resolution YY. The grids created using this sensor were more closely aligned with what was originally anticipated; the grid was comprised of unsuccessful insertion tests, while the center of the grid was comprised of a tight, circular shape of successful tests. In total, 71 tests have been completed as of the preliminary development of this publication; 25 random order, 24 vertical order, and 22 horizontal order. These tests ranged in size from 12 observations (a very preliminary 3 x 4 grid to confirm the Matlab code) to 2500 observations. Test times ranged in duration from about five minutes to about 13 hours.

FIGURE 7: TEST RESULTS FROM 12X12 GRID TEST OF A 0.001" TOLERANCE BETWEEN THE KEY AND SS PVS

Some tests had unexpected anomalies; there were unsuccessful insertions in the middle of the grid where successful insertions were expected or successful insertions on the outside of the grid where failed insertions were expected. This was a very common problem that was faced throughout the entire testing process. FIGURE 7 presents three, 12 x 12 grid test results from random, horizontal, and vertical tests using the SS PVS that had a designed key/sensor tolerance of 25 μm. This means that the PVS opening is nominally 25 μm larger than the diameter of the key. For the specific tests that have been run and are discussed below, the PVS circular opening has a machined tolerance of 6.375 mm -0.0 to +12 μm while the tolerance of the cylinder key is 6.350 mm -0 to +5.08 μm. The non-binary numbers in FIGURE 7 represent the position, in millimeters, in the X and Y directions of travel from the X, Y coordinate origin of the key that is mated to the test stand.

Other tests included larger grid dimensions, such as 20 x 20 grids. FIGURE 8 presents a composite result of five separate, 20 x 20 tests that were performed. The results of the five tests were overlaid onto one another. The number provided at each individual point on the grid in FIGURE 8 is the number of total tests (out of 5) for which a successful insertion was observed. For example, a 3 represents a 60 % success rate where 3 insertions were successful while 2 insertions failed at the same point across five separate tests.

6. DISCUSSION

The material that is used to fabricate the two precision components of a single PVS was found to have a significant impact on the result of the test. 3D printed plastic yields less precise parts as compared to its machined SS counterpart. SS is a much stronger material that can be machined to tight tolerances making it a more advantageous material to use for the PVS's precision components. The PVS with the 3D printed plastic component has been removed from all further testing and workcell implementations. All PVS' in operation contain precision components made out of machined SS.

Further analysis uncovered additional deficiencies: 1) inconsistencies with the oscilloscope being used, 2) a defective automated linear stage, and 3) the geometry of the key. First, the oscilloscope that is used to measure the voltage from the PVS sensor would often emit a significant amount of electronic noise. This noise would cause the voltage values from the sensor to fluctuate to a degree that prevented the Matlab program from discerning between a successful and unsuccessful insertion test, leading to inaccurate results. Second, additional error stemmed from a breakdown of the linear, multi-axis stage that was used to move the pin to different points. The malfunction of the stage

FIGURE 8: COMPOSITE TEST RESULTS FROM 20X20 GRID TEST OF A 0.001" TOLERANCE BETWEEN THE KEY AND PVS

limited its range of motion and prevented it from moving to the desired location when commanded to do so by the Matlab program, which significantly impacted the results of some of the tests. The malfunctioning stage was replaced with a new, identical stage and testing continued. Lastly, it is important to note that the keys inserted into the PVS are COTS high precision cylinders with notionally known dimensions. Unfortunately, the cylinder contains a very small chamfer at the cylindrical edges. This chamfer feature likely resulted in several additional boundary test points being successful, as opposed to failing, since this chamfer would allow the pin to 'slide in' if the pin was slightly out of tolerance.

The impacts of these deficiencies were obvious for several tests whose results have been discarded entirely, however, the deficiencies may have also affected tests that have been considered "good". The results of the insertion process at one or more points in these "good" tests could have been changed due to these shortcomings. The malfunctioning stage issue has been resolved and will have minimal effect on future testing. The oscilloscope issue is still being investigated in order to find a solution to the problem, which may involve changing oscilloscope settings or changing the method used to measure sensor voltage. Regarding the COTS keys with slight chamfer, these keys are still in use until a viable replacement is determined. One potential solution is to machine custom keys of similarly tight tolerances with no chamfer, yet there will have to be some type of finishing operation performed on the edges of the cylinders to remove any sharp edges. This would provide a natural, yet slight chamfer. It's possible that the long-term solution is to continue to use the COTS keys and appropriately adjust the subsequent results. For example, a known, designed tolerance of 25 µm between the COTS key and the PVS could translate into successful insertion test results demonstrating a 63.5 µm tolerance.

The optimal test (i.e., size of grid, spacing between points, and optimal point selection process) for verification of the PVS is still being determined. Ideally, this verification test would provide enough information on the behavior and integrity of the PVS to generate a quantifiable confidence in its measurement capability; and be performed within a reasonable amount of time. The grid sizes that have been used so far have ranged from 3 x 4 to 50 x 50 and the resolution of the spacing between points has ranged from 100 µm to 5 µm. The results of the tests performed at each of these sizes and resolutions varied between the three different selection methods. The three order of observations methods (random, vertical, and horizontal) were applied at each of grid sizes and resolutions considered. More detailed grids generate more data on the PVS and its behavior, until a capacity is achieved where no new information can be gathered.

Overall, the preliminary test efforts proved insightful, both in terms of developing an initial understanding of the PVS' performance and the capability of this specific verification test method. From preliminary test results, including several composites that have been produced, it's evident that a key and PVS pairing with a designed 25 µm clearance will have successful insertion tests greater than 25 µm due to the factors discussed earlier in this section.

7. FUTURE EFFORTS

More testing is still required before reaching the end goal of releasing the sensor to industry for ubiquitous use. All the testing that has been performed so far has been done using PVS' with the specific clearance of 25 µm relative to the key. Future efforts will involve more testing of sensors with a key clearance of 25 µm, as well as other sensors with larger key clearances (e.g. 50 µm, 100 µm, 254 µm etc.). With additional testing and improvements, the PVS can be verified for implementation and use in manufacturing environments. The ultimate goal is for the *Identification and Isolation of Robot Workcell Accuracy Degradation* test method and the PVS to be used by industry to monitor and respond to changes in the health of their robot workcells.

The Matlab program used in the testing process will also be updated to add three new functionalities: a graphical user interface (GUI), an option to test grid boundary conditions (the regions where the test results change from successful to unsuccessful), and an expanded analysis and visualization capability within the Matlab platform. The GUI will make the testing process more user friendly for personnel who are not familiar with the program. The GUI is currently in the very early stages of development. The boundary testing functionality will allow the user to move the stage to the boundary points of the center circle and increment outwards by very small amounts (less than the distance between points) until reaching a point where the key and sensor are no longer able to mate. This will give the user a more accurate distribution, along with a more accurate representation of how the PVS behaves and crystallize the PVS' boundaries in terms of where successful tests become unsuccessful. This testing approach will gather new information about the PVS, such as a more accurate representation of the room for error that is acceptable to successfully insert the key into the PVS.

The current PVS that is being used in the test method is a binary sensor. It can communicate to users that an element along the workcell's kinematic chain either passes or fails the test, indicating whether the workcell is healthy or not. A new PVS is being developed with the ability to communicate a greater granularity of workcell health. For example, the workcell is healthy and no maintenance is needed, the workcell health is degrading but it is not affecting part quality, or the workcell is unhealthy and part quality is negatively impacted (this scenario would require immediate attention). This new PVS design expands upon the initial iteration adding another inner button and nesting a second outer circle of specific diameter. Additional details on the sensor are discussed in [28]. This intelligence would better enable manufacturers to optimize their maintenance efforts and schedules. This new generation of PVS will also require testing and verification. Future efforts will involve using the same, or a similar, process to test and verify this new sensor for release to manufacturers.

Lastly, it is intended that the data from the execution of the *Identification and Isolation of Robot Workcell Accuracy Degradation* will augment process and equipment intelligence with respect to health and maintenance activities. The PVS' binary output (pass or fail) of key elements along a robot workcell's kinematic chain, could be coupled with one or more of the data types presented in the BACKGROUND section to enhance overall maintenance intelligence of a manufacturing operation or speed deeper troubleshooting of a workcell. Once the PVS is further verified through additional testing, it's continued use within manufacturing facilities will present opportunities to capture binary test method data with real manufacturing data. This data will be correlated to better understand degradation trends and relationships among data types. Identifying redundant or inconsequential data can have a substantial impact on future data collection and analysis efforts. Ideally, manufacturers will only capture data from specific sources to acquire targeted intelligence leading to decisive and cost-effective maintenance actions.

UNDERSTANDING AND EVALUATING NAIVE DIAGNOSTICS ALGORITHMS APPLICABLE IN MULTISTAGE MANUFACTURING FROM A RISK MANAGEMENT PERSPECTIVE

Mehdi Dadfarnia, Michael Sharp, Timothy Sprock
National Institute of Standards and Technology
Gaithersburg, MD 20899

ABSTRACT

The world has entered a state of unprecedented access to machine intelligence algorithms, where the ease of deployment has created a scenario where nearly every facet of life and industry has been affected by AI. Especially within industry, where the options for enacting AI systems are wide and varied, the choice of which system will work best for a given application can be daunting. Understanding when, where, and why to apply a particular algorithm can provide competitive advantage on effectiveness as well as greater trust and justification when using the algorithms' outputs. This paper examines multistage manufacturing processes, where system complexity can greatly influence the burden of creating custom tailored monitoring solutions. Such barriers have encouraged many manufacturing small and medium enterprises (SME) to look towards generic 'black box' commercial software solutions, although they may lack the sufficient expertise to objectively determine which product best meets their requirements. Some of the considerations faced by SMEs are identifying tools that can successfully be deployed alongside a potential lack of sensor coverage and/or the desire for rapid system reconfiguration to accommodate smaller custom batch production sizes. In these environments, detailed analytics-based solutions are often not feasible for production equipment monitoring. This paper provides a procedure for assessing the suitability of various tools or algorithms used to evaluate production process performance based on product quality output. This paper also presents a preliminary comparative example study of several algorithms to demonstrate this process and evaluate the selected algorithms.

Keywords: Manufacturing simulation, problem diagnosis, fault isolation, evaluating algorithms.

1. INTRODUCTION

Manufacturing is a highly competitive industry where every decision should be qualified to ensure both effectiveness as well as a solid return on investment. A common choice faced by manufactures is the decision of if, when, and how to monitor both the quality of their product and the effectiveness of the machines used in the processes. Due to limits in resources, especially for SME manufacturers, the availability of information sources such as sensors to monitor individual machine effectiveness may be severely restricted or otherwise unsuitable for analysis. However, the two forms of information available to nearly any sized manufacturer are the end part quality and process path used to create each individual part.

Tracking part quality information and quickly identifying sources of problems has become particularly important in agile multistage manufacturing facilities where small batch sizes and rapid reconfiguration are vital to maintain a competitive edge. Rapidly changing system dynamics can exacerbate and propagate problems in machine performance across multiple product sets, costing thousands of dollars if not quickly identified and managed. Selecting proper tools and methods for monitoring system performance is a significant decision that can have long-term implications for management and factory operators who will have to interpret and interact with any deployed monitoring system. Being able to understand and justify decisions regarding the selection of a monitoring system can increase confidence in that system and help users understand any risk associated with its use on a factory floor.

Past research has focused on utilizing part quality data and part process path information to aid in the determination of problematic equipment or process links as the basis for maintenance activities [1]. Some of these activities are very specific, such as using historical part quality degradation to augment and improve linear system dynamics models to predict metrics such as tool wear [2]. The effort and effectiveness of each technique can vary widely between applications. This work seeks to provide a comparative analysis of several popular fault or problem isolation algorithms and to explore the general areas where they are most and least effective at identifying causes of part quality degradation. From this, a workflow is developed for testing the range of applicability of any algorithm

Dadfarnia, Mehdi; Sharp, Michael; Sprock, Timothy. "Understanding and Evaluating Naive Diagnostics Algorithms Applicable in Multistage Manufacturing from a Risk Management Perspective." Paper presented at ASME Manufacturing Science and Engineering Conference 2020 (MSEC 2020), Cincinnati, OH, US. June 22, 2020 - June 26, 2020.

as well as a basic guide for determining suitability of tested algorithms for various system setups. This paper is not meant to be an exhaustive comparison of all popular methods of multistage manufacturing monitoring, instead it is directed at developing an environment which can be used to critically evaluate tools and methods in a manner which allows for objective comparative assessment.

1.1. Background and Motivation

Stream of variance modeling has been a staple of multistage manufacturing since it was introduced in the 1990s [3]. Developed because rigid body assumptions do not always hold through production, stream of variance modeling recognizes that multistage processes can add compounding errors through both parts handling and machining. Some work focused directly on diagnosing fixture variation in multistage manufacturing processes [4] and led to further investigations of machining errors through explicit system modeling, such as via linear state space models [5]. Later work in statistical process control with linear state space models was able to utilize probability and hypothesis testing to capture faulty elements within a process [6]. Intuitively, many of these techniques are sensitive to the measurements and recordings used as inputs to the monitoring algorithm [7], meaning that they require significant sensing capabilities throughout the system. Other barriers to correctly implementing stream of variance algorithms include creating an accurate representation of features, selecting an optimal parts sampling criteria for inspection, and developing an adequate level of detail in modeling of the possible process faults [8].

Although these and related methodologies can provide important and accurate information regarding the propagation of errors as well as their initial incident location, explicit system models tend to require an advanced level of expertise, both with the system dynamics and the algorithms themselves, to properly implement. Additionally, many monitoring strategies relying on explicit system modeling become impractical for increasingly complex systems. To combat this, Huang et al. (2002) suggest simplifications and substitutions to mitigate this problem of growing complexity [9]. Many of these simplifications are based around the notion that there are certain configurations which will obfuscate areas from pinpoint diagnosis by simple virtue of their design. Zhou et al. (2003) understood that areas of obfuscation within a system, while unavoidable in some situations, would be strictly undesirable from a monitoring standpoint and proposed ways to quantify them [10]. In general terms, areas within a system become indistinguishable from one another if no unique information is generated between any subset of elements (within that area of the system).

Even with methods for simplifying the system model, often smaller enterprises do not develop monitoring tools that require explicit system models because the system dynamics change too rapidly to make any explicit modeling a practicality. This has driven investigations into less analytically-explicit monitoring algorithms. Further, due to the comparatively low amount of "stable data" produced by reconfigurable systems, practitioners seek algorithms that can operate with minimum input. One approach relies on using historical data to develop patterns of expected behavior from the machines based on post-production (or intermittent production) product quality reports, then comparing current behavior to develop diagnostic information. For example, methods for comparing expected distribution curves [11] and data- data-driven techniques for variation reduction [12] are gaining acceptance in multistage manufacturing.

Ultimately increasing data integration in automation and manufacturing depends on strong algorithms supporting human decision-making [13]. The strength of these algorithms depends on their performance evaluation and applicability. Evaluating the wide variety of algorithms in development and in practice has been inconsistent and traditionally reliant on the expertise levels of the developers or practitioners involved in the algorithm deployment. Most evaluations will stop if there exists a comparative analysis against one other algorithm on a limited set of system scenarios or data. This is due in part to the large time investment required to set up a large comparative study, but also due to a lack of understanding about how to set up such a study. In order to best evaluate an algorithm's suitability for a system, a majority of potentially disruptive scenarios must be considered. Regardless of the method or selection and availability of input data, the procedure for qualifying an algorithm or tool on a system must consider a majority of relevant edge cases as well as the nominal expected scenarios.

This work explores evaluating process fault or problem diagnostic tools with a very limited set of input data, specifically process path and part quality. That does not preclude extension of these procedures to more extensive algorithm testing. The choice to focus on algorithms that utilize limited information was motivated to both highlight the procedure on a simple comparative case with standard input parameters and to help shed light on real decision-making problems faced by SMEs. This case study will examine some of the 'black-box' solutions that are being applied to this problem. These include probabilistic statistical algorithms, gradient descent, genetic algorithms, and neural networks. These solutions will be framed to evaluate unsophisticated applications similar to that as may be identified by an SME seeking low-cost solutions to integrating new monitoring programs.

2. METHODOLOGY

This paper utilizes a general workflow for testing various fault or problem isolation algorithms. Defined or obtained series of system configurations will serve as the validation environment for obtaining exemplar data to investigate representations of a wide range of normal and off-normal operations. Special emphasis should be placed on investigating scenarios for both configurations and conditions that are reasonably expected to exhibit themselves in practice and would be antagonistic towards the algorithms being evaluated. In most multistage manufacturing systems, it is unreasonable to attempt to investigate all possible scenarios; part of this work is meant to help guide and highlight the process of determining high-risk edge cases that will provide the most pertinent information regarding the algorithm being evaluated. The final steps of the evaluation procedure are to apply the selected algorithms and measure them via metrics most suited to the end goals of the production line and, if necessary, iterate through the antagonistic scenarios to develop confidence in the coverage and performance of the algorithms.

2.1. Selecting Testing Scenarios

To show the viability and effectiveness of this workflow, a simulator was developed that can represent a variety of multistage manufacturing systems and conditions. For an actual manufacturing facility, it may be sufficient to simulate the actual or possible configurations for that specific production floor, possibly augmented with available historical data. This paper focuses on cases where the particular system that an algorithm will be tested on is not known beforehand. This additionally addresses the broader research perspective on which types of systems an algorithm is useful for. Testing various configurations follows from understanding that system configuration can profoundly impact the performance of the manufacturing process [14], and thus any monitoring tools deployed on them.

Each testing scenario consists of two major aspects: the system configuration and the condition. The configuration relates to how the equipment is connected and the process flow. The condition conveys the health of machines, production rates, etc. In many systems, the large number of possible system configurations and conditions makes it impractical to test every single one. Therefore, the testing methodology focuses on three primary classes of scenarios: nominal, high-risk, and those that are antagonistic towards the algorithm being tested. Some scenarios may fall into multiple classes, but a proper set of testing scenarios should provide sufficient coverage representing these classes as evenly as is practical. Finally, each scenario has a likelihood that gives a relative expectation of how often that scenario would be expected to occur in the lifetime of the system.

A major driver in selecting scenarios is the potential consequences of that scenario, both good and bad. Understanding the potential outcomes of combinations of missed fault alarms, false fault alarms, as well as correct alarms all can help drive the selection of scenarios. Coupled with the associated frequency, a potential risk for each scenario can be developed and used to identify important test cases. The risk metric (frequency * consequences) should be evaluated in terms most suited to the application. In a manufacturing setting, for example, risk can be measured as production loss per hour. Once acceptable levels of risk are established, any scenario which falls below that can be safely ignored.

2.1.1. Low-Risk High-Frequency and High-Risk Scenarios

The scenarios that should be developed first are those capturing the most common configurations and expected conditions of the factory environment. Even if the risk of these scenarios is fairly low, the fact that they are the most common scenarios necessitates their evaluation for any potential monitoring algorithm. These include scenarios such as a single faulty machine that does not stop operations. One occasionally overlooked scenario that should always be included is the most common configuration(s) with fault-free, nominal conditions. This is critical to help characterize the false positive rates of any diagnostic algorithms and establish a risk based on false alarms.

The second priority scenarios are those that may or may not be common but present a high-risk factor if the algorithm is unable to correctly identify the source of incipient defects or problems. High risk can come from both false positives and false negatives in terms of identification and must be evaluated for different combinations of both.

2.1.2. Antagonistic Scenarios

Antagonistic scenarios are less intuitive because they are typically more dependent on the algorithm than the physical process, but they are important to understand when interpreting evaluation testing. Antagonistic scenarios are configurations and conditions for which an algorithm is expected to perform poorly based on the assumptions and capabilities of that particular algorithm. These types of scenarios may not be known prior to the evaluation of the algorithm, but if a set of poor performing scenarios begins to develop, any identifiable commonalities can be used to group the full set of test scenarios and add extra examples to those groups if needed.

Once a set of antagonistic scenarios is developed, the existing suite of test scenarios can be checked for how commonly those antagonistic qualities occur. If they are prevalent, especially in high risk scenarios, there may not be a need to continue evaluating that algorithm, because it would be expected to perform poorly in these high-risk scenarios. However, if there are not many scenarios with these common traits, it is prudent to construct more such scenarios and evaluate if these have a high enough cumulative risk to affect the decision of accepting the algorithm.

2.2. Obtain Evaluation Data

Simulations and/or historic data will be required to perform these tests. Where available, simulators would generally be desirable to augment the available scenarios that can be evaluated. Real systems with huge backlogs of data can be used as an initial set of testing scenarios, but it is unlikely that real systems have substantial amounts of high-risk data under the array of faulted conditions that would be desired to fully evaluate a potential scenario. The flexibility of a simulator, augmenting any available real scenario data, allows for better exploration of high risk and antagonistic scenarios. Existing data or logs of activities can also be used to help develop the associated frequencies and consequences of any scenario. Maintenance and production logs may be a good source of this information.

2.3. Evaluate Algorithms

Once the test scenarios and data has been obtained, the algorithms should be streamed onto the data as they would receive it in an actual production environment. For example, if there is not a live stream of the product quality available in the plant, then the algorithm should be provided batch style updates with corresponding time stamps and other relevant meta-data. The processing time of the algorithm under evaluation should also be noted at this time. If the routine takes longer to process than the update rate for the system, special considerations and accommodations must be made, such as artificially slowing the input rate. If this cannot be done, or the accommodations are too severe to work at scale, the algorithm may be deemed unusable without further testing.

2.4. Representing Key Algorithm Performance Indicators

When evaluating algorithms, it is important to select performance indicators that not only reflect the performance of the algorithms but do it in a way that is relatable to the end goals of the monitoring algorithms. For most diagnostic isolation problems, the most important metrics are those that directly relate to negative consequences: false positives - identifying a fault where there isn't one, false negatives - failing to identify a fault, and circumstances that produce both. Because the repercussions of these three outcomes are generally significantly different and may even relate to specific equipment within the system, it is most appropriate and convenient to record the performance of the algorithms as a series of confusion matrices, one for each testing scenario. The important aspect for a risk-based evaluation is that each testing scenario have a numeric representation of the rate of negative consequences that can be translated into a probability during the final evaluation.

2.5. Summary

Below is a summary of the algorithm evaluation process presented in this section. The methods and selection criteria presented in this section are not intended to be interpreted as the only, or best possible criteria for every case. Instead they are described as a possible set that would be applicable in most cases and are the methods used in this work. The next section will describe the specifics of this work as applied to the developed test cases. The algorithms chosen for evaluation are also described, followed by the general outcomes of that investigation.

1. Define Testing Environment
2. Select Testing Scenarios
   a. Nominal and High-Risk Scenarios
   b. Antagonistic Scenarios
3. Obtain Data Covering Selected Scenario
4. Evaluate Selected Algorithm(s)
   a. Check Usability / Operational Concerns
   b. Evaluate Performance
5. Repeat as needed to discover edge cases with poor performance

3. PROOF OF CONCEPT CASE STUDY

This case study highlights the methodology for evaluating a specific class of monitoring algorithms that may be used to determine potential locations of induced damage or defects in products output from multistage manufacturing processes. The scenarios and configurations presented are selected to allow broad level performance investigation of algorithms on a potentially unknown system. A simulator was created as part of this work to rapidly create arbitrary scenarios generating the required end-of-line part quality and part process production path data. This data is then used to evaluate multistage manufacturing system diagnostic algorithms. The setup of the simulator includes the manufacturing system configuration (section 3.1), test case scenarios that characterize nominal and edge cases faced by the system (section 3.2), and diagnostic algorithms applied to analyze the scenarios (section 3.3). This evaluation is presented as preliminary work and additional work is needed to completely characterize the algorithms under evaluation.

3.1. Define Testing Environment

Figure 1 shows an example of different multistage manufacturing paths to produce a part, given a limited number of paths and available machines. Machines can be used across multiple paths (process plans), subject to timing restrictions, resulting in a directed graph representation of product production. Here we assume that it is possible for different production paths to use the same machine, but not possible for any path to use a particular machine more than once (reentrant flows). The subset of machines within each process path is assigned, either randomly or manually, at the beginning of each scenario and held static for the duration of the test.

The type of manufactured product is unspecified during the simulation, but it is assumed that quality metrics of any produced parts are scalable to some equivalent metric. Each part is given a single score (*Q_part***)** to indicate its build quality at the end of its sequence (end-of-line part quality). End quality assessments (*Q_part*) are scaled to a percentage of acceptability, where 100 % is perfect and anything below 0 % is considered lost product. This score relies on the added value from each machine that the part interacts with in its production path. Added quality value to the part is uniform across all machines unless the part interacts with a machine that underwent a sudden degradation or failure. In this case, the degraded machine will subtract from the part's accumulated value. Currently, part quality inspection is limited to the end of each production path.

Although simplified and abstract, this system configuration simulator exhibits key behaviors of real-world production settings, including resource constraints, a limited number of production path setups, and the limited number of available machines for production. Further development of the system configuration in future studies will include constraints on machine-ordering in a path (i.e., having rules such as "machine #6 may never be used before machine #3") and available

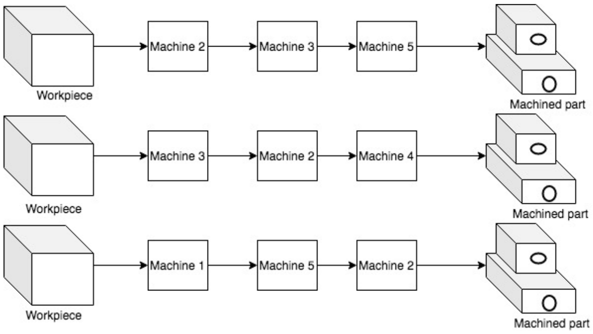

Figure 1. An example of three, unique three-stage machining paths to produce a part given five available machines.

machines categorized by different types, with constraints on the number of each machine type required to build a part. The machines may also have a more expansive feature space that determines each machine's added value to a part's quality.

3.2. Select Testing Scenarios

The above setup provides a framework to simulate different scenarios that could be used to evaluate multistage manufacturing system diagnostic algorithms that attempt to identify causes for part quality degradation. The focus in this paper is on part quality degradation due to sudden machine degradation or failure. The simulator receives specifications that after a certain number of products, a subset of the total set of available machines will degrade their added manufacturing values to the quality of parts that interact with it. As the quality for each part relies on the accumulation of the added values from all machines that are in the part's production path, the paths that have one or more of these degraded machines will output parts with lower end-of-line part quality values. Figure 2 illustrates a temporal view of the part quality outputs for an example test case scenario. Note that although the scalar part quality values are arbitrary, there is a drop-in value for parts that have been processed by some of the paths (that include the machine degradation at *t*=200 s).

The inputs into the configuration of the simulator are the number of machines on the "production floor", the number of processing steps each item needs to be created, the number of production paths or lines that a part can be created on, and the rate at which those parts are made. These inputs define a system of machines and paths involved in the multistage manufacturing process to produce each part. These key manufacturing parameters that go into the system configuration are summarized in Table 1. Presented in this paper are two preliminary scenarios defined by the values given in Table 1.

Test case scenarios are built to evaluate how well diagnostic algorithms identify degraded machines. In particular, it is interesting to evaluate the response of these diagnostic algorithms to different numbers of machines degraded at a time. Using the number of degraded machines as the main experimental factor in test case scenarios provides insight into the usability and accuracy of each tested algorithm for different numbers of degraded machines. These test cases are implemented on the two system configurations in Table 1.

Table 1. System Configuration Parameters

Description	System #1	System #2
Total number of available machines	10	12
Machines in a production path	4	6
Number of unique production paths	13	20
Part production rate (part per second)	1	1

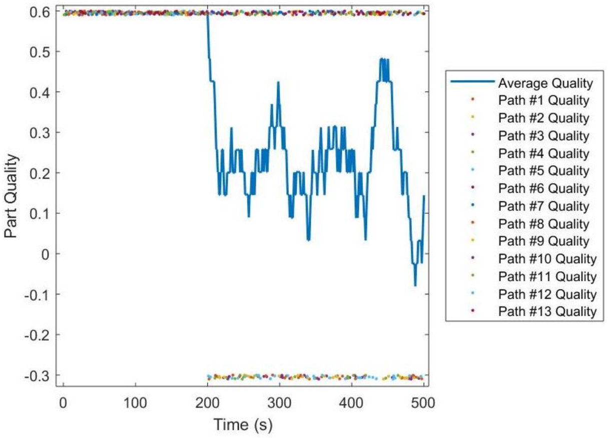

Figure 2. Example of a temporal view of part quality production. Machine degradation begins at t=200 s. Subsequently, paths that include the degraded machine produce lower-quality products.

For the first system configuration example, where there are 13 unique production paths and 4 machines (selected from an available 10) in each path, there are three levels to the experiment factor: one, two, or three machines are degraded. A maximum of three degraded machines is selected because it reaches sufficient coverage over scenarios where most of the machines in some production paths (3 of 4) are producing undesirable results.

Ten experiments, or test case scenarios, are performed for each of these three machine degradation levels. Each of these experiments is performed with different randomly-selected permutations of degraded machines. Ten is the maximum number of permutations when only one machine degradation occurs out of ten available machines. The number of possible permutations for two or three machine degradations is much higher. For the sake of brevity and producing initial results, the other machine degradation levels were limited to ten test case scenarios as well.

Table 2. Test Case Scenario Setup

	System #1	System #2
Number of Factor Levels	3	4
Number of Experiments Per Level	10	12
Total Number of Test Case Scenarios	30	48
Degradation Start Time (s)	200	200
Number of parts (stopping time)	500	800

Test case scenarios are similarly designed on the second system configuration example, where there are 20 unique production paths and 6 machines (out of an available 12) in each path. Since the scope of this example's multistage manufacturing system is larger, there are instead four levels to the experiment factor (a maximum of four degraded machines) and 12 experiments with different permutations at each level (12 is the maximum number of permutations when only one of 12 available machines degrade). Table 2 summarizes the test case scenario setup for each of the system configurations in Table 1.

The simulator generates the scenarios and stores the machines that degrade in each test case. The sequence of machines in the paths of each system configuration is held constant against the different machine degradation schemes from the test cases. This allows for applying diagnostic algorithms on each of these test case scenarios to compare their prediction of degraded machines against the actual machine failures as well as to evaluate their applicability to different machine degradation scenarios (i.e. different numbers of machines that degrade at a time).

The system configuration and test case scenario setups also enable the derivation of different properties from the system configurations. These properties may include the frequency of degraded machines within all the production paths or the amount of information that can be distinguished from the machines traversed in each path. This gives the opportunity to manipulate the properties and observe the prediction response of diagnostic algorithms to changes in different properties in the system configuration. This provides insight into the applicability and limitations of the diagnostic algorithms when there are changes in the system configuration. Discovering these insights requires changing the test case scenario setup to use the derived properties as experimental factors in a more extensive, robustly-designed experimental methods [15]. Deriving these properties and designing experiments around them are topics intended to be explored in future studies. Also, this paper has only been looking into the case of sudden machine failures. Future studies will expand to look at different types of machine failure modes, such as observing when diagnostic algorithms identify more gradual machine degradations.

3.3. Diagnostic Algorithms Application Setup

Five different diagnostic algorithms have been selected for evaluation and applied on each of the test scenarios for this work. Each algorithm makes use of only two sources of information: the end-of-production-line part quality, and the part process production path. Testing different algorithms allows to identify strengths and weaknesses of each one with respect to the different system configurations, amounts of machine induced degradation, and locations of induced damage. The selected algorithms are only a small random sampling of potentially useful methods for isolating induced faults on a multistage production line. The following describe the five algorithms tested.

3.3.1. Probabilistic Statistical Algorithms

One of the more intuitive mechanisms for performing diagnostic isolation is to evaluate the probability or likelihood that a given machine is producing a defective part based directly on the observed outputs corresponding to that process element. This could be framed under the guise of temporal difference reinforcement learning, a relative to Q learning. Presented below are two algorithms that utilize the intuitive nature of the process to create logical evaluations of the relative probability any given machine (process element) is inducing damage on the final observed product.

Part Quality Contribution Indicator (PQCI):

The first algorithm uses a running log of parts produced by each machine. It checks the ratio of the quality of parts operated on by a particular machine versus the quality of parts that were not. It uses this comparison to determine an estimate of the average induced damage at that machine. For this study, the quality of the last ten parts to be operated on by each machine is kept and measured. One of the obvious shortcomings of this method is that if a machine does operate on a significant number of parts as compared to the total number produced, it will be slow to identify the problem machine. However, with even levels of part flow or if the problem element is not a high-risk machine, then this algorithm may be expected to perform suitably for many scenarios.

Estimated Part-Path Contribution Indicator (EPPCI):

The second algorithm investigated also makes use of a moving window of part quality to produce diagnostic indicators. However, this algorithm keeps running logs of each process path instead of one for each individual processing element. In scenarios with relatively few process paths, this may improve scalability. Conversely this could also hinder scalability in highly complex system configurations with a large number of paths.

By performing a simple calculation using the system configuration and path quality logs, this algorithm calculates the average product quality of each machine per path to identify both the best and the average part quality produced by each machine based on the paths that include it. This method attempts to circumvent the potential problem of having certain process links, instead of individual machines, be the source of induced errors. For this paper, isolation of links was strictly excluded as it is intended for future papers, but the setup of this algorithm begins that process. Regardless, this algorithm would also be expected to perform well in isolating individual problem machines and so is evaluated on such here.

3.3.2. Prediction Error Minimization Algorithms

There are a class of low entry barrier machine learning tools and algorithms that attempt to minimize some predictive function designed to describe the observed output of the system. The commonality of this class is the need for that descriptive function. In this case, a simple minimization between the observed product damage (1 – Quality) for each machine and the predicted total amount of added damage from the processing machines. Assuming each machine linearly adds a calculable amount of damage to the product during processing, this class of algorithms can estimate the average amount of that damage that is added by each machine.

$$EQ(1) \quad Error = abs(\,(1 - sum(IDam\_machs\_part)) - (1 - Q\_part)), \qquad for\ all\ parts$$

The selected predictive equation of error for a system, shown in Eq(1), is utilized for three different diagnostic algorithms. Based on simple Gradient Descent (GD), one on Genetic Algorithms (GA), and one on applied Neural Networks (NN). Regardless of the mechanical implementation, these tress routines are all essentially trying to minimize this error function by producing induced damage estimations (IDam) for each machine.

Gradient Descent (GD): The Gradient Descent based method utilizes a standard off-the-shelf product (Matlab's *fmincon*) to search the possibility space for the combination of each machining element between sensible limits set by the user. For simplicity in this test, the choice was made to limit the possible damage induced by each machine to be between 0 (no damage) and 1 (complete loss of product acceptance). While other implementations of this algorithm may find other bounds more suitable, these are simple enough to cover a broad range of cases and limit processing time to a functionally usable amount.

Genetic Algorithms (GA): Considered a generally more robust optimization method, genetic algorithms have been used extensively on optimization problems due to their broad applicability, ease of use, and global perspective [16]. Like the gradient descent method above, a genetic algorithm is applied to test case scenarios to minimize the objective function in Eq. (1). The optimization process also outputs each machine's contribution to part quality degradation and a prediction of the machines that have degraded. To ensure the feasibility of the predictions of machine degradations, the algorithm was iterated 5 times over each test case scenario and its predictions were averaged. The genetic algorithm implemented in Matlab's Global Optimization Toolbox was evaluated using its default options (i.e., population size = 50, maximum number of generations = 100).

Neural Networks (LSTM): The final prediction error minimization technique applied in this work is a Long Short Term Memory (LSTM) based neural network. These are a special form of recurrent neural networks, which as explained by [17], are better able to process time series information due to having storage potential creating an effective memory of local trends. Neural networks have become standard machine learning tools due to their ease of use, effectiveness as classifiers, and practicality for obtaining features out of a dataset. The LSTMs created for this work serve to provide not only preliminary insights on their applicability, but also to justify further testing on additional architectures and configurations in future studies.

The selected network configuration under evaluation has a sequence input layer, a series of two hidden LSTM layers (each followed by a 20 % dropout layer), one fully connected layer, and a final regression layer. The input vector to the LSTM network includes the part quality and a corresponding binary vector representing production path elements of that part. Creation and execution of the LSTM network was performed using Matlab's Deep Learning Toolbox. The specifics of hyperparameter selection and architecture development are beyond the scope of this work. The process used here to compare various algorithms could be equally suited for comparing various neural network architectures.

4. TEST RESULTS

The results of evaluating the algorithms discussed in Section 3.3 compare their ability to identify damage-inducing machines in different scenarios and begin to establish their expected performance for classes of scenarios. The five diagnostic algorithms are evaluated and compared by applying them to the test scenarios (see Table 2) developed for each of the two multistage manufacturing system configurations (see Table 1). That is 30 test case scenarios for system configuration #1, evenly divided into 3 different categories of test cases, and 48 test case scenarios for system configuration #2, evenly divided into 4 different categories.

Each algorithm is evaluated using metrics chosen to measure the algorithm's performance at diagnosing machine degradation. To relate to real world based effects, metrics that can be directly combined with negative scenario consequences were selected: the false negative rate (FNR), the false positive rate (FPR), and the combination of the two. The false positive rate is calculated as the number of good machines incorrectly predicted to be inducing damage divided by the total number of machines that are operating in the system (Type-I error). Likewise, the false negative rate is calculated as the number of machines inducing damage not isolated by the algorithm divided by the total number of machines that are indeed producing damaged units (Type-II error). Not identifying a machine as a source of damage incurs costs associated with manufacturing defective parts and goods. While incorrectly identifying a machine as a source of damage incurs costs from misspent maintenance, inspection, and production downtime.

Figures 3A and 3B summarize the evaluation results from applying each of the five diagnostic algorithms to the selected test scenarios. In system configuration #1 there are three classes of test case scenarios corresponding to the number of machines that are producing degraded products: one, two, or three machines. Each diagnostic algorithm, except the LSTM neural network, is applied over the ten scenarios in each category. The resulting FNR and FPR evaluations are averaged for each category. This is similarly done for system configuration #2, but with four different level categories of test case scenarios and twelve test cases in each category.

Due to the requirements for development of a neural network, the LSTM network testing was performed differently. Rather than evaluate its performance on each category of test scenarios individually, the LSTM was trained, tested, and evaluated on all the test case scenarios available for each system configuration (30 test cases for system #1 and 48 for system #2). The model randomly selected 67 % of each configuration's test case scenarios as training data and the rest of the scenarios as testing data. This ensured that the network had training of various conditions on each configuration, allowing it to produce predictions of both nominal and problem status of machines. This also means that the LSTM's evaluated FNR and FPR metrics in Figures 3A and 3B cannot be directly compared to the corresponding evaluations of the other algorithms, but it still points towards preliminary insights into the applicability of neural networks for machine failure predictions. The LSTM results are included here for completeness but will be readdressed in future work.

As structured in Section 3.3, the algorithms listed each produce relative values for problem likelihood. In order to translate this into a classification of 'problem', 'no problem', a series of thresholds must be established. A threshold of -0.1 likely induced damage is selected as a discriminator for evaluating PQCI and EPPCI. GD and GA have been framed to operate on a different scale which translates their cutoff to a threshold of 0.6 is selected as the discriminator for evaluating both GA and GD.

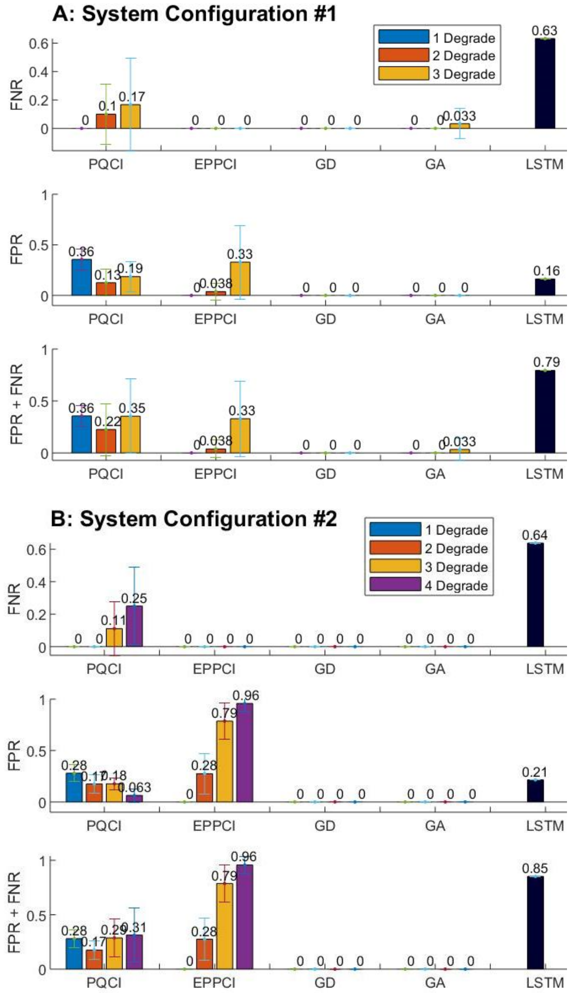

Figure 3. Evaluation results for applying the five diagnostic algorithms to predict machine degradation for three different test case scenario categories of: (A) system #1 and (B) system #2.

Like the GD and GA, the LSTM neural network also tries to predict which machines have contributed to part quality degradation. This means the threshold must also be between 0 and 1 to quantify the degree of a machine's contribution to part degradation. However, training the neural network on all the test case scenarios of each system configuration means that it tried learning from a wider range of antagonistic test case scenarios (rather than make a prediction from one test case at a time like the other four algorithms). This decreases the confidence in the predictions and so the discriminating threshold was lowered to 0.3.

At first glance, the results in Figures 3A and 3B show that the GD and GA algorithms provide superior performance to all the other algorithms. GD results in FNR and FPR values of 0, meaning it never identifies a failed machine as operational or an operational machine as degraded. This result is similar for GA, except a small false negative rate is produced when there are 3 machine degradations in system configuration #1. This supports a hypothesis that GD and GA will not make perfect predictions when there are too many machine failures in a production line. More testing is needed to see if this is indeed the case and to identify antagonistic test scenarios that may hamper the performance of GD and GA.

The PQCI and EPPCI algorithms exhibit trade-offs with each other. EPPCI produced no false negatives – no predictions of failed machines as operational - in any of the test case scenario levels for either system configuration. However, EPPCI produces a lot of false positives, especially for test cases where there are more machines that simultaneously degrade. It especially showed bad performance for multiple machine degradations in the second system configuration. On the other hand, PQCI produced false negatives that increased with more machine degradations, but it showed consistent levels of false positive rates that did not increase (drastically) with more machine degradations. The strength of one of these two algorithms over the other depends on the costs of having false negatives versus false positives in a manufacturing setting.

The predictive performance of both PQCI and EPPCI does not show to be as good as GD and GA, but their potential for scalability of more complex systems and to search for more indirect link based problems shows more promise. GD and GA attempt to search a full error space which grows exponentially with system complexity, while the evaluation space of the Q-learning space of PQCI and EPPCI grows linearly.

These insights are invaluable for creating antagonistic scenarios for further testing and evaluation of the algorithms. When identifying antagonistic test scenarios, an algorithm may have associated ranges of FNR and FPR that could help to further generalize the evaluation outcome. By properly combining the likelihood of these categories of test cases, their FNR and FPR values, an aggregated weighted evaluation of each diagnostic algorithm could be made to augment the existing test scenarios. This additional 'virtual testing' can save time and resources, while still valuably expand the coverage of the algorithm evaluation.

The LSTM neural network does provide many false negatives but produced false positive rates that are comparable to PQCI and EPCCI. A portion of the unfavorable results is due to training the LSTM on all test case scenarios for each system configuration. This points to the conclusion that learning on too many different antagonistic scenarios may not be as helpful for making machine failure predictions – there is a trade-off between the number of different antagonistic scenarios and the quality of the machine failure predictions. It will be helpful to see how the LSTM network performs when learning from and being applied to only one test case category level at a time. Furthermore, the LSTM network presented here is supposed to showcase preliminary work in the area, and more work will be done to fine-tune LSTM-related hyperparameters or evaluate other neural network structures.

5. CONCLUSIONS AND FUTURE WORK

This study showcases a preliminary understanding, applicability, and comparison of diagnostic algorithms (Section 3.3) when applied to predict machine failures in different simulated scenarios. The goal is to develop procedure recommendations for applying diagnostic monitoring algorithms across different scenarios, ranging from nominal expected scenarios to edge cases, faced by generic system configurations or particular configurations.

Further work needs to be done to extend the selection space of testing scenarios that are covered by the evaluation methodology, and to increase diagnostic algorithm development and evaluation. Two areas of particular interest right now include, 1) further development of risk assessment as an algorithm evaluation criteria, and 2) extending quality inspection to include mid-production process inspections. Algorithm evaluation can more precisely assess risk by incorporating costs and consequences associated with false negative and false positive machine degradation predictions, as well as relative likelihoods of different scenarios faced by the system configuration. This risk metric will represent more-practical effects and trade-offs of algorithms in relatable real-world measures beyond abstract classification metrics. In this preliminary study, the part quality inspection was conducted only at the end of the production path. This inspection data can be used to determine points in the production line that may require additional inspection or maintenance effort. These additional inspection points may provide diagnostic algorithms with more data collected throughout the production path and more context to make better predictions.

cyber-physical systems, high level architecture, network simulation, smart grid

ABSTRACT: *Cyber-physical systems (CPS) use logical computation informed by measurements of the environment to actuate changes on the physical world. These systems have significant impact on people, and must be designed for resilience against fault and attack. However, due to their large scale, assurance of CPS trustworthiness is better suited to modeling and simulation than deployment of a real system. This paper describes an approach to integrate a network simulator with the High Level Architecture (HLA) to investigate the effects of different network conditions on CPS performance. Using this approach, an HLA interaction class can be configured to use network simulation rather than the default reliable HLA delivery mechanism. A technique similar to regions defined in HLA data distribution management is used to allow each federate to receive the same interactions at different logical time steps, as simulated by the network simulator. This is implemented in a piece of reusable code shared by federates that sits between the runtime infrastructure (RTI) and application code. The implementation can be used to create a test harness around the federates that represent the operation of a CPS to validate its behavior under unreliable network conditions.*

1. Introduction

Cyber-physical systems (CPS) are smart systems that include engineered interacting networks of both physical and computational components [1]. These systems have a high degree of complexity at numerous spatial and temporal scales and need highly networked communications to integrate the computational and physical components. The smart grid is an example of a CPS that is defined as the integration of digital computing and communication technologies and services with the power-delivery infrastructure. The smart grid is often referred to as a system of systems that enables the bi-directional flow of both communication and power. Because the smart grid integrates information communication technology (ICT) with the electrical grid, network communication is one very important system component.

Grid operations are becoming more complex with the widespread deployment of distributed energy resources (DER) and distributed sensors that provide intelligence at the grid edge [2]. DER are comprised of many different types of resources such as solar photovoltaic (PV), wind, battery, and electric vehicle (EV). Some of these

Roth, Thomas; Nguyen, Cuong; Burns, Martin; Neema, Himanshu. "Integrating a Network Simulator with the High Level Architecture for the Co-Simulation of Cyber-Physical Systems." Paper presented at 2020 Simulation Innovation Workshop, Orlando, FL, US. February 10, 2020 - February 14, 2020.

resources such as PV and wind have volatility in energy production, and grid operators need robust communication capabilities to monitor and control them. Sensors distributed at the grid edge also have firm communication requirements to collect data, report, and fulfill their intended functions.

There are common standard-based communication protocols in use for grid operations. For substation automation, the two common protocols are IEC 61850 and Distributed Network Protocol 3 (DNP3). For DER communication, common protocols include IEEE 2030.5, DNP3, and SunSpec Modbus. Distributed sensors use protocols similar to both substation and DER. Beside these standardized protocols, there are manufacturer specific proprietary protocols. The choice of communication protocol for smart grid deployment depends on its performance capability, existing infrastructure, and the intended application. For example, if an operator plans to deploy an inverter for a PV installation, they need to consider what communication protocol their system can support to communicate with the inverter. If the operator plans to control DER, they will need a high-speed communication protocol for that application instead of a low bandwidth protocol that is only sufficient for monitoring alone. Other considerations may include whether the network connection between DER and the system is wired or wireless, and what cybersecurity mechanisms are required to protect the communication that still allow for the performance requirements.

Due to the complexity of the smart grid and its communication requirements, network simulation is essential and needs to represent the distributed nature of the evolving grid architecture. Sophisticated network simulation capabilities are needed to simulate the different communication protocols for the applications of interest to grid operators. Although such capabilities could be integrated into the implementation of grid simulators, it’s more intuitive to leverage the capabilities of existing network simulators. IEEE 1516-2010 High Level Architecture (HLA) is a standard for the co-simulation of distributed processes [3], such as the joint simulation of an electric grid and a network model. In HLA, the simulators that participate in a co-simulation are called federates, and the set of federates in the joint simulation are called a federation. The federates communicate and coordinate using software called the runtime infrastructure (RTI) that implements the common set of services described in the HLA federate interface specification [4]. An alternative to HLA is the Functional Mock-up Interface (FMI) standard often implemented by the developers of modeling tools [5]. Unlike HLA in which federates are independent processes in distributed system, FMI uses a master-slave architecture in which the master algorithm imports each simulator as a shared library and makes direct function calls into the slave code. The FMI standard for co-simulation prescribes the function definitions that each slave must implement to be interoperable with the master algorithm. This work uses HLA as its basis for co-simulation because it is more natural to consider a network simulator and a grid model as independent processes rather than sub-modules of one master program. In addition, networked co-simulation requires strict time management and distributed object management that are directly defined in HLA.

The remainder of this paper is organized as follows. Section 2 provides the motivation for the need of network simulation in the smart grid and lists the high level requirements that must be satisfied for network simulation to be meaningful in this context. Section 3 gives an overview of related work in the area, and Section 4 describes the specific approach to network simulation proposed by this work. The paper is then concluded in Section 5.

2. Motivation and Approach

For holistic system of systems evaluations, CPS require complex co-simulations including an integrated simulation of the cyber communication network as well as hardware- and human-in-the-loop. Owing to their use in critical system operations, the performance and trustworthiness of CPS must be evaluated under a variety of communication network modes which include the extreme cases of failures and attacks. In the smart grid, there are a variety of distributed sensors that are deployed at the system edge to provide situational awareness for monitoring and control. These sensors provide the condition at various points in the grid to detect any potential issues that could lead to system failure. One type of widely deployed sensor in the smart grid is the phasor measurement unit (PMU) or synchrophasor. PMUs provide voltage and current phasor and frequency measurements that are synchronized against a common time reference typically provided by global positioning system (GPS) [6]. Since these sensors provide time sensitive measurements, they need reliable communication to send the data to the grid control center. An attack on the timing infrastructure used by these devices could cause them to provide erroneous data to the operator that could lead to incorrect operating decisions such as unnecessary tripping of a line or not acting on a potential failure. Similarly, with the emergence of a plethora of innovative Internet of Things (IoT) devices for industrial control systems, edge computing, remote system monitoring and control, and home automation, it is equally critical to analyze the operational impacts of communication network failures for systems that incorporate IoT devices.

In order to analyze how communication network failures impact the operation of CPS and IoT, a careful consideration of the networked communication is necessary. In particular, analysis of a simple cyber attack might consider the impact of delaying the network packets, data corruption, replaying or reordering network packets, and packet loss. The HLA standard does not provide any direct means to support the co-simulation of these attack effects and supports only two options for delivering messages: receive order and timestamp order. In receive order, the messages are sent over UDP transport protocol and are delivered to the receiving federate with the best effort, without any explicit guarantee that a given message will be eventually delivered. In timestamp order, the messages are marked with a timestamp for delivery and are scheduled for delivery at that time to the receiving federate. A naïve approach may involve simply adding a delay to the timestamp of the delivered messages via HLA, but that does not realistically represent the behavior of unreliable message delivery. Even in cases in which a piece of manual code could be added to associated HLA federates' source code, this approach is highly inflexible and not representative of the flow of network packets in a real network. This is in contrast to using a communication network simulator that is integrated into the federation as a separate federate, where the networked communication between federates flows through the network simulator. The use of an integrated network simulator achieves not only faithful, high-fidelity network simulation, but also enables the realistic network characteristics such as unreliable message delivery against which the CPS and IoT systems can be evaluated.

The remainder of this section summarizes several desirable features for approaches to network simulation of CPS that are shown in Figure 1. The figure contains three federates, which consist of a federate implementation and the local RTI component (LRC) at each federate that implements the HLA message bus. Each federate has a unique representation in the simulated network model, depicted on the right. The remaining features in this figure are described in the subsections that follow.

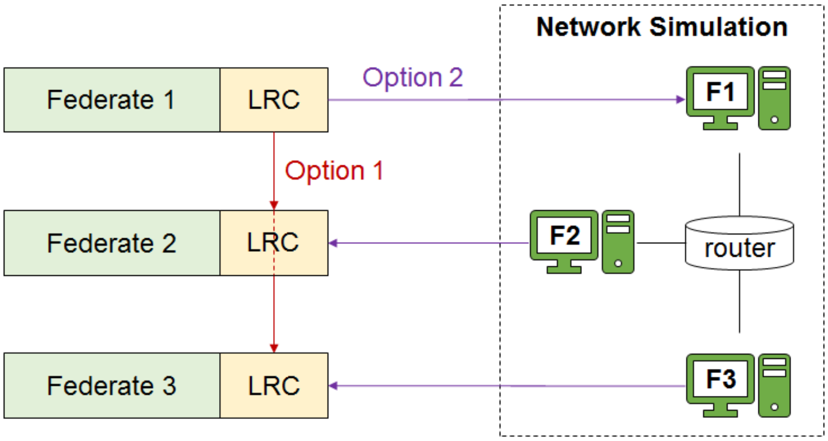

Figure 1: Approach to Network Simulation using the High Level Architecture (HLA)

2.1 The network model should contain nodes that represent a subset of the federates

At least two nodes from the network model should represent federates. The *Network Simulation* box from Figure 1 shows an example network model. A subset of the nodes in the network model indicated by labels F1 through F3 have a 1-to-1 correspondence to HLA federates. These federate nodes are connected through the simulated network topology. Although Figure 1 shows one network topology, the network model must be reconfigurable to allow the same federation to be executed with any number of different network configurations.

The network model does not need to define nodes to represent all federates in the federation. For instance, this federation could have a Federate 4 without the network model containing a corresponding node labeled F4. In this case, Federate 4 would not use the network simulation and all of its messages would use the default HLA provisions for object management. The network model also does not need to be fully connected. For instance, if node F1 cannot reach node F2 in the network topology, then none of the messages sent by Federate 1 using network simulation will be delivered to Federate 2.

2.2 The network simulator should be synchronized with the federation logical time

One responsibility of the network federate is to synchronize time progression of the simulated network with HLA federation logical time. The network federate is both time constrained and time regulating to operate in lock-step with HLA logical time. It also defines a function that maps a unit of HLA logical time to an exact number of seconds elapsed in the network simulation. This binding between the time representations of the federation and the network simulation ensures that a message is delivered to a federate only when the corresponding network packet is scheduled for delivery to that federate's node in the network simulation.

The optimal value for the logical step size of the network federate depends on the timing requirements of the federates using the simulated network. These timing requirements include concerns such as the smallest time interval between generation of network messages, and the shortest possible delivery time for messages sent from one federate to another. There is a trade-off between performance and simulation accuracy when choosing the logical step size. If the step size is too large, there will be delays in the delivery of messages to federates when a message arrives between time steps. If the step size is too small, the network simulator will synchronize more frequently with the federation which will lead to slower progression of logical time.

2.3 Network simulation should be configurable by both message type and sender

Even when a federate has a corresponding node in the network model, not all messages that originate from that federate are sent through the network simulation. A federate might want to coordinate with its peers or communicate with a federate that does not use the network simulation. For this reason, the use of network simulation is not configured per federate but rather per message that originates from a federate. This is shown in Figure 1 with two alternative paths for message flow listed as *Option 1* and *Option 2*. *Option 1* represents the normal HLA object management services where a federate can send and receive interactions and attribute updates using the RTI. *Option 2* is an alternative mode where specific messages are routed through a network simulator, rather than the usual set of HLA services.

In an ideal implementation, the LRC would perform this function of re-routing certain messages from the normal object management services into an alternative delivery mechanism based on the current network model. The RTI Initialization Data (RID) file could be modified to list the interactions and object classes that use network simulation. When the LRC received a message from the federate implementation, it would first check whether that specific message was configured for network simulation. If the message used simulation network, the LRC would send the message out-of-band to the network simulator. Otherwise, the LRC would continue to invoke the normal set of HLA object management services.

In this paper, the network simulator is a federate and *Option 2* is instead realized through re-encoding the message into a special interaction class that represents network packets. The network federate re-creates the original message once its corresponding network packet has propagated through the simulated network.

2.4 Federates should receive network simulated messages at different logical times

When the network federate receives a message from a LRC, it injects that message as one or more packets into the network simulation with the source of the packet set to the node representing the sending federate. If the network model is not based on multicast, then it is likely that one message will generate a unique packet for each federate node configured to receive that message that is reachable in the network model. All these packets will experience different delays, some may be dropped, and others might be modified through various forms of cyber-attacks. In the end, each federate node can receive a different packet, at different times, and perhaps with different content.

It is essential for cases such as network congestion and packet loss to break the reliable and uniform delivery of interactions and object classes guaranteed by HLA. Figure 1 shows an approach where this is implemented inside the RTI rather than the federates to reduce the amount of implementation required for each federate. However, the same effect could be achieved through implementation of a common library, shared by the federates, that sits between the LRC and the federate business logic.

2.5 Federate implementations should be agnostic to the presence of network simulation

Reusability is a desirable trait for federates developed for both CPS and IoT applications. Suppose a federate was developed to represent a PMU that reports time-synchronized voltage phasors measurements to some higher level application. This implementation could be useful for a number of different federation designs for different smart grid applications. Some of these applications might require realistic network delays to analyze the impacts of network congestion, some might require use of a specific communication protocol for hardware-in-the-loop testing, and some might just want to use a PMU with no network specific details. Despite differences in the interface on how the PMU is used, its basic implementation remains unchanged between these different applications.

While a typical HLA design flow might develop federations to achieve a specific purpose, in CPS and IoT applications, it is better to produce a federate like this PMU that can be composed into different scenarios. How this federate will be used is unknown at development time, and its implementation should support a broad range of scenarios without the need to develop additional code. For that reason, support for network simulation must be embedded into each federate as an option that can be enabled or disabled through configuration files. In addition, for different CPS and IoT federates to be interoperable, all the federates must implement their approach to optional network simulation using a consistent methodology.

3. Related Work

The integration of grid simulators and ICT into a co-simulation has over a decade of research. The first published approach in this area is the electric power and communication synchronizing simulator (EPOCHS) which uses HLA to integrate electromagnetic and electromechanical transient simulators with Network Simulator 2 (NS-2) [7]. Following EPOCHS, many co-simulation platforms were developed to integrate different grid simulators to different network simulators using different middleware [8]. The integrated co-simulation of power and ICT systems for real-time evaluation (INSPIRE) platform considers how to incorporate standard-based communication protocols into the co-simulation to support wide area monitoring, protection, and control (WAMPAC) applications [9]. The Hierarchical Engine for Large-scale Infrastructure Co-Simulation (HELICS) platform considers how to address scalability to handle grid scenarios that contain tens of thousands of independent agents [10].

The US National Institute of Standards and Technology (NIST) researched the effectiveness of different smart grid operating scenarios using the Framework for Network Co-Simulation (FNCS) developed by the Pacific Northwest National Laboratory that provides an integration of GridLAB-D, MATPOWER, and Network Simulator 3 (NS-3) [11]. The goal of this effort was to simulate a power grid segment that contained a substation and residential loads using different scenarios such as demand response and dynamic pricing. The work provided benchmarking for performance of the communication network under different operating conditions.

A follow-on work was on performance evaluation of DER and storage devices in terms of cost and impact on grid reliability [12]. This work was done by applying network traffic routing concepts to the routing of power in a grid segment with DER and storage devices. The premise for this work was that the resources are controllable, and the energy can be routed like network traffic management.

Additional research combined the smart grid operating scenarios (demand response and dynamic pricing) with the integration of DER in the grid [13]. This simulation work used a standard IEEE bus model with an integrated simulation platform that included GridMat, FNCS, GridLAB-D, and NS-3. The intent was to evaluate the performance of the grid with DER under different operating scenarios.

This paper attempts to address the feature from Section 2.4 on breaking the reliable delivery of HLA messages based on the results of network simulation. Other approaches largely limit their scope to adding message delays, and rarely consider the impact of packet loss or modification due to fault or cyber-attack.

4. Implementation Details

4.1 Universal CPS Environment for Federation (UCEF)

NIST has developed a software tool to expedite the development of federates and federations called the Universal CPS Environment for Federation (UCEF) [14]. UCEF is distributed as an Ubuntu virtual machine pre-configured with a suite of software useful in the development of different federate types. The latest 1.0.1 version of UCEF includes support for Java and C++ federates, and several grid simulators including GridLAB-D, TRNSYS, and EnergyPlus. The front end of UCEF is the Web-based Generic Modeling Environment (WebGME) developed at Vanderbilt University that provides a graphical web environment where users can model federations using simple building blocks. At the back end are JavaScript extensions to WebGME that perform code generation to transform the federate models into stub code for the different supported federate types. A core concept of UCEF is the separation of a federate implementation into two layers: a user layer that implements the intended function of the federate, and an infrastructure layer generated from WebGME that implements shared boiler plate code.

The UCEF infrastructure layer handles functions such as joining a federation, declaring publication and subscription interests, providing helper methods to send and receive interactions and object attributes, and other application independent utility functions. It also prescribes a basic federate lifecycle with hooks that an application developer can extend to customize the behavior of the federate at specific points in the HLA state machine, such as after the grant of an advance time request. The WebGME generated code closely resembles the structure of a Functional Mock-up Unit (FMU) as defined in the FMI standard for co-simulation.

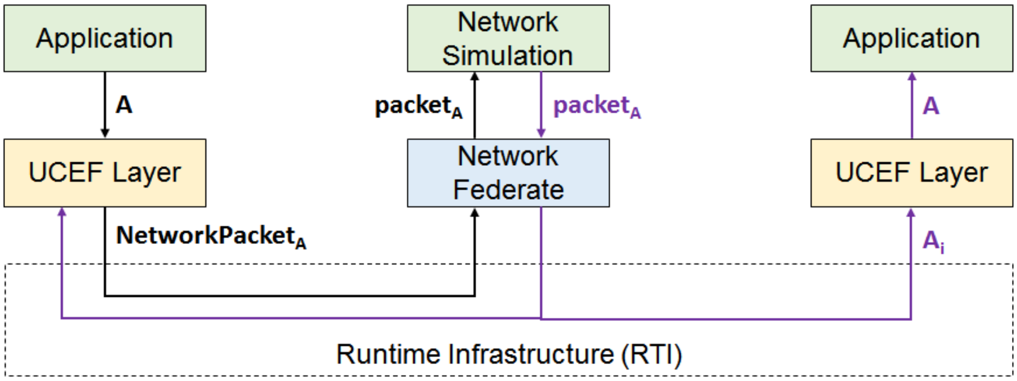

Figure 2: The UCEF Architecture for Network Simulation

Figure 2 shows how network simulation is implemented in UCEF to satisfy the requirements enumerated in Section 2. Rather than implement a new RTI, or modify an existing RTI, the logic related to network simulation was implemented in the UCEF infrastructure layer. In the figure, the user application on the left sends an interaction class A which has been flagged for network simulation. Before the UCEF layer passes this interaction to the RTI, it converts it into a special NetworkPacket interaction class to ensure it is routed to the network federate.

The network federate subscribes to the NetworkPacket interaction class, and encodes the received interaction instance as one or more packets in a format compatible with the network simulation. These packets are injected into the network simulation, where they propagate through the simulated network. When a packet arrives at its destination, it is delivered back to the network federate along with the name of the destination node from the network simulation. Then the network federate reconstructs the original interaction embedded inside the NetworkPacket and watermarks this new interaction with the destination node name. The network federate is implemented using a library called the UCEF Gateway [15], which enables it to create dynamic publications based on the current federation object model. As such, the network federate is not bound to a specific data model and can be used in any federation without code modification.

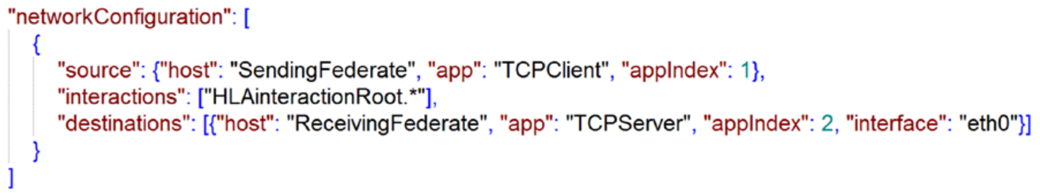
Because the network federate sends the watermarked interaction using the standard HLA services, all subscribed federates will receive it. However, each federate is configured to know the name of its representation in the network simulation, and the UCEF layer can use the watermark to check if an interaction was meant for its user application. In this manner, even though the left most federate receives a copy of its own interaction A_i¸ this interaction will be dropped at the UCEF layer before it reaches the user application.

One constraint of this approach is that all federates that use network simulation must have the same UCEF layer, which means they must be code generated from the UCEF virtual machine. The benefit of the approach is that the application never has to know about the network simulation and only must consider its native interaction class A. When network simulation is required, the infrastructure will take care of it. The remainder of this section describes how network simulation was embedded into the UCEF layer.

4.2 Network Configuration of UCEF Federates

There are three requirements to support network simulation in the UCEF layer: (1) the interaction classes that require network simulation must be specified in a configuration file, (2) the NetworkPacket interaction class must be defined, and (3) a filtering mechanism must be defined to ensure that interactions sent by the network federate are received only by the intended federates.

The same configuration file for network simulation is shared by all federates, including the network federate. This JavaScript Object Notation (JSON) file lists which interactions from which federates should use network simulation and how those interactions should be routed through the network simulation. Figure 3 shows an example instance of this configuration file. This JSON configuration was designed for use with the OMNeT++ network simulator using its INET Framework.



```
"networkConfiguration": [
    {
        "source": {"host": "SendingFederate", "app": "TCPClient", "appIndex": 1},
        "interactions": ["HLAinteractionRoot.*"],
        "destinations": [{"host": "ReceivingFederate", "app": "TCPServer", "appIndex": 2, "interface": "eth0"}]
    }
]
```

Figure 3: Example JSON for Network Configuration

The network configuration is a list of network rules. Each network rule defines the list of *interactions* for a given *source* federate that are configured to use network simulation. These interactions are injected into the network model at the *source* node and routed to each of the listed *destinations*. The same *source* federate can appear in multiple network rules for the case when different interactions from the same source have different destinations. This implementation assumes for simplicity that the federate name is identical to the host name of its equivalent network node. Under this assumption, the *host* fields are both the federate name and the network node name.

A network node in the OMNeT++ INET Framework contains submodules for different network applications. For example, a node could define a submodule for a Representational State Transfer (REST) server running on localhost:8080. These network applications are identified using an application name (*app*) and an application or submodule index (*appIndex*). The destination applications are bound to a specific network interface (*interface*) to handle cases where a node has more than one available network interface.

Figure 4 shows the WebGME representations of the two interaction classes *HLAinteractionRoot.InteractionBase* and *HLAinteractionRoot.InteractionBase.NetworkPacket*.

NetworkPacket
<InteractionBase>

PARAMETERS	
data:	String
interactionClass:	String
networkHost:	String
federateFilter:	String

Figure 4: Example Object Model for Network Simulation

The UCEF layer encodes all interactions it sends to the network federate using the NetworkPacket interaction class. Besides the *federateFilter* parameter that will be discussed later, this interaction class has three parameters. The *interactionClass* and *data* parameters are used to embed the original interaction from the user application into the NetworkPacket. When an instance of interaction class A is converted into a NetworkPacket, the *interactionClass* parameter would be the fully qualified class path of A and the *data* parameter would be the serialized parameters of A. These fields are used by the network federate to reconstruct the original interaction after the packet propagates through the network simulation. The final parameter, *networkHost*, is set to the unique identifier of the sending federate. This allows the network federate to inject the packet into the network simulation at the correct node.

When the UCEF layer receives an interaction, it checks if that interaction was sent by the network federate. If the interaction was sent by the network federate, then it is possible that it was only intended for receipt by a single federate. The network federate uses the *federateFilter* parameter to specify this destination. If the *federateFilter* is empty, then the UCEF layer processes the interaction as normal. Otherwise, the UCEF layer discards the interaction unless the *federateFilter* is string equivalent to the federate's own unique identifier.

4.3 Implementation of the UCEF Layer

Figure 5 shows a flowchart for how interaction classes are handled from both the sending and the receiving federates. The first decision box at the top of the figure, whether to use network simulation, is determined by the content of the JSON file from Figure 3. The second decision box at the bottom of the figure, whether the received interaction should be delivered to this specific federate, performs the string comparison between the *federateFilter* parameter from Figure 4 and the federate name of the receiving federate. If the federate filter parameter is set but not equivalent to the receiving federate name, then the packet is dropped and not delivered to the user application.

This filtering mechanism allows different federates to receive the same interaction at different logical times, dependent on the results of network simulation. An equivalent implementation could have been achieved using regions from the HLA data distribution management (DMM) services instead of as a parameter of a base interaction type. However, as the configuration management of regions can be quite cumbersome, this simple filtering mechanism was implemented at the UCEF layer instead.

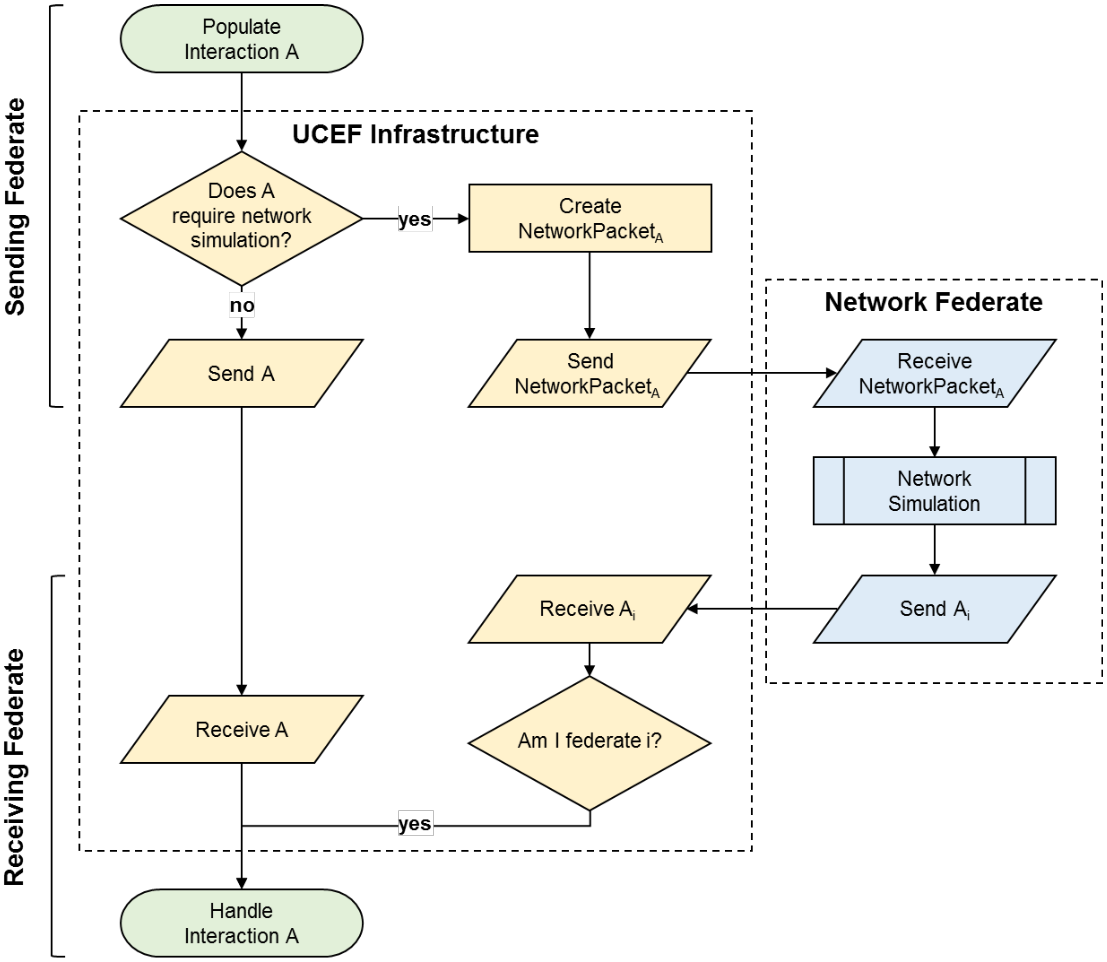

Figure 5: Flow of Interactions through the UCEF Layer

4.4 Implementation of the Network Federate

Algorithm 1 shows pseudocode for the network simulation from Figure 5. This algorithm uses the OMNeT++ network simulator, and extends the OMNeT++ *cSimpleModule* class which defines the *step* and *handleMessage* methods. The *step* method executes each HLA logical time step and checks for either packets from the network simulator or interactions from the federation. When an interaction is received, the *step* method parses the JSON network configuration to create packets in the network simulation for each configured destination. These packets propagate through the simulated network until they arrive at their destination, causing OMNeT++ to invoke the *handleMessage* method. In *handleMessage*, a customized interaction is created for the node that received the packet. The current implementation of time synchronization maps a unit of HLA logical time to a second of network simulation time. The *advanceTimeRequest* method could be replaced with an alternative implementation that uses a scaling function to make each logical time step some configurable multiple of seconds.

Algorithm 1: Network Simulation Pseudocode

```
variable: toHlaQueue
variable: toNetQueue
variable: networkConfiguration

method step() // inherited from cSimpleModule
    foreach $interaction \in toHlaQueue$ do
        sendToHla($interaction$)
    foreach $interaction \in toNetQueue$ do
        rule ← getNetworkRule($interaction.networkHost$, $interaction.interactionClass$)
        // create unique packet for each destination
        foreach $destination \in rule.destinations$ do
            packet ← convertToPacket($interaction.data$)
            packet.destination ← rule.destination
            sendDirect($packet$, $rule.source$) // inject packet into OMNeT++
    advanceTimeRequest() // synchronize with HLA logical time

method handleMessage($packet$) // inherited from cSimpleModule
    if $interaction$ ← convertToInteraction($packet$) then
        toHlaQueue.push(interaction) // ignore packets that do not contain embedded interactions

method receiveInteraction($networkPacket$)
    toNetQueue.push(networkPacket)

method getNetworkRule($host$, $interaction$)
    foreach $rule \in networkConfiguration$ do
        // the ∈ operation must handle the wildcard character
        if $host = rule.source.host \wedge interaction \in rule.interactions$ then
            return rule
    return $\emptyset$
```

5. Conclusion

This paper proposed an approach to incorporate network simulation into the High Level Architecture (HLA). Whether the proposed approach is HLA compliant depends on the interpretation of the rule that *"During a federation execution, all exchange of FOM data among federates shall occur via the RTI"* [4]. From the federate perspective, this rule is upheld because the NetworkPacket interaction is transmitted to the federation via the RTI. However, from the user application perspective, the interaction that the user wants to send is automatically converted into a different interaction class and the RTI is never used to transmit the data in its intended format. This approach was chosen because co-simulation of CPS requires network simulations that support the concepts of message delay and packet drop, and integrating the semantics of network simulation into each individual federate - while feasible - is far too burdensome.

The next step is to complete the implementation of this approach in UCEF. An implementation that addresses the need for packet loss and modification was developed by Vanderbilt University for their Command and Control Wind Tunnel (C2WT) platform [16][17]. However, it requires source code modifications when changes are made to the network configuration. Another implementation was released by Calytrix for their open-source Portico RTI [18]. However, it requires the use of multiple network federates which leads to poor scalability for large federation sizes, and the approach may be incompatible with the popular OMNeT++ INET Framework. Future work will merge these implementations to produce one network federate configurable using JSON that is compatible with the OMNeT++ INET Framework. This future work will aim to improve the time synchronization strategy to be more flexible than a 1-to-1 equivalence between HLA logical time and the network simulator time.

IDENTIFICATION OF GEOMETRIC NONLINEARITY FORMULATIONS AND THE INFLUENCES ON STRUCTURAL DYNAMIC RESPONSES

K.K.F. Wong[(1)]

[(1)] *Research Structural Engineer, National Institute of Standards and Technology, USA, kfwong@nist.gov*

Abstract

Both ASCE/SEI 7-16 [1] and ASCE/SEI 41-17 [2] design standards require that P-Δ effects be included in the nonlinear dynamic analysis procedure for designing new and existing structures. However, software packages that perform nonlinear dynamic analysis typically only allow users to either 'turn on' or 'turn off' the effect of geometric nonlinearity without informing users what type of nonlinear effect is being included, such as whether both large P-Δ and small P-δ effects are included. Coupling this geometric nonlinearity effect with material nonlinearity of the structure can lead to significant differences in the predicted responses, especially when the structure is at near-collapse. Therefore, study on how geometric nonlinearity can affect structural performance is important to performance-based seismic engineering.

The challenge of how each software package handles the coupling between geometric and material nonlinearities often comes down to their interaction. The traditional method of structural analysis with material nonlinearity uses changing stiffness to quantify the stiffness reduction after yielding has occurred in the structure, which requires reformulation of the global stiffness matrix before solving for the displacement response. The difficulty comes in when the axial force reduces the stiffness of the member and at the same time when tangent stiffness is used after a nonlinear component has yielded. Will this axial force further reduce the tangent stiffness, and by how much? On the other hand, the use of tangent stiffness is typically derived based only on material nonlinearity with no consideration of geometric nonlinearity. At the same time, the use of geometric stiffness was derived based only on geometric nonlinearity with no consideration of material nonlinearity. Therefore, one needs to go back to the original derivation with the basic principles to answer this question.

In this paper, a detailed formulation of the nonlinear stiffness matrices taking into consideration both geometric and material nonlinearities is derived for a column member. It is followed by a study on how different software packages implement different geometric nonlinearity formulations and identify whether such formulation include both large P-Δ and small P-δ effects in the analysis. Finally, examples are presented to demonstrate how different formulations of geometric nonlinearity affect the nonlinear responses of framed structures.

Wong, Kevin K F. "Identification of Geometric Nonlinearity Formulations and the Influences on Structural Dynamic Responses." Paper presented at 17th World Conference on Earthquake Engineering, Sendai, JP. September 13, 2020 - September 18, 2020.

1. Introduction

Buildings constructed in seismic regions are vulnerable to strong ground shaking and thus are designed to sustain damage caused by material nonlinearity and remain stable by overcoming geometric nonlinearity. Nonlinear dynamic analysis with both geometric and material nonlinearities is currently the most accurate method of estimating the response to seismic events. For this reason, both ASCE/SEI 7-16 [1] and ASCE/SEI 41-17 [2] require that geometric nonlinearity be included in the nonlinear dynamic analysis procedure. However, software packages provide a geometric nonlinearity "button" but do not explicitly state the specific geometric nonlinearity formulation implemented in these packages. For example, some software packages may implement the full geometric stiffness formulation that includes both large *P*-Δ and small *P*-δ effects, while other software packages may implement the simpler *P*-Δ stiffness formulation that accounts for only *P*-Δ effect.

This research investigates how different software packages implement geometric nonlinearity affect the nonlinear dynamic response calculations. To accomplish this work, a detailed formulation of the nonlinear stiffness matrices taking into consideration both geometric and material nonlinearities is first derived for a column member. It is followed by a study on how different software packages implement different geometric nonlinearity formulations and identify whether such formulation include both large *P*-Δ and small *P*-δ effects in the analysis. Finally, examples are presented to demonstrate how different geometric nonlinearity formulations affect the nonlinear responses of framed structures.

2. Derivations of Stiffness Matrix with Both Geometric and Material Nonlinearities

The original beam theory with geometric nonlinearity [3-4] was first developed for elastic columns in the 1960's without consideration of any material nonlinearity. But its use is limited because of its complexity in the closed-form solution as compared to those formulations based on either the *P*-Δ stiffness approach [5] or the geometric stiffness approach [6]. However, to identify the geometric nonlinearity used in software packages, it is often important to go back to the fundamental principle and understand how each geometric nonlinearity formulation is developed. Therefore, the original theory that included geometric nonlinearity is rederived here and extended to include material nonlinearity. This is done by deriving the stiffness matrix for a column member with plastic hinges at both ends and subjected to a compressive force.

Four degrees of freedom (DOFs) and two plastic hinge locations (PHLs) are used to describe the movements at the two ends of a column member in a moment-resisting frame. These movements at the two ends include lateral displacement ($v(0)$ and $v(L)$), rotation ($v'(0)$ and $v'(L)$), and plastic rotations at the two plastic hinges (θ''_a and θ''_b). To compute the member stiffness matrix $\mathbf{k}_i$, where *i* denotes the i^{th} member in the frame, each of these 4 DOFs and 2 PHLs is displaced independently by one unit as shown in Fig.1 while subjected to an axial compressive load *P*. Here, V_{1k}, M_{1k}, V_{2k}, and M_{2k} represent the required shear forces and moments at the two ends of the member to cause the deformation in the prescribed pattern, where $k = 1,\ldots,6$ represents the six cases of unit displacement patterns of the member's movements, and M_{ak} and M_{bk} represent the moment at plastic hinges '*a*' and '*b*', respectively, due to the prescribed pattern. Note that the '1' end coincides with plastic hinge '*a*' and the '2' end coincides with plastic hinge '*b*' in Fig.1.

Using the classical Bernoulli-Euler beam theory with homogeneous and isotropic material properties, where the moment is proportional to the curvature and plane sections are assumed to remain plane based on small displacements, the governing equilibrium equation describing the deflected shape of the member is

$$(EIv'')'' + Pv'' = 0 \tag{1}$$

where *E* is the elastic modulus, *I* is the moment of inertia, *v* is the lateral deflection, *P* is the axial compressive force on the member, and each prime represents taking derivatives of the corresponding variable with respect to the *x*-direction of the member. By assuming *EI* is constant along the member, the solution to the fourth-order ordinary differential equation given in Eq. (1) becomes:

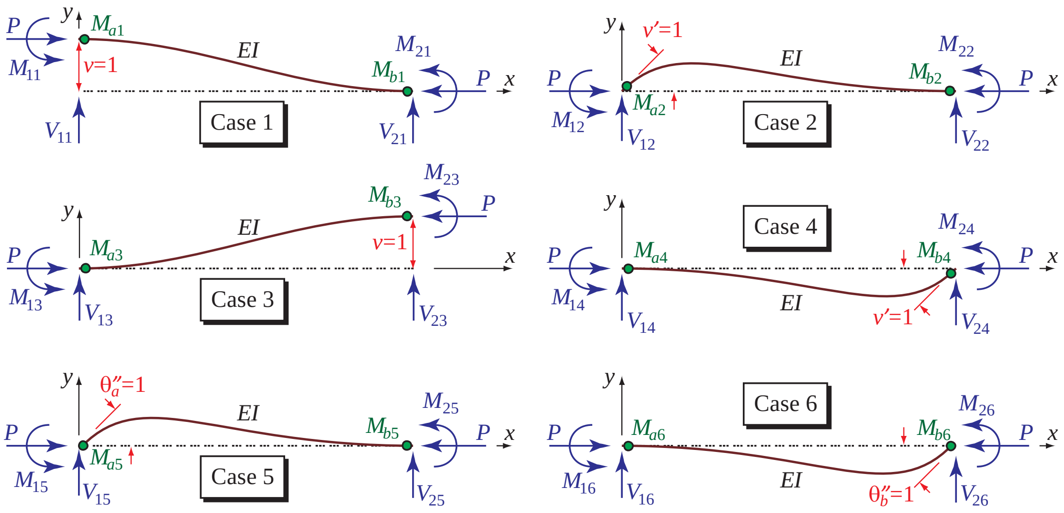

Fig. 1 – Six cases of unit displacement patterns and corresponding fixed-end forces and hinge moments

$$v = A\sin kx + B\cos kx + Cx + D \tag{2}$$

where $k^2 = P/EI$ and A, B, C, and D are constants to be determined by imposing different boundary conditions. Let $\lambda = kL$ to simplify the derivations, where L is the length of the member. The following cases of boundary conditions (starting with Case 4) are now considered.

2.1 Case 4

For Case 4 as shown in Fig.1, imposing the boundary conditions $v(0)=0$, $v'(0)=0$, $v(L)=0$, $v'(L)=1$, and $\theta''_a = \theta''_b = 0$ on Eq. (2) gives

$$v(0)=0: \qquad B + D = 0 \tag{3a}$$

$$v'(0)=0: \qquad kA + C = 0 \tag{3b}$$

$$v(L)=0: \qquad A\sin\lambda + B\cos\lambda + CL + D = 0 \tag{3c}$$

$$v'(L)=1: \qquad kA\cos\lambda - kB\sin\lambda + C = 1 \tag{3d}$$

Solving simultaneously for the constants in Eq. (3) gives

$$A = \frac{L(1-\cos\lambda)}{\lambda(\lambda\sin\lambda + 2\cos\lambda - 2)} \ , \quad B = \frac{L(\sin\lambda - \lambda)}{\lambda(\lambda\sin\lambda + 2\cos\lambda - 2)} \ , \quad C = -kA \ , \quad D = -B \tag{4}$$

Therefore, Eq. (2) along with the constants in Eq. (4) gives the deflected shape for Case 4. The shears (i.e., V_{14} and V_{24}) and moments (i.e., M_{14} and M_{24}) at the two ends of the member (see Fig.1) are then evaluated using the classical Bernoulli-Euler beam theory formula:

$$M(x) = EIv'' \quad , \quad V(x) = EIv''' + Pv' \tag{5}$$

Now taking derivatives of Eq. (2) and substituting the results into Eq. (5) while using the constants calculated in Eq. (4), the shears and moments at the two ends of the member are calculated as:

$$M_{14} = -EIv''(0) = EIk^2B = \hat{s}\hat{c}EI/L \tag{6a}$$

$$V_{14} = EIv'''(0) + Pv'(0) = -EIk^3A + P\times 0 = \bar{s}EI/L^2 \tag{6b}$$

$$M_{24} = EIv''(L) = -EIk^2(A\sin\lambda + B\cos\lambda) = \hat{s}EI/L \tag{6c}$$

$$V_{24} = -EIv'''(L) - Pv'(L) = EIk^3\left(A\cos\lambda - B\sin\lambda\right) - P\times 1 = -\bar{s}EI/L^2 \tag{6d}$$

where $\hat{s}$, $\hat{c}$, and $\bar{s}$ are the first three stability coefficients computed by the formula

$$\hat{s} = \frac{\lambda\left(\sin\lambda - \lambda\cos\lambda\right)}{2-2\cos\lambda-\lambda\sin\lambda} \quad , \quad \hat{c} = \frac{\lambda - \sin\lambda}{\sin\lambda - \lambda\cos\lambda} \quad , \quad \bar{s} = \hat{s} + \hat{s}\hat{c} = \frac{\lambda^2\left(1-\cos\lambda\right)}{2-2\cos\lambda-\lambda\sin\lambda} \tag{7}$$

In addition, the moments at the two PHLs can be evaluated by recognizing that these moments must equal to the end moments by equilibrium, i.e., $M_{a4} = M_{14}$ and $M_{b4} = M_{24}$. Therefore,

$$M_{a4} = M_{14} = \hat{s}\hat{c}EI/L \quad , \quad M_{b4} = M_{24} = \hat{s}EI/L \tag{8}$$

2.2 Case 3

For Case 3 as shown in Fig.1, imposing the boundary conditions $v(0)=0$, $v'(0)=0$, $v(L)=1$, $v'(L)=0$, and $\theta''_a = \theta''_b = 0$ on Eq. (2) gives

$$v(0)=0: \qquad B + D = 0 \tag{9a}$$
$$v'(0)=0: \qquad kA + C = 0 \tag{9b}$$
$$v(L)=1: \qquad A\sin\lambda + B\cos\lambda + CL + D = 1 \tag{9c}$$
$$v'(L)=0: \qquad kA\cos\lambda - kB\sin\lambda + C = 0 \tag{9d}$$

Solving simultaneously for the constants in Eq. (9) gives

$$A = -\frac{\sin\lambda}{\lambda\sin\lambda + 2\cos\lambda - 2} \quad , \quad B = \frac{1-\cos\lambda}{\lambda\sin\lambda + 2\cos\lambda - 2} \quad , \quad C = -kA \quad , \quad D = -B \tag{10}$$

These constants in Eq. (10) are used to give the deflected shape in Eq. (2) for Case 3. Now substituting Eq. (2) into Eq. (5) and using the constants calculated in Eq. (10), the shears and moments at the two ends of the member are calculated as:

$$M_{13} = -EIv''(0) = EIk^2B = -\bar{s}EI/L^2 \tag{11a}$$
$$V_{13} = EIv'''(0) + Pv'(0) = -EIk^3A + P\times 0 = -s'EI/L^3 \tag{11b}$$
$$M_{23} = EIv''(L) = -EIk^2\left(A\sin\lambda + B\cos\lambda\right) = -\bar{s}EI/L^2 \tag{11c}$$
$$V_{23} = -EIv'''(L) - Pv'(L) = EIk^3\left(A\cos\lambda - B\sin\lambda\right) - P\times 0 = s'EI/L^3 \tag{11d}$$

where s' is the fourth and final stability coefficient given by the formula

$$s' = 2\bar{s} - \lambda^2 = \frac{\lambda^3\sin\lambda}{2-2\cos\lambda-\lambda\sin\lambda} \tag{12}$$

In addition, the moments at the two PHLs are evaluated by equilibrium as

$$M_{a3} = M_{13} = -\bar{s}EI/L^2 \quad , \quad M_{b3} = M_{23} = -\bar{s}EI/L^2 \tag{13}$$

2.3 Case 2

For Case 2 as shown in Fig.1, by imposing the boundary conditions $v(0)=0$, $v'(0)=1$, $v(L)=0$, $v'(L)=0$, and $\theta''_a = \theta''_b = 0$ on Eq. (2), solution can be obtained via the same procedure presented above while solving for a different set of constants. On the other hand, a more direct solution can be obtained by recognizing that Case 2 is exactly the same as ‘rotating’ Case 4 by 180°. Doing so, the solution becomes

$$V_{12} = -V_{24} = \bar{s}EI/L^2 \quad , \quad V_{22} = -V_{14} = -\bar{s}EI/L^2 \tag{14a}$$
$$M_{12} = M_{24} = \hat{s}EI/L \quad , \quad M_{22} = M_{14} = \hat{s}\hat{c}EI/L \tag{14b}$$
$$M_{a2} = M_{b4} = \hat{s}EI/L \quad , \quad M_{b2} = M_{a4} = \hat{s}\hat{c}EI/L \tag{14c}$$

2.4 Case 1

For Case 1 as shown in Fig.1, by imposing the boundary conditions $v(0)=1$, $v'(0)=0$, $v(L)=0$, $v'(L)=0$, and $\theta''_a=\theta''_b=0$ on Eq. (2), solution can be obtained via the same procedure presented above while solving for a different set of constants. On the other hand, a more direct solution can be obtained by recognizing that Case 1 is exactly the same as 'flipping' Case 3 by 180°. Doing so, the solution becomes

$$V_{11}=V_{33}=s'EI/L^3 \quad , \quad V_{21}=V_{13}=-s'EI/L^3 \tag{15a}$$
$$M_{11}=-M_{23}=\bar{s}EI/L^2 \quad , \quad M_{21}=-M_{13}=\bar{s}EI/L^2 \tag{15b}$$
$$M_{a1}=-M_{b3}=\bar{s}EI/L^2 \quad , \quad M_{b1}=-M_{a3}=\bar{s}EI/L^2 \tag{15c}$$

2.5 Case 5

For Case 5 as shown in Fig.1, by imposing the boundary conditions $\theta''_a=1$, $\theta''_b=0$, and $v(0)=v'(0)=v(L)=v'(L)=0$ on Eq. (2), solution can be obtained via direct comparison of Case 2 and Case 5, where a unit plastic rotation at hinge '*a*' gives the same displacement pattern as a unit rotation at the '1' end. It follows that the forces and moments at the four DOFs and two PHLs are the same for both cases, i.e.,

$$V_{1a}=V_{12}=\bar{s}EI/L^2 \quad , \quad V_{2a}=V_{22}=-\bar{s}EI/L^2 \tag{16a}$$
$$M_{1a}=M_{12}=\hat{s}EI/L \quad , \quad M_{2a}=M_{22}=\hat{s}\hat{c}EI/L \tag{16b}$$
$$M_{aa}=M_{a2}=\hat{s}EI/L \quad , \quad M_{ba}=M_{b2}=\hat{s}\hat{c}EI/L \tag{16c}$$

2.6 Case 6

Finally, for Case 6 as shown in Fig.1, by imposing the boundary conditions $\theta''_a=0$, $\theta''_b=1$, and $v(0)=v'(0)=v(L)=v'(L)=0$ on Eq. (2), solution can be obtained via direct comparison of Case 4 and Case 6, where a unit plastic rotation at hinge '*b*' gives the same displacement pattern as a unit rotation at the '2' end. It follows that the forces and moments at the four DOFs and two PHLs are the same for both cases, i.e.,

$$V_{1b}=V_{14}=\bar{s}EI/L^2 \quad , \quad V_{2b}=V_{24}=-\bar{s}EI/L^2 \tag{17a}$$
$$M_{1b}=M_{14}=\hat{s}\hat{c}EI/L \quad , \quad M_{2b}=M_{24}=\hat{s}EI/L \tag{17b}$$
$$M_{ab}=M_{a4}=\hat{s}\hat{c}EI/L \quad , \quad M_{bb}=M_{b4}=\hat{s}EI/L \tag{17c}$$

2.7 Stiffness Matrices

In summary, based on Eqs. (6), (8), (11), (13), and (14)-(17) for the above six cases, the small-displacement-based stiffness matrix of the i^{th} member $\mathbf{k}_i^{SF}$ for bending while considering both geometric and material nonlinearities becomes

$$\mathbf{k}_i^{SF}=\frac{EI}{L^3}\begin{array}{c}\left[\begin{array}{cccc:cc} s' & \bar{s}L & -s' & \bar{s}L & \bar{s}L & \bar{s}L \\ \bar{s}L & \hat{s}L^2 & -\bar{s}L & \hat{s}\hat{c}L^2 & \hat{s}L^2 & \hat{s}\hat{c}L^2 \\ -s' & -\bar{s}L & s' & -\bar{s}L & -\bar{s}L & -\bar{s}L \\ \bar{s}L & \hat{s}\hat{c}L^2 & -\bar{s}L & \hat{s}L^2 & \hat{s}\hat{c}L^2 & \hat{s}L^2 \\ \hdashline \bar{s}L & \hat{s}L^2 & -\bar{s}L & \hat{s}\hat{c}L^2 & \hat{s}L^2 & \hat{s}\hat{c}L^2 \\ \bar{s}L & \hat{s}\hat{c}L^2 & -\bar{s}L & \hat{s}L^2 & \hat{s}\hat{c}L^2 & \hat{s}L^2 \end{array}\right]\end{array}\begin{array}{l} \leftarrow v(0) \\ \leftarrow v'(0) \\ \leftarrow v(L) \\ \leftarrow v'(L) \\ \leftarrow \theta''_a \\ \leftarrow \theta''_b \end{array} \tag{18}$$

where the superscript '*SF*' denotes the member stiffness matrix $\mathbf{k}_i$ is formulated by using the stability functions method that is computed based on the stability coefficients in Eqs. (7) and (12). Note again that $\mathbf{k}_i$ is 6×6, where the 6 movements are associated with the displacements and rotations at the two ends (i.e., 4 DOFs) and the plastic rotations at the two plastic hinge locations (i.e., 2 PHLs).

Linearization of Eq. (18) can be performed by using Taylor series expansion on each term of the member stiffness matrix and truncating higher-order terms. Doing so gives

$$\mathbf{k}_i^{GS}=\frac{EI}{L^3}\begin{bmatrix}12 & 6L & -12 & 6L\\ 6L & 4L^2 & -6L & 2L^2\\ -12 & -6L & 12 & -6L\\ 6L & 2L^2 & -6L & 4L^2\end{bmatrix}-\begin{array}{cl}\begin{bmatrix}6P/5L & P/10 & -6P/5L & P/10\\ P/10 & 2PL/15 & -P/10 & -PL/30\\ -6P/5L & -P/10 & 6P/5L & -P/10\\ P/10 & -PL/30 & -P/10 & 2PL/15\end{bmatrix} & \begin{array}{l}\leftarrow v(0)\\ \leftarrow v'(0)\\ \leftarrow v(L)\\ \leftarrow v'(L)\end{array}\end{array}\qquad(19)$$

where the first matrix in Eq. (19) represents that classic stiffness matrix without considering any geometric nonlinearity, and the second matrix represents the geometric stiffness. The superscript ‘*GS*’ denotes the member stiffness matrix $\mathbf{k}_i$ is formulated by using the geometric stiffness method. Note that the member stiffness matrix in Eq. (19) is a 4×4 matrix, where the rows and columns associated with θ''_a and θ''_b are dropped. This is because solution algorithms among various software packages that incorporate geometric nonlinearity using the geometric stiffness method usually adopt a different and independent algorithm for material nonlinearity.

Finally, the member stiffness matrix $\mathbf{k}_i$ in Eq. (19) can be further simplified by retaining only the large *P*-Δ effect while ignoring small *P*-δ effect. This is done by removing all geometric nonlinear terms associated with bending. Doing so gives

$$\mathbf{k}_i^{PD}=\frac{EI}{L^3}\begin{bmatrix}12 & 6L & -12 & 6L\\ 6L & 4L^2 & -6L & 2L^2\\ -12 & -6L & 12 & -6L\\ 6L & 2L^2 & -6L & 4L^2\end{bmatrix}-\begin{array}{cl}\begin{bmatrix}P/L & 0 & -P/L & 0\\ 0 & 0 & 0 & 0\\ -P/L & 0 & P/L & 0\\ 0 & 0 & 0 & 0\end{bmatrix} & \begin{array}{l}\leftarrow v(0)\\ \leftarrow v'(0)\\ \leftarrow v(L)\\ \leftarrow v'(L)\end{array}\end{array}\qquad(20)$$

where the superscript ‘*PD*’ denotes the member stiffness matrix $\mathbf{k}_i$ is formulated by using the *P*-Δ stiffness method.

3. Identification of Geometric Nonlinearity Using a Single Degree of Freedom System

An appropriate model should be used to serve the purpose of the study. To identify the geometric nonlinearity used in different software packages, consider the single degree of freedom (SDOF) column model as shown in Fig.2a be subjected to a constant axial compressive force *P*. Let the mass be *M*, damping be *C*, elastic modulus be *E*, moment of inertia be *I*, and length be *L*. The degree of freedom is set up so that the mass is restrained from rotation, but it is free to translate in the horizontal direction.

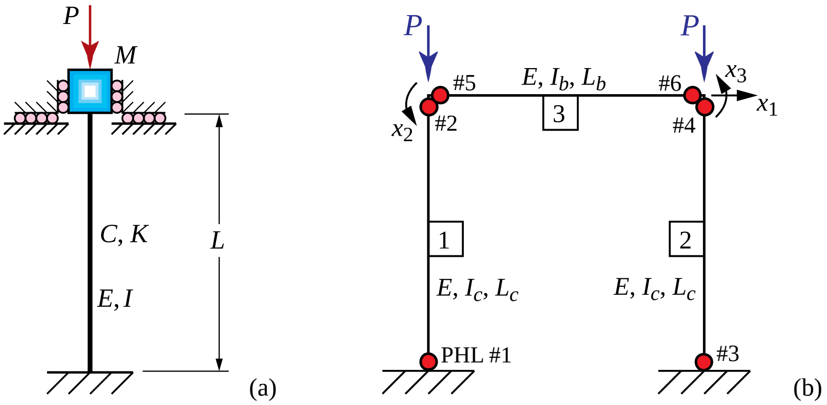

Fig. 2 – Single degree of freedom models with geometric nonlinearity

Based on this set up, the column experiences a constant axial force due to the gravity load only and also experiences shear and moment due to the earthquake ground motion only. Therefore, the lateral stiffness of the column remains constant with a constant axial force throughout the entire earthquake time history analysis. If geometric nonlinearity is totally ignored in this problem, the lateral stiffness related to the horizontal translation degree of freedom at the top of the column is simply:

$$K_{OR} = \frac{12EI}{L^3} \tag{21}$$

where K_{OR} represents the original stiffness of the SDOF system without considering any geometric nonlinearity. If geometric nonlinearity is considered using the *P*-Δ stiffness approach, the lateral stiffness of the SDOF column (see Eq. (20)) becomes:

$$K_{P\Delta} = \frac{12EI}{L^3} - \frac{P}{L} \tag{22}$$

where $K_{P\Delta}$ denotes the geometrically nonlinear stiffness of the column using the *P*-Δ approach (i.e., including large *P*-Δ effect but excluding small *P*-δ effect). If geometric nonlinearity is considered using the geometric stiffness approach, the lateral stiffness of the SDOF column (see Eq. (19)) becomes:

$$K_{GS} = \frac{12EI}{L^3} - \frac{6P}{5L} \tag{23}$$

where K_{GS} denotes the geometrically nonlinear stiffness of the column using the geometric stiffness approach (i.e., including both large *P*-Δ and small *P*-δ effects). Finally, if geometric nonlinearity is considered through the use of stability functions, the stiffness matrix (see Eq. (18)) becomes:

$$K_{SF} = \frac{s'EI}{L^3} \tag{24}$$

where K_{SF} denotes the geometrically nonlinear stiffness computed using the stability functions approach (i.e., including both large *P*-Δ and small *P*-δ effects in a consistent form), and s' is the stability coefficients defined in Eq. (12).

In this study, let $E = 100$ GPa, $I = 6.4\times10^5$ mm^4, $L = 4$ m, and $P = 4$ kN in compression. Using a mass of $M = 9500$ kg, the calculated stiffnesses and the corresponding periods of vibration are summarized in Table 1. Note that the critical buckling load for the SDOF column is $P_{cr} = \pi^2 EI/L^2 = 39.48$ kN, which means the applied load is at 10.1 % of the critical buckling load (i.e., $P / P_{cr} = 0.101$). At this axial compressive force level, it is observed that $K_{GS} \approx K_{SF}$, but there is a 1.9 % difference in stiffness between $K_{P\Delta}$ and K_{GS}. This suggests that ignoring small *P*-δ effect can result in an increase in lateral stiffness by 1.9 %. Table 1 also shows that the difference between using $K_{P\Delta}$ and using K_{GS} results in a 1.0 % difference in the calculated period of vibration of the SDOF column. Note that 1.0 % elongation of period is sufficient to provide the phase shift needed to identify the geometric nonlinearity used in software packages.

Table 1 – Comparison of geometric nonlinear stiffnesses, periods, and maximum responses

	Stiffness (kN/m)	Period (s)	Max Displacement (m)	Max Velocity (m/s)	Max Acceleration (*g*)
K_{OR}	12.0	1.496	0.6990	2.996	1.258
$K_{P\Delta}$	11.0	1.562	0.6737	2.789	1.111
K_{GS}	10.8	1.577	0.6625	2.746	1.073
K_{SF}	10.799	1.577	0.6624	2.746	1.073

By assuming 0 % damping, the SDOF column shown in Fig.2a is now subjected to the 1995 Kobe earthquake as shown in Fig.3. The resulting displacement responses using the original stiffness (OR), *P*-Δ stiffness (PD), geometric stiffness (GS), and stability function stiffness (SF) are presented in Fig.4. In addition, the maximum displacement, velocity, and absolute acceleration for using various geometric nonlinear stiffness approaches are summarized in Table 1. It can be seen from Fig. 4 that the responses using K_{GS} match those using K_{SF} well at such a small axial compressive force. The differences are more noticeable between the responses using $K_{P\Delta}$ and those using K_{GS}, where the maximum displacement response using $K_{P\Delta}$ increases by 1.7 % and the maximum acceleration response also increases by 3.5 %.

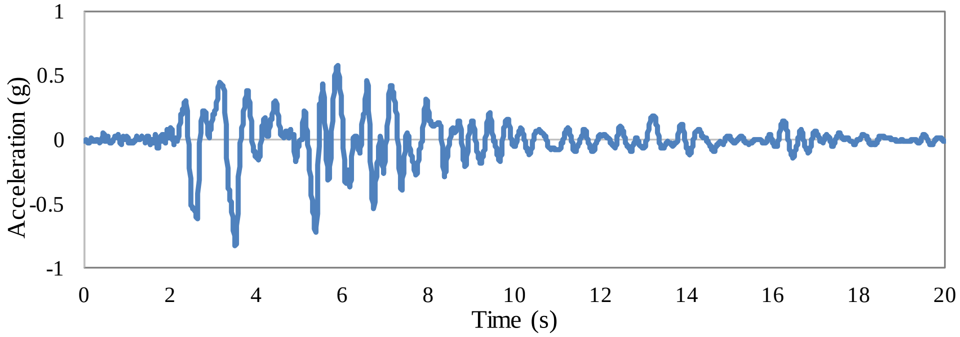

Fig. 3 – 1995 Kobe earthquake ground acceleration time history

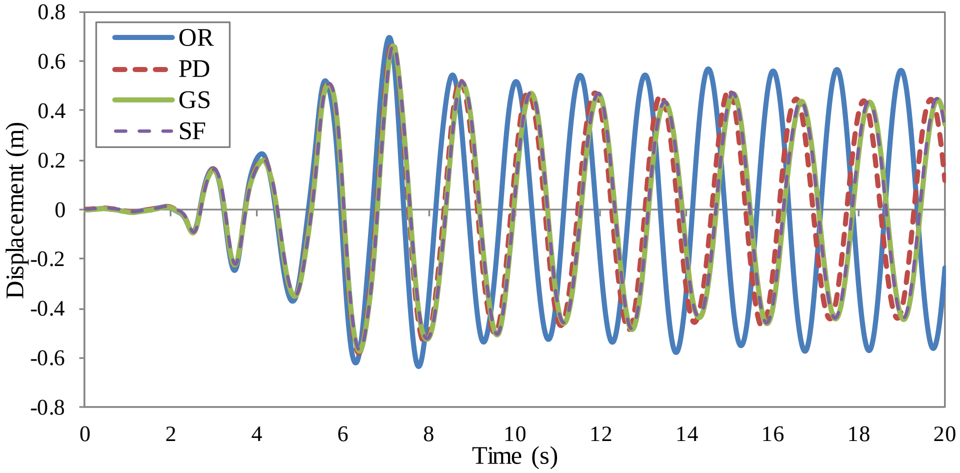

Fig. 4 – Displacement responses of the SDOF column using different stiffnesses

Knowing the stiffness of the column is important because it can be used to assess the type of geometric nonlinearity that is embedded in various software packages. Consider the same SDOF column shown in Fig.2a is now modeled using four small-displacement-based software packages commonly used in the United States, randomly labeled as S1, S2, S3, and S4, and is subjected to the 1995 Kobe earthquake shown in Fig.3. By assuming 0 % damping, Fig.5 shows the displacement responses from these software packages, and these responses are compared with those in Fig.4. As shown in Fig.5a, the comparison shows an exact match between the current analysis method using K_{GS} and the software packages S1 and S4. Similarly, Fig.5b shows an exact match between the current analysis method with $K_{P\Delta}$ and software packages S2 and S3. This indicates two of the small-displacement software packages use geometric stiffness that considers both large P-Δ and small P-δ effects in the formulation, while the other two of the small-displacement software packages use P-Δ stiffness that considers only large P-Δ effects and ignores the small P-δ effects. Note that even though using 0 % damping is an idealized situation, it helps eliminate the potentially differing effects of using damping parameters on the responses that may occur due to differences in damping formulations used in different software packages.

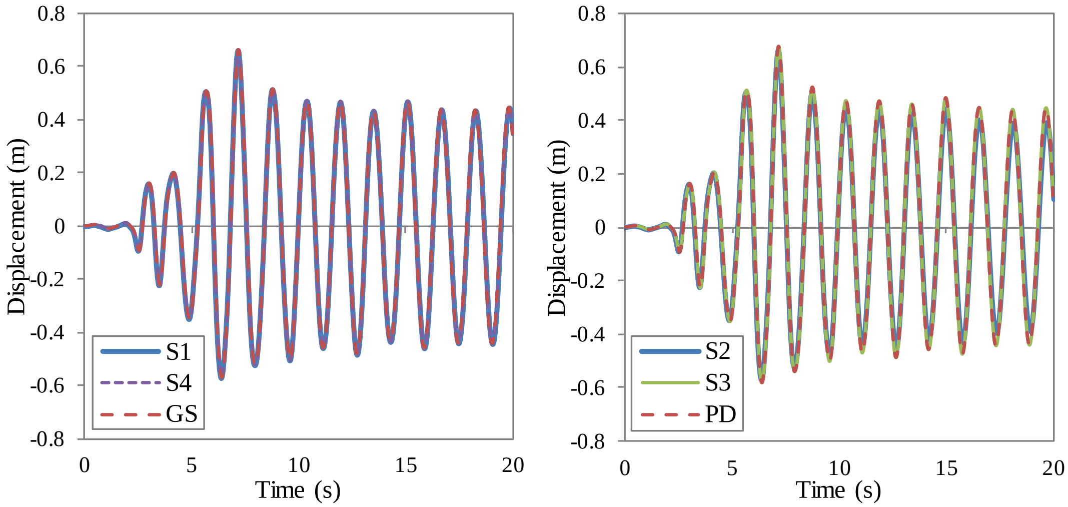

Fig. 5 – Displacement response comparisons between various software packages and manual calculations

4. One-Story Moment Frame

Once the type of geometric nonlinearity is known, the influence of using different types of geometric nonlinearity on displacement responses can be assessed. As a simple numerical example, consider a one-story one-bay moment-resisting frame as shown in Fig.2b with members assumed to be axially rigid. This gives a total of 3 DOFs (i.e., $n = 3$) and 6 PHLs (i.e., $m = 6$) as shown in the figure. Software packages S1 (based on GS) and S2 (based on PD) are selected for this study along with the SF method. Since using SF formulation is an uncommon approach with limited documentations, it is therefore worthwhile to discuss the analysis approach here. Based on Eq. (18), the member stiffness matrix for the two columns can be written as:

$$\mathbf{k}_i = \frac{EI_c}{L_c^3}\left[\begin{array}{cccc|cc} s'_i & \bar{s}_i L_c & -s'_i & \bar{s}_i L_c & \bar{s}_i L_c & \bar{s}_i L_c \\ \bar{s}_i L_c & \hat{s}_i L_c^2 & -\bar{s}_i L_c & \hat{s}_i \hat{c}_i L_c^2 & \hat{s}_i L_c^2 & \hat{s}_i \hat{c}_i L_c^2 \\ -s'_i & -\bar{s}_i L_c & s'_i & -\bar{s}_i L_c & -\bar{s}_i L_c & -\bar{s}_i L_c \\ \bar{s}_i L_c & \hat{s}_i \hat{c}_i L_c^2 & -\bar{s}_i L_c & \hat{s}_i L_c^2 & \hat{s}_i \hat{c}_i L_c^2 & \hat{s}_i L_c^2 \\ \hline \bar{s}_i L_c & \hat{s}_i L_c^2 & -\bar{s}_i L_c & \hat{s}_i \hat{c}_i L_c^2 & \hat{s}_i L_c^2 & \hat{s}_i \hat{c}_i L_c^2 \\ \bar{s}_i L_c & \hat{s}_i \hat{c}_i L_c^2 & -\bar{s}_i L_c & \hat{s}_i L_c^2 & \hat{s}_i \hat{c}_i L_c^2 & \hat{s}_i L_c^2 \end{array}\right] , \quad i = 1, 2 \tag{25}$$

where $\hat{s}_i$, $\hat{c}_i$, $\bar{s}_i$, and s'_i are stability coefficients of the i^{th} column member computed using Eqs. (7) and (12). No axial force is acting on the beam member, and therefore the beam member stiffness matrix becomes:

$$\mathbf{k}_3 = \frac{EI_b}{L_b^3}\left[\begin{array}{cccc|cc} 12 & 6L_b & -12 & 6L_b & 6L_b & 6L_b \\ 6L_b & 4L_b^2 & -6L_b & 2L_b^2 & 4L_b^2 & 2L_b^2 \\ -12 & -6L_b & 12 & -6L_b & -6L_b & -6L_b \\ 6L_b & 2L_b^2 & -6L_b & 4L_b^2 & 2L_b^2 & 4L_b^2 \\ \hline 6L_b & 4L_b^2 & -6L_b & 2L_b^2 & 4L_b^2 & 2L_b^2 \\ 6L_b & 2L_b^2 & -6L_b & 4L_b^2 & 2L_b^2 & 4L_b^2 \end{array}\right] \tag{26}$$

Assembling the above member stiffness matrices into the global stiffness matrix gives a 9×9 stiffness matrix, which can be partitioned into the form

$$\mathbf{K}^{SF}=\left[\begin{array}{c|c}\mathbf{K}_{n\times n} & \mathbf{K}'_{n\times m}\\ \hline \mathbf{K}'^{T}_{m\times n} & \mathbf{K}''_{m\times m}\end{array}\right]=\left[\begin{array}{c|c}\mathbf{K}_{3\times 3} & \mathbf{K}'_{3\times 6}\\ \hline \mathbf{K}'^{T}_{6\times 3} & \mathbf{K}''_{6\times 6}\end{array}\right]\begin{array}{l}\leftarrow x_1,x_2,x_3\\ \leftarrow \theta''_1,\ldots,\theta''_6\end{array} \tag{27}$$

where

$$\mathbf{K}_{3\times 3}=\begin{bmatrix}(s'_1+s'_2)EI_c/L_c^3 & \bar{s}_1EI_c/L_c^2 & \bar{s}_2EI_c/L_c^2\\ \bar{s}_1EI_c/L_c^2 & \hat{s}_1EI_c/L_c+4EI_b/L_b & 2EI_b/L_b\\ \bar{s}_2EI_c/L_c^2 & 2EI_b/L_b & \hat{s}_2EI_c/L_c+4EI_b/L_b\end{bmatrix}\begin{array}{l}\leftarrow x_1\\ \leftarrow x_2\\ \leftarrow x_3\end{array} \tag{28a}$$

$$\mathbf{K}'_{3\times 6}=\left[\begin{array}{cc|cc|cc}\bar{s}_1EI_c/L_c^2 & \bar{s}_1EI/L_c^2 & \bar{s}_2EI_c/L_c^2 & \bar{s}_2EI_c/L_c^2 & 0 & 0\\ \hat{s}_1\hat{c}_1EI_c/L_c & \hat{s}_1EI_c/L_c & 0 & 0 & 4EI_b/L_b & 2EI_b/L_b\\ 0 & 0 & \hat{s}_2\hat{c}_2EI_c/L_c & \hat{s}_2EI_c/L_c & 2EI_b/L_b & 4EI_b/L_b\end{array}\right]\begin{array}{l}\leftarrow x_1\\ \leftarrow x_2\\ \leftarrow x_3\end{array} \tag{28b}$$

$$\mathbf{K}''_{6\times 6}=\left[\begin{array}{cc|cc|cc}\hat{s}_1EI_c/L_c & \hat{s}_1\hat{c}_1EI_c/L_c & 0 & 0 & 0 & 0\\ \hat{s}_1\hat{c}_1EI_c/L_c & \hat{s}_1EI_c/L_c & 0 & 0 & 0 & 0\\ \hline 0 & 0 & \hat{s}_2EI_c/L_c & \hat{s}_2\hat{c}_2EI_c/L_c & 0 & 0\\ 0 & 0 & \hat{s}_2\hat{c}_2EI_c/L_c & \hat{s}_2EI_c/L_c & 0 & 0\\ \hline 0 & 0 & 0 & 0 & 4EI_b/L_b & 2EI_b/L_b\\ 0 & 0 & 0 & 0 & 2EI_b/L_b & 4EI_b/L_b\end{array}\right]\begin{array}{l}\leftarrow \theta''_1\\ \leftarrow \theta''_2\\ \leftarrow \theta''_3\\ \leftarrow \theta''_4\\ \leftarrow \theta''_5\\ \leftarrow \theta''_6\end{array} \tag{28c}$$

Assume that the frame shown in Fig.2b has a mass of 318.7 Mg and a damping of 0 %. Also, let $E=200$ GPa, $I_b=I_c=4.995\times10^8$ mm^4, $L_b=7.62$ m, $L_c=4.57$ m, and $P=5{,}338$ kN. To include material nonlinearity in the analysis, assume that all six plastic hinges exhibit elastic-plastic behavior with plastic moment capacities of $m_b=3130$ kN·m for the beam and $m_c=3909$ kN·m for the two columns. By subjecting the frame to the 1995 Kobe earthquake ground motion as shown in Fig.3 with a scale factor of 1.3, the global displacement response at DOF #1 (i.e., roof displacement) is plotted in Fig.6 based on the stiffness matrices using stability function formulations (SF) in Eq. (28). In addition, the same undamped responses obtained from the software package S1 that uses geometric stiffness (GS) and the software package S2 that uses P-Δ stiffness (PD) are plotted in the figure for comparison. It is observed that the choice of geometric nonlinearity used in the analysis can influence the response calculations even for a simple SDOF system. While the responses calculated using SF and GS are reasonably close to each other, the calculated response using PD is quite different from the other two calculated responses.

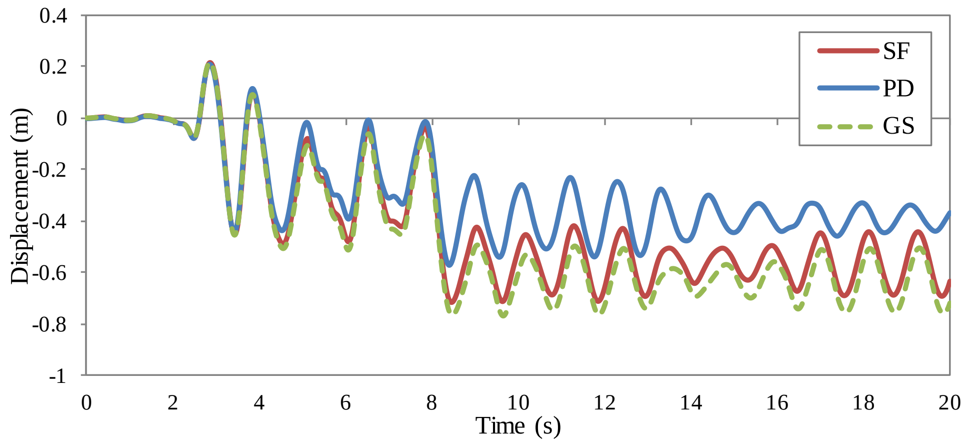

Fig. 6 – Displacement response comparisons of a one-story frame with various geometric nonlinearities

5. Four-Story Moment-Resisting Frame

Consider the four-story moment-resisting steel frame as shown in Fig.7a. This frame contains 36 DOFs (i.e., $n = 36$) and 56 PHLs (i.e., $m = 56$). Assume a mass of 72 670 kg is used on each floor, and no mass or mass moment of inertia is assigned to any of the vertical translation DOFs nor rotation DOFs. A gravity load of 863 kN is applied on each exterior column member and 1263 kN is applied on each interior column member as shown in Fig.7b. In addition, 0 % damping is assumed in order to provide a better comparison of the response among different software packages, including software package S2 that uses *P*-Δ stiffness (PD) and LS-DYNA finite element software package (LD) that uses large displacement formulation. For stability function (SF), the global stiffness matrix in Eq. (27) after assembly includes $\mathbf{K}_{36\times36}$, $\mathbf{K}'_{36\times56}$, and $\mathbf{K}''_{56\times56}$.

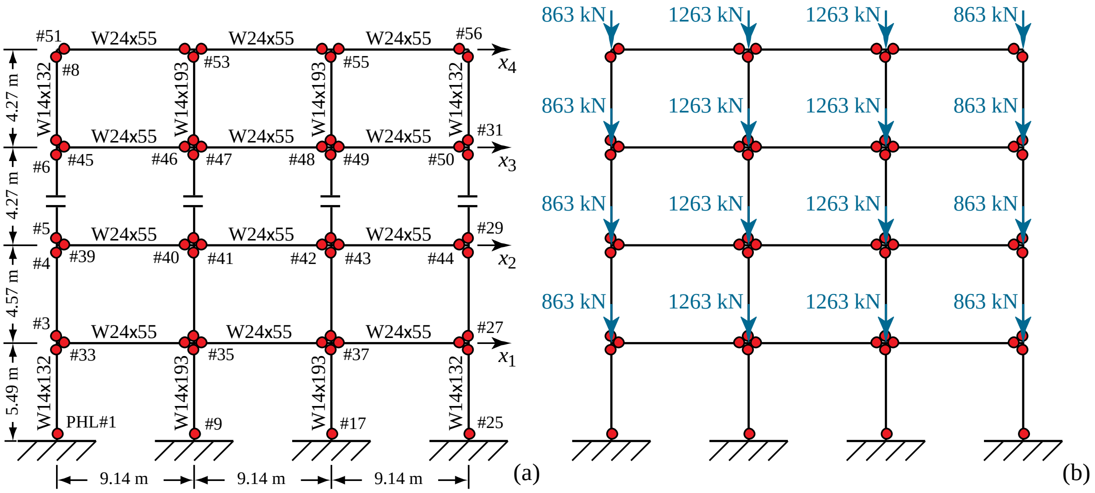

Fig. 7 – Four-story moment-resisting steel frame with gravity loads

Assume the yield stress of the member is 345 MPa and all 56 plastic hinges exhibit elastic-plastic behavior. The steel frame is now subjected to the 1995 Kobe earthquake ground motion as shown in Fig.3 with scale factors of 0.6, 0.8, 1.0, and 1.2. The roof displacement responses are summarized in Fig.8. Based on the results, it is observed that the responses computed using different geometric nonlinearity are similar at a scale factor of 0.6 when the response is only slightly nonlinear. However, the PD response begins to deviate at a scale factor of 0.8 with significant differences at a scale factor of 1.0. This suggests that using PD software packages that captures only large *P*-Δ effect while ignoring small *P*-δ effects may not be appropriate for computation when the significant coupling between geometric nonlinearity and material nonlinearity is expected.

6. Conclusion

In this paper, different formulations of geometric nonlinearity were presented with a detailed derivation of the stability functions stiffness matrix while incorporating material nonlinearity. Through this derivation, how each formulation captures large *P*-Δ and small *P*-δ effects were explained, and the investigation continued with a study on how different software packages implement geometric nonlinearity. A SDOF column was modeled using four different small-displacement-based software packages. Based on the output dynamic responses it was identified that two packages use *P*-Δ stiffness that includes only large *P*-Δ effects while the other two packages use geometric stiffness that includes both large *P*-Δ and small *P*-δ effects. The study was then extended to see how different formulations of geometric nonlinearity impact the response of moment-resisting frame, and it was shown that software packages implementing *P*-Δ stiffness can lead to different calculated results when there is significant coupling between geometric and material nonlinearities.

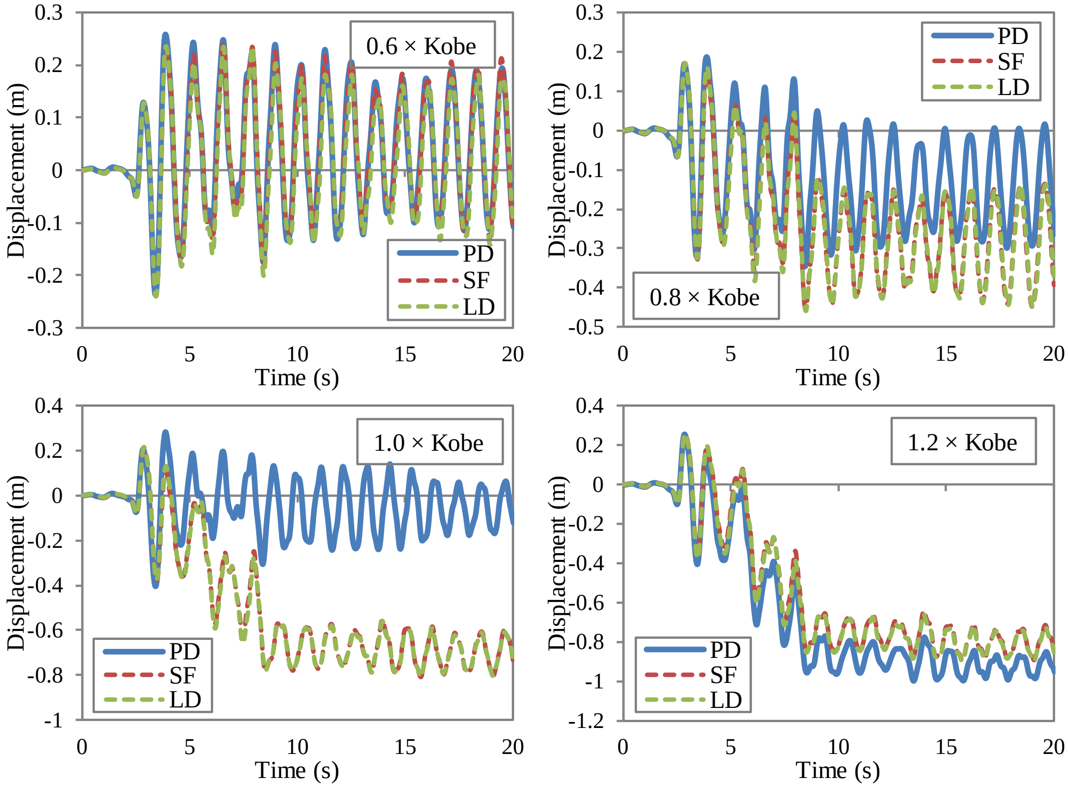

Fig. 8 – Roof displacement response of the four-story frame with various geometric nonlinearities

Since both ASCE/SEI 7-16 and ASCE/SEI 41-17 are design standards with the purpose of limiting damages in structures during major earthquakes, only slight material nonlinearity is expected in the analysis of the designed models. Therefore, any formulation of geometric nonlinearity is appropriate for use in these standards as long as users 'turn on' geometric nonlinearity in the analysis. However, if the analysis requires significant coupling between geometric and material nonlinearities, such as in the case of analyzing structural collapse or near-collapse, the applicability of software packages that implement *P*-Δ stiffness warrants further study.

Abstract. In 2013, Tao et al. introduced the ABC Simple Matrix Scheme for Encryption, a multivariate public key encryption scheme. The scheme boasts great efficiency in encryption and decryption, though it suffers from very large public keys. It was quickly noted that the original proposal, utilizing square matrices, suffered from a very bad decryption failure rate. As a consequence, the designers later published updated parameters, replacing the square matrices with rectangular matrices and altering other parameters to avoid the cryptanalysis of the original scheme presented in 2014 by Moody et al.

In this work we show that making the matrices rectangular, while decreasing the decryption failure rate, actually, and ironically, diminishes security. We show that the combinatorial rank methods employed in the original attack of Moody et al. can be enhanced by the same added degrees of freedom that reduce the decryption failure rate. Moreover, and quite interestingly, if the decryption failure rate is still reasonably high, as exhibited by the proposed parameters, we are able to mount a reaction attack to further enhance the combinatorial rank methods. To our knowledge this is the first instance of a reaction attack creating a significant advantage in this context.

Keywords: Multivariate Cryptography, Simple Matrix, encryption, MinRank

1 Introduction

Since the discovery by Peter Shor in the 1990s, cf. [26], of polynomial-time quantum algorithms for computing discrete logarithms and factoring integers the proverbial clock has been ticking on our current public key infrastructure. In reaction to this discovery and the continual advancement of quantum computing technologies, a large community has emerged dedicated to the development and deployment of cryptosystems that are immune to the exponential speedups quantum computers promise for our current standards. More recently, the National

Moody, Dustin; Perlner, Ray; Smith-Tone, Daniel; Apon, Daniel; Verbel, Javier. "Combinatorial Rank Attacks Against the Rectangular Simple Matrix Encryption Scheme." Paper presented at PQCrypto 2020: The Eleventh International Conference on Post-Quantum Cryptography, Paris, FR. April 15, 2020 - April 17, 2020.

Institute of Standards and Technology (NIST) has begun directing a process to reveal which of the many new options for post-quantum public key cryptography are suitable for widespread use.

One family of candidate schemes relies on the known difficulty of solving large systems of nonlinear equations. These multivariate public key cryptosystems are inspired by computational problems that have been studied by algebraic geometers for several decades. Still, even in the past two decades this field of study has changed dramatically.

When multivariate public key cryptography was still early in its community building phase, a great many schemes were proposed and subsequently attacked. Notable examples of this phenomenon include C^*, HFE, STS, Oil-Vinegar, PMI and SFLASH, see [14, 22, 32, 19, 6, 20, 21, 9, 25, 10, 8].

While multivariate cryptography has seen some lasting success with digital signatures, see, for example, [12, 4, 2, 23, 5], multivariate encryption seems to be particularly challenging. In the last several years there have been many new proposals inspired by the notion that it may be easier to create a secure injective multivariate function if the codomain is larger than the domain. Such schemes include ZHFE, Extension Field Cancellation (EFC), SRP, HFERP, EFLASH and the Simple Matrix Encryption Scheme, see [7, 28, 34, 11, 3, 29, 30]. Of these, many have since endured attacks either outright breaking the scheme or affecting parameters, see [1, 27, 24, 15–17].

In this work we present a new attack on the rectangular variant of the Simple Matrix Encryption Scheme, see [30]. This version of the Simple Matrix Encryption Scheme was designed to repair the problems that the original scheme, see [29], had with decryption failures and to choose large enough fields to avoid the attack of [15]. Our new attack is still a MinRank method, but one that exploits the rectangular structure, showing that the new parameterization is actually less secure than the square variant.

In an interesting twist, we also develop a reaction attack based on the decryption failures that the scheme is designed to minimize. This method further boosts the performance of the MinRank step by a factor related to the field size. With these attacks we break all of the published parameter sets at the most efficient field size of 2^8, the only parameters for which performance data were offered.

The article is organized as follows. In Section 2, we present the Simple Matrix Scheme. We next review the MinRank attack techniques using properties of the differential that was used against the original square variant of the Simple Matrix scheme. In the subsequent section, we present the improvement obtained in attacking the rectangular variant. Next, in Section 5, we present the reaction attack and discuss its affect on key recovery. We then present a thorough complexity analysis including our experimental data verifying our claimed complexity. Finally, we conclude noting the effect this attack has on the status of multivariate encryption.

2 ABC Simple Matrix Scheme

The ABC Simple Matrix Encryption Scheme was introduced in [29] by Tao et al. This scheme was designed with a new guiding principle in mind: make the codomain much larger than the domain. The motivation for this notion comes from the fact that there is a much richer space of injective functions with a large codomain than the space of bijective functions; thus, it may be easier to hide the types of properties we use to efficiently invert nonlinear functions such as low rank or low degree in this larger context. In this section we present the scheme and its functionality.

For clarity of exposition, we establish our notational standard. Throughout this text bold font will indicate a matrix or vector, e.g. **T** or **z**, while regular fonts indicate functions (possibly with outputs considered as matrices) or field elements.

2.1 ABC Public Key Generation

Let $\mathbb{F}$ be a finite field with q elements. Let s be a positive integer and let $n = s^2$. Let $\mathbb{F}[\mathbf{x}]$ be the polynomial ring over $\mathbb{F}$ in the variables $\mathbf{x} = \begin{bmatrix} x_1 \cdots x_n \end{bmatrix}$.

The public key will be a system of $m = 2n = 2s^2$ (for our purposes homogeneous) quadratic formulae in $\mathbb{F}[\mathbf{x}]$. The public key will ultimately be generated by the standard isomorphism construction $P = T \circ F \circ U$ where T and U are invertible linear transformations of the appropriate dimensions, and F is a specially structured system of quadratic polynomials. The remainder of this section is devoted to the construction of F. (In general the scheme can and does use rectangular matrices, but for the ease of writing this note, we will assume that the matrices are square for now.)

Define the matrix

$$\mathbf{A} = \begin{bmatrix} x_1 & \cdots & x_s \\ x_{s+1} & \cdots & x_{2s} \\ \vdots & \ddots & \vdots \\ x_{s^2-s+1} & \cdots & x_{s^2} \end{bmatrix}.$$

Further define the $s \times s$ matrices of $\mathbb{F}[\mathbf{x}]$ linear forms $\mathbf{B} = \begin{bmatrix} b_{ij} \end{bmatrix}$ and $\mathbf{C} = \begin{bmatrix} c_{ij} \end{bmatrix}$.

From these matrices one can construct the matrices $\mathbf{E}_1 = \mathbf{AB}$ and $\mathbf{E}_2 = \mathbf{AC}$. Then we construct a system of m polynomials by concatenating the vectorizations of these two products: $F = Vec(\mathbf{E}_1) \| Vec(\mathbf{E}_2)$. The public key is then $P = T \circ F \circ U$. (Note that we can eliminate U by replacing $\mathbf{A}$ with random linear forms.)

In the rectangular version of this scheme we replace $\mathbf{A}$ by a similar $r \times s$ version (and we can make the matrices $\mathbf{B}$ and $\mathbf{C}$ of size $s \times u$ and $s \times v$, respectively) where the algebra still works the same.

2.2 Encryption and Decryption

Encryption is accomplished by evaluating the public key at a plaintext value encoded as a vector $\mathbf{x}$. One computes $P(\mathbf{x}) = \mathbf{y}$.

Decryption is accomplished by inverting each of the components of the public key. One first sets $\mathbf{v} = T^{-1}(\mathbf{y})$. Then $\mathbf{v}$ can be split in half producing $\mathbf{v}_1$ and $\mathbf{v}_2$. Each of these can be parsed as a matrix by inverting the vectorization operator $\mathbf{E}_1 = Mat(\mathbf{v}_1)$ and $\mathbf{E}_2 = Mat(\mathbf{v}_2)$.

We note that we can consider this pair of matrices as values derived from functions on either the inputs $\mathbf{x}$ or the outputs $\mathbf{y}$. The legitimate user knows both of these representations. We will abuse notation slightly and denote these functions as $E_1(\mathbf{u})$, $E_1(\mathbf{v})$, $E_2(\mathbf{u})$ and $E_2(\mathbf{v})$, where $\mathbf{v} = F(\mathbf{u})$ (and we use similar notation for functions of $\mathbf{u}$ representing the matrices $\mathbf{A}$, $\mathbf{B}$ and $\mathbf{C}$. Thus, we have computed $\mathbf{E}_1 = E_1(\mathbf{v})$ and $\mathbf{E}_2 = E_2(\mathbf{v})$. These values must be equal to $E_i(\mathbf{u})$. For both values of i, the function involves a left product by the square matrix $A(\mathbf{u})$. We construct a matrix $\mathbf{W}$ of new variables w_i for $0 < i \leq s^2$. We suppose that the correct assignment of values in $A(\mathbf{u})$ produces a matrix with a left inverse, so the correct assignment of variables w_i produces a valid left inverse. Then we have

$$\mathbf{W}\mathbf{E}_1 = \mathbf{W}E_1(\mathbf{u}) = \mathbf{W}A(\mathbf{u})B(\mathbf{u}) = B(\mathbf{u}),$$

and similarly for $\mathbf{E}_2$. Since the legitimate user knows the linear forms b_{ij} and c_{ij}, this setup provides a system of $m = 2s^2$ equations in the $s^2 + s^2$ variables w_i and u_i. Via Gaussian elimination, the w_i variables can be eliminated and values for u_i can be recovered.

Once $\mathbf{u}$ is recovered, one applies the inverse of U to this quantity to recover $\mathbf{x}$, the plaintext.

3 Previous Cryptanalysis

In this section, we summarize the technique from [15] recovering a secret key in the square case, that is when $r = s$, via MinRank informed by differential invariant structure. For convenience, we present the relevant definitions we will use in Section 4, possibly generalized to the rectangular setting.

The main object used in the attack from [15] is the discrete differential of the public key.

Definition 1 *Let $F : \mathbb{F}^n \to \mathbb{F}^m$. The* discrete differential *of F is a bivariate analogue of the discrete derivative; it is given by the normalized difference*

$$DF(\mathbf{a}, \mathbf{x}) = F(\mathbf{a} + \mathbf{x}) - F(\mathbf{a}) - F(\mathbf{x}) + F(\mathbf{0}).$$

DF is a vector-valued function since the output is in $\mathbb{F}^m$. Since DF is bilinear, we can think of each coordinate DF_i as a matrix. We can then consider properties of these matrices as linear operators. In particular, we can consider rank and perform a MinRank attack.

Definition 2 *The* MinRank(q, n, m, r) *Problem is the task of finding a linear combination over $\mathbb{F}_q$ of m matrices, $\mathbf{DQ}_i$, of size $n \times n$ such that the resulting rank is at most r.*

Although there are many different techniques for solving MinRank, the most relevant technique here is known as *linear algebra search*. One attempts to guess $\ell = \lceil \frac{m}{n} \rceil$ vectors that lie in the kernel of the same map. Since matrices with low rank have more linearly independent vectors in their kernels, the distribution of maps whose kernels contain these vectors is skewed toward lower rank maps. Therefore, to solve MinRank, one guesses ℓ vectors $\mathbf{x}_i$, sets up the linear system

$$\sum_{i=1}^{m} \tau_i \mathbf{D}\mathbf{Q}_i \mathbf{x}_j = \mathbf{0},$$

for $j = 1, \ldots, \ell$, solves for τ_i and computes the rank of $\sum_{i=1}^{m} \tau_i \mathbf{D}\mathbf{Q}_i$. If the rank is at or below the target rank then the attack has succeeded. Otherwise another set of vectors is chosen and the process continues.

In [15], the attack is formulated in the language of differential invariants.

Definition 3 *A* subspace differential invariant *of a vector-valued map F is a triple of vector spaces (X, V, W) such that $X \subseteq \mathbb{F}^m$, and $V, W \subseteq \mathbb{F}^n$ satisfying $(\mathbf{x} \cdot DF)V \subseteq W$ for all $\mathbf{x} \in X$ where $dim(W) \leq dim(V)$.*

In other words, a subspace differential invariant is a subspace X of the span of the DF_i along with a subspace that is mapped linearly by every map in X into another subspace of no larger dimension. The definition is supposed to capture the idea of a subspace of the span of F acting like a linear map on a subspace of the domain of F.

Differential invariants are related to low rank, but not equivalent. They are useful at providing an algebraic condition on interlinked kernels, that is, when there are very many maps in the span of F that have low rank and share a large common subspace in their kernels, see [33]. In such a case, the invariant structure provides a tiny and insignificant savings in some linear algebra steps after the hard MinRank step of the attack is complete. The main value of the idea lies in providing algebraic tools for determining whether an interlinked kernel structure is present in a map.

Considering the Simple Matrix Scheme, there are maps in the span of the public maps that correspond to products of the first row of $\mathbf{A}$ and linear combinations of the columns of $\mathbf{B}$ and $\mathbf{C}$. The differential of this type of map has the following structure, where gray indicates possibly nonzero coefficients.

$Dg =$ 
This map is clearly of low rank, probably $2s$, and illustrates a differential invariant because a column vector with zeros in the top s entries is mapped by this matrix to a vector with zeros in everything except the top s entries. Also, it is important to note that there is an entire $u + v$ dimensional subspace of the public key corresponding to the X in Definition 3 that produces differentials of this shape which we call a band space. There is nothing special about the first row. We could use anything in the rowspace of $\mathbf{A}$ and express our differential as above in the appropriate basis. This motivates the following definition modified from [15, Definition 4]:

Definition 4 *Fix an arbitrary vector* $\mathbf{v}$ *in the rowspace of* $\mathbf{A}$*, i.e.* $\mathbf{v} = \sum_{d=1}^{r} \lambda_d \mathbf{A}_d$ *where* $\mathbf{A}_d$ *is the dth row of* $\mathbf{A}$*. The* $u + v$ *dimensional space of quadratic forms* $\mathcal{B}_v$ *given by the span of the columns of* $\mathbf{vB}$ *and* $\mathbf{vC}$ *is called the generalized band-space generated by* $\mathbf{v}$*.*

Thus, recovery of an equivalent private key is accomplished by discovering r linearly independent band spaces in the span of the public key. Since these maps all share the property that they are of rank $2s$, the band spaces can be recovered with a MinRank attack.

Due to the differential invariant structure, it is shown in [15] that there is a significant speed-up in the standard linear algebra search variant of MinRank. The attack proceeds by finding $\lceil \frac{m}{n} \rceil$ vectors in the kernel of the same band space map.

A series of statements about such maps are proven in [15] in the square case revealing the complexity of the MinRank step of the attack.

Definition 5 *Let* $u_1, \ldots, u_{rs}$ *be the components of* $\mathbf{Ux}$ *and fix an arbitrary vector* $\mathbf{v}$ *in the rowspace of* $\mathbf{A}$*, i.e.* $\mathbf{v} = \sum_{d=1}^{r} \lambda_d \mathbf{A}_d$ *where* $\mathbf{A}_d$ *is the dth row of* $\mathbf{A}$*. An* rs*-dimensional vector,* $\mathbf{x}$ *is in the band kernel generated by* $\mathbf{v}$*, denoted* $\mathcal{B}_{\mathbf{v}}$ *if and only if* $\sum_{d=1}^{r} \lambda_d u_{ds+k} = 0$ *for* $k = 1, \ldots, s$*.*

As shown in [15] membership in the band kernel requires that s linear forms vanish; the probability of this occurrence is q^{-s}. They then show that given two maps in the same band kernel, the probability that they are in the kernel of the same band space map is q^{-1}. Therefore the complexity of searching for a second vector given one vector in a band kernel is q^{s+1}. Since $\mathbf{A}$ is singular with probability approximately q^{-1} for sufficiently large q, the total probability of randomly selecting two vectors that are simultaneously in the kernel of the same band space map is q^{-s-2}.

While in [15] it was noted that there are some dependencies in the linear systems resulting in the need to search through a nontrivial space in the case that the characteristic is 2 or 3, it was discovered in [17] that we can add constraints to the system reducing the dimension and eliminating the search. Therefore the complexity of searching for a band space map is the same for all fields. The techniques in [17] can also be adapted to require only 2 band space maps for key recovery, the second of which can be found more cheaply by reusing one of the vectors used to find the first band space map. Since we have to compute the rank of an $n \times n$ matrix for each guess, the complexity of the attack is $\mathcal{O}(n^{\omega} q^{s+2})$ including the linear algebra overhead.

4 Combinatorial Key Recovery, the Rectangular Case

The change from square instances of the Simple Matrix scheme to rectangular instances was proposed in [30] as a way of improving efficiency by having smaller fields while maintaining a low decryption failure rate. Still requiring a left inverse of $\mathbf{A}$, the proposal requires that $r > s$. Notice, however, that this implies that there is a nontrivial left kernel of $A(\mathbf{x})$ for any vector $\mathbf{x}$!

Specifically, notice that since there are more rows than columns in $\mathbf{A}$ for the new parameters, there is always a linear combination of the rows producing the zero vector for any input. Thus, there is no search through plaintexts to find a vector in some band kernel.

In fact, the situation is worse. Note that any plaintext $\mathbf{x}$ is guaranteed to produce an $\mathbf{A}$ for which there are $r - s$ linearly independent combinations of row vectors producing zero. Therefore $\mathbf{x}$ is in very many distinct band spaces. This fact reduces the complexity of finding a second vector in the band kernel considerably, as we now show.

4.1 The Probability of Choosing a Second Band Kernel Vector

A vector $\mathbf{u} = (u_1, u_2, \ldots, u_{rs})$ belongs to a band kernel $\mathcal{B}_\mathbf{v}$ if there is a nonzero vector $\mathbf{v} \in \mathbb{F}^r$ such that for $i = 1, \ldots, s$

$$\mathbf{v} \cdot \mathbf{u}_i = 0, \text{ where } \mathbf{u}_i = (u_i, u_{r+i}, \ldots, u_{((r-1)s+i)}).$$

That is, each subvector $\mathbf{u}_i$ belongs to the orthogonal space $\langle \mathbf{v} \rangle^\perp$.

Since the space $\langle \mathbf{v} \rangle^\perp$ has dimension $r - 1$, membership of each subvector in this space can be modeled as the satisfaction of one linear relation; therefore, there are a total of s linear constraints on $\mathbf{u}$ defining membership in the $\mathcal{B}_\mathbf{v}$. Thus, for any uniformly chosen vector $\mathbf{u} \in \mathbb{F}^{rs}$ we have

$$Pr\left(\mathbf{u} \in \mathcal{B}_\mathbf{v}\right) = q^{-s}.$$

Now consider a vector $\mathbf{w} \in \mathbb{F}^r$ linearly independent with $\mathbf{v}$. The dimension of the orthogonal space $(\mathbf{w} \oplus \mathbf{v})^\perp$ is $r - 2$. Thus by the same reasoning as above,

$$Pr\left(\mathbf{u} \in \mathcal{B}_\mathbf{w} \cap \mathcal{B}_\mathbf{v}\right) = q^{-2s}.$$

In the case $r = s + 1$, we are assured that a plaintext $\mathbf{x}$ gives us $\mathbf{u} \in \mathcal{B}_\mathbf{v}$, where $\mathbf{u} = U\mathbf{x}$. Therefore membership of a second vector in the same band kernel occurs with probability q^{-s}, and the complexity of finding the second vector is q^s.

In the case that $r > s + 1$, for each plaintext $\mathbf{x}$ we are guaranteed that there are $r - s$ linearly independent vectors $\mathbf{v}_1, \ldots, \mathbf{v}_{r-s}$ such that $\mathbf{u} \in \mathcal{B}_{\mathbf{v}_i}$. Therefore $\mathbf{u}$ belongs to

$$\ell = \frac{q^{r-s} - 1}{q - 1} = q^{r-s-1} + q^{r-s-2} + \cdots + q + 1$$

distinct band kernels. Let them be $\mathcal{B}_{v_1}, \mathcal{B}_{v_2}, \ldots, \mathcal{B}_{v_\ell}$. Here it might be the case that $\mathcal{B}_{v_i} \cap \mathcal{B}_{v_j} \neq \mathcal{B}_{v_s} \cap \mathcal{B}_{v_k}$, but all the intersections have the same dimension $rs - 2s$. So, the probability $\mathbf{u}$, chosen at random, belongs to one of them is roughly

$$\begin{aligned} Pr\left(\mathbf{u} \in \bigcup_{k=1}^{\ell} \mathcal{B}_{v_k}\right) &\approx \frac{(\sum_{i=0}^{r-s-1} q^i) q^{rs-s} - \binom{\sum_{i=0}^{r-s-1} q^i}{2} q^{rs-2s}}{q^{rs}} \\ &\approx q^{r-2s-1} - q^{2(r-2s-1)} \\ &\approx q^{r-2s-1}. \end{aligned}$$

Thus, the complexity of finding a second band kernel vector is roughly q^{2s+1-r}.

4.2 The effect of $u + v > 2s$

A further effect of the rectangular augmentation of the Simple Matrix Scheme is that it requires the number of columns of the matrices $\mathbf{B}$ and $\mathbf{C}$ to be increased for efficiency. We therefore find that all of the proposed parameters with $q < 2^{32}$ have $u + v \geq 2s + 4$.

Theorem 1 *If $\mathbf{x}_1$ and $\mathbf{x}_2$ fall within the band kernel $\mathcal{B}_{\mathbf{v}}$, then they are both in the kernel of some generalized band-space differential $\mathbf{DQ} = \sum_{Q_i \in \mathcal{B}_{\mathbf{v}}} \tau_i \mathbf{DQ}_i$ with probability approximately q^{-1} if $u + v = 2s$ and probability 1 if $u + v > 2s$. Further, if $u + v > 2s$ then there exists, with probability 1, some $(u + v - 2s)$-dimensional subspace of $\mathcal{B}_{\mathbf{v}}$, all elements of which have both vectors in their kernel.*

Proof. There are two cases: (i) $u + v = 2s$ and (ii) $u + v > 2s$. The first case follows exactly from [15, Theorem 2]. The second case is new, so we focus on this second case in what follows. This will be quite similar to the original proof, but we include the full details for the reader.

A $\mathbf{DQ}$ meeting the above condition exists iff there is a nontrivial solution to the following system of equations

$$\begin{aligned} \sum_{Q_i \in \mathcal{B}_v} \tau_i \mathbf{DQ}_i \mathbf{x_1}^T &= 0 \\ \sum_{Q_i \in \mathcal{B}_v} \tau_i \mathbf{DQ}_i \mathbf{x_2}^T &= 0. \end{aligned} \tag{1}$$

Expressed in a basis where the first s basis vectors are chosen to be outside the band kernel, and the remaining $n - s$ basis vectors are chosen from within the band kernel, the band-space differentials take the form:

$$\mathbf{DQ}_i = \left[\begin{array}{c|c} \mathbf{S}_i & \mathbf{R}_i \\ \hline \mathbf{R}_i^T & 0 \end{array}\right], \tag{2}$$

where R_i is a random $s \times n - s$ matrix and S_i is a random symmetric $s \times s$ matrix. Likewise $\mathbf{x_1}$ and $\mathbf{x_2}$ take the form $(0|\ \mathbf{x_k}\ )$. Thus removing the redundant degrees of freedom we have the system of $2s$ equations in $u + v$ variables:

$$\begin{aligned} \sum_{i=1}^{u+v} \tau_i \mathbf{R}_i {\mathbf{x_1}}^T &= 0 \\ \sum_{i=1}^{u+v} \tau_i \mathbf{R}_i {\mathbf{x_2}}^T &= 0. \end{aligned} \tag{3}$$

This has a nontrivial solution precisely when the following matrix has a nontrivial right kernel:

$$\left[\begin{array}{c|c|c|c} | & | & & | \\ \mathbf{R}_1{\mathbf{x_1}}^T & \mathbf{R}_2{\mathbf{x_1}}^T & \cdots & \mathbf{R}_{u+v}{\mathbf{x_1}}^T \\ | & | & & | \\ \hline | & | & & | \\ \mathbf{R}_1{\mathbf{x_2}}^T & \mathbf{R}_2{\mathbf{x_2}}^T & \cdots & \mathbf{R}_{u+v}{\mathbf{x_2}}^T \\ | & | & & | \end{array}\right] \tag{4}$$

By the assumption that $u + v > 2s$, this matrix has more columns than rows, and therefore must have a nontrivial right kernel with probability 1. Moreover, with probability 1, this right kernel has dimension at least $u + v - 2s$. Therefore, any differential produced by taking the direct product of $(Q_1, ..., Q_{u+v})$, where $Q_1, ..., Q_{u+v}$ are the generators of $\mathcal{B}_v$, and a right kernel vector of the aforementioned matrix will have both $\mathbf{x}_1$ and $\mathbf{x}_2$ in its kernel.

4.3 Controlling the Ratio $\frac{m}{n}$.

The new parameters presented in [30] added another feature to Simple Matrix: the ability to decouple the number of variables n from the size rs of the matrix $\mathbf{A}$. The authors want to ensure that the number of equations is not significantly more than twice the number of variables so that the first fall degree of the system is not diminished.

In all but the case of $q = 2^8$, the authors of [30] propose parameters with $m = 2n$. In the case of $q = 2^8$, however, the relationship is more complicated. All parameters in this case are functions of s. Specifically, $r = s + 3$, $u = v = s + 4$, $n = s(s + 8)$ and $m = 2(s + 3)(s + 4)$. Therefore $m - 2n = 24 - 2s$.

For small s, this change poses a challenge to the linear algebra search MinRank method. The reason is that choosing merely two kernel vectors results in a system that is underdetermined, and since the size of the field is still fairly large $q = 2^8$, it is very costly to search through the solution space. On the other hand, if we increase the number of kernel vectors we guess to three, we have an additional factor of q^s in our complexity estimate.

Luckily, there is an easy way to handle this issue. We simply ignore some of the public differentials. Consider the effect of removing a of the public equations on the MinRank attack. If $a \geq m - 2n$, then we need to only consider $\lceil \frac{m-a}{n} \rceil = 2$ kernel vectors. Since the expected dimension of the intersection of any band space, which is of dimension $u + v$, and the span of the $m - a$ remaining public maps is $(u+v)+(m-a)-m = u+v-a$, we can apply Theorem 1 with $u+v-a$ in place of $u + v$. We have now shown the following:

Corollary 1 *Consider the public key P with a equations removed. Let $\widehat{\mathcal{B}}_{\mathbf{v}}$ be the intersection of the band space $\mathcal{B}_{\mathbf{v}}$ and the remaining public maps. If $\mathbf{x}_1, \mathbf{x}_2 \in \mathcal{B}_{\mathbf{v}}$, then there exists a band-space differential $\mathbf{DQ} = \sum_{Q_i \in \widehat{\mathcal{B}}_{\mathbf{v}}} \tau_i \mathbf{DQ}_i$ whose kernel contains both $\mathbf{x}_1$ and $\mathbf{x}_2$ with probability approximately q^{-1} if $u+v-a = 2s$ and probability 1 if $u+v-a > 2s$. Further, if $u+v-a > 2s$ then there exists, with probability 1, some $(u+v-a-2s)$-dimensional subspace of $\widehat{\mathcal{B}}_{\mathbf{v}}$, all elements of which have both vectors in their kernel.*

Considering the parameters from [30], we see that the largest value of a required to produce a fully determined MinRank system with two kernel vectors is in the case that $s = 8$ producing $a = m - 2n = 24 - 2s = 8$. In this same set of parameters $u = v = s + 4$ so that $u + v = 2s + 8$. Therefore, Corollary 1 applies.

5 Improvements from a Reaction Attack

As noted in [30], the original proposal of the square version of Simple Matrix, cf. [29], did not properly address decryption failures. To maintain performance and avoid the attack from [15], the rectangular scheme was introduced with many possible field sizes. Still, the proposed parameters only made decryption failures less common but not essentially impossible. The smallest decryption failure rate for parameters in [30] is 2^{-64} and the only parameters with sufficiently good performance to advertise had decryption failure rates of 2^{-32}.

These augmentations addressed decryption failures out of precaution, but had no claim of how such failures could be used to undermine the scheme. In this section we develop an enhancement of our combinatorial key recovery from the previous section utilizing these decryption failures. To our knowledge, this is the first example of a key recovery reaction attack against a multivariate scheme in this context.

5.1 Decryption Failures in the Simple Matrix scheme

As described in Subsection 2.2, the decryption algorithm of Simple Matrix assumes that the matrix $A(\mathbf{u})$ has a left inverse. This property is exactly the same assumption in the more general case of rectangular matrices as well. The failure of $A(\mathbf{u})$ to be full rank makes the decryption algorithm fail, producing decryption failures. One could imagine guessing which rows of $\mathbf{WA}$ could be made into elementary basis vectors trying to recover linear relations on the values of $\mathbf{u}$ to recover a quadratic system in fewer variables which may produce an unique preimage, but this is costly in performance and still allows an adversary to detect when $A(\mathbf{u})$ is not of full rank.

If we consider $\mathbf{A}$ to be rectangular, say $r \times s$, then we need the number of rows r to be greater than or equal to s. Then we may still have a left inverse $\mathbf{W}$, an $s \times r$ matrix satisfying $\mathbf{WA} = \mathbf{I}_s$. The probability of the existence of at least one such $\mathbf{W}$ is the same as the probability that the rows of $\mathbf{A}$ span $\mathbb{F}^s$. Thus

$$Pr(\text{Rank}(\mathbf{A}) < s) = 1 - \prod_{i=r-s+1}^{r} (1 - q^{-i}) \approx q^{s-r-1}.$$

Notice that decryption failure reveals precise information about the internal state of the decryption algorithm. Specifically, the quantity $A(\mathbf{u})$ where $\mathbf{u} = U(\mathbf{x})$ is not of full rank. Even for very large q, one requires a disparity in the values r and s to make the decryption failure rate very low. Even for the parameters proposed having the smallest decryption failure rate, $q = 2^{32}$ and $r = s + 1$, the probability of decryption failure is 2^{-64} and 2^{64} decryption queries on average are needed to detect a decryption failure.

5.2 The Reaction Attack

Consider, for a moment, the square case of the Simple Matrix Scheme, that is, when $r = s$. In the search process, you try to find two vectors $\mathbf{x}_1$ and $\mathbf{x}_2$ that are simultaneously in the kernel of the same linear combination of the public differentials. For the search to succeed in finding a band map you need three events to simultaneously occur: (P_1) $\mathbf{x}_i$ to be in the band kernel of a band space; (P_2) $\mathbf{x}_{3-i}$ to be in the band kernel of the same band space; and, (P_3) for them to both be in the kernel of the same band space map.

The probability of these events occurring simultaneously is then

$$Pr(P_1 \wedge P_2 \wedge P_3) = Pr(P_1)Pr(P_2|P_1)Pr(P_3|P_1 \wedge P_2) = q^{-1} \cdot q^{-s} \cdot q^{-1} = q^{-s-2}.$$

So, it takes q^{s+2} guesses in expectation to succeed in finding two such vectors and thereby recover a band space.

Notice that decryption failure occurs when the matrix $\mathbf{A}$ is singular, which is exactly the condition for membership in some band kernel. Thus, the first vector lying in a band kernel need not be found by search. If you already have access to a decryption failure producing plaintext, then the first condition is satisfied saving a factor of q in complexity at the cost of q decryption queries. So this component of q is now, in some sense, additive instead of multiplicative in the complexity analysis of the attack. Therefore, if the decryption failure rate is sufficiently low, a reaction attack can be employed.

We find that decryption failures provide a similar advantage in the rectangular case as well. When $r > s$, a decryption failure $\mathbf{x}$ assures the existence of $r - s + 1$ linearly independent vectors $v_1, \ldots, v_{r-s+1} \in \mathbb{F}^r$ such that $\mathbf{u} \in \mathcal{B}_{v_1} \cap \cdots \cap \mathcal{B}_{v_{r-s+1}}$, where $\mathbf{u} = U\mathbf{x}$. Thus we know for sure there are

$$\ell = \frac{q^{r-s+1} - 1}{q - 1} = q^{r-s} + q^{r-s-1} + \cdots + q + 1$$

distinct band kernel spaces in which $\mathbf{u}$ belongs. Let them be $\mathcal{B}_{v_1}, \mathcal{B}_{v_2}, \dots, \mathcal{B}_{v_\ell}$. Here it might be the case that $\mathcal{B}_{v_i} \cap \mathcal{B}_{v_j} \neq \mathcal{B}_{v_s} \cap \mathcal{B}_{v_k}$, but all the intersection have the same dimension $rs - 2s$. So, the probability that $\mathbf{u}$, chosen at random, belongs to one of them is roughly

$$\begin{aligned} Pr\left(\mathbf{u} \in \bigcup_{k=1}^{\ell} \mathcal{B}_{v_k}\right) &\approx \frac{(\sum_{i=0}^{r-s} q^i) q^{rs-s} - \binom{\sum_{i=0}^{r-s} q^i}{2} q^{rs-2s}}{q^{rs}} \\ &\approx q^{r-2s} - q^{2(r-2s)} \\ &\approx q^{r-2s}. \end{aligned}$$

6 Complexity

Noting that there is statistically no difference between using the input transformation U and choosing $\mathbf{A}$ to consist of random linear forms, we note that full key extraction including the input and output transformations proceeds as in [17]. Since this last part occurs after the recovery of the band spaces, it is of additive complexity. Therefore the complexity of the attack is equivalent to the MinRank step plus some additive overhead.

Recovering a band space then requires q^{2s+1-r} iterations of solving a linear system of size n and rank calculations on a matrix of size n. (Note that in this case, finding the second map from the same band space is cheaper by a factor of q.) Thus the complexity of the combinatorial key recovery is $\mathcal{O}(n^\omega q^{2s+1-r})$, where ω is the linear algebra constant. We note that in practice that assuming ω takes a value of approximately 2.8 results in a big-oh constant of less than one.

In the case of the reaction attack, recovering two maps from a band space requires only $2q^{2s-r}$ iterations of system solving and rank calculations. Therefore, for the reaction attack, the complexity is $\mathcal{O}(n^\omega q^{2s-r})$. The actual complexity in field operations for completing the attacks are listed in Table 3.

Using SAGE[1] [31], we performed some minrank computations on small scale variants of the ABC scheme. The computations were done on a computer with a 64 bit quad-core Intel i7 processor, with clock cycle 2.8 GHz. We were interested in verifying our complexity estimates on the most costly step in the attack, the MinRank instance, rather than the full attack on the scheme. Given as input the finite field size q, and the scheme parameter s, we computed the average number of vectors $\mathbf{x}$ required to be sampled in order to recover a matrix of rank $2s$. For our first experiment we set our parameters to $u = v = s + 1$, $r = s + 2$, and $n = ru = (s + 1)(s + 2)$. Our results are provided in Table 1.

For higher values of q and s the computations took too long to produce sufficiently many data points and obtain meaningful results with SAGE. Our analysis predicted the number of vectors needed would be on the order of Exp=$(q - 1)q^{s-3}$. Table 1 shows the comparison between our experiments and the expected value. We only used a small number of trials, particularly for the higher values of s listed for each q.

[1] Any mention of commercial products does not indicate endorsement by NIST.

We also ran another experiment exhibiting the behavior of the attack when $2n > m$. We used $u = v = s + 1$, $r = s + 2$, and $n = ru - 1 = s^2 + 3s + 1$. We then threw away two of the equations generated. Our analysis predicted the number of trials required to be roughly $(q-1)q^{s-2}$. The resulting data are given in Table 2. The expected number of trials was Exp=$(q-1)q^{s-2}$.

		$s = 3$	Exp	$s = 4$	Exp	$s = 5$	Exp	$s = 6$	Exp	$s = 7$	Exp
	$q = 2$	1.8	1	3.0	2	4.7	4	6.6	8	15.8	16
	$q = 3$	2.5	2	6.6	6	19.1	18	53.1	54	173	162
	$q = 4$	3.1	3	11.9	12	47.6	48	189.0	192		
!htbp	$q = 5$	4.3	4	20.6	20	99.4	100	520.8	500		
	$q = 7$	6.5	6	40.6	42	281.4	284	1873	1988		
	$q = 8$	8	7	62.8	56	444.2	448				
	$q = 11$	9.8	10	113.6	110	1318.8	1210				
	$q = 13$	11.7	12	157.7	156	2026.7	2028				

Table 1. Average number of vectors needed for the rank to fall to $2s$. This experiment used $u = v = s + 1$, $r = s + 2$, and $n = ru = (s + 1)(s + 2)$.

		$s = 3$	Exp	$s = 4$	Exp	$s = 5$	Exp	$s = 6$	Exp
	$q = 2$	1.9	2	4.4	4	7	8	14.5	16
	$q = 3$	5.9	6	16.3	18	47	54	138.9	162
!htbp	$q = 5$	17.9	20	86.2	100	500.3	500	2137.3	2500
	$q = 7$	36.6	35	277.7	245	2092.3	1715		
	$q = 11$	100.4	110	1175	1210				
	$q = 13$	148.3	156	1855.4	2028				

Table 2. Average number of vectors needed for the rank to fall to $2s$. This experiment used $u = v = s + 1$, $r = s + 2$, and $n = ru - 1 = s^2 + 3s + 1$, and did not use two of the equations generated.

7 Conclusion

The rectangular version of the Simple Matrix Encryption Scheme is needed to avoid a high decryption failure rate and known attacks. From the analysis made in this paper, we conclude that the security of this version is actually worse than that of the square version. Furthermore, we showed that decryption failures are actually still exploitable in a concrete reaction attack that clearly undermines the security claims of the scheme.

It is interesting to consider the historical difficulty of achieving secure multivariate public key encryption. Even using the relatively new approach of defining public keys with vastly larger codomains— a change which on the surface would

Scheme	Sec. Level	a	Comb. Att. Comp.	React. Att. Comp.
$\text{ABC}(2^8, 11, 8, 12, 12, 264, 128)$	80	8	$2^{\mathbf{75.6}}$	$2^{\mathbf{67.6}}$
$\text{ABC}(2^8, 12, 9, 13, 13, 312, 153)$	90	6	$2^{\mathbf{76.3}}$	$2^{\mathbf{68.3}}$
$\text{ABC}(2^8, 13, 10, 14, 14, 364, 180)$	100	4	$2^{\mathbf{85.0}}$	$2^{\mathbf{77.0}}$

Table 3. Complexity of our Combinatorial MinRank and Reaction attacks against $q = 2^8$ parameters of the ABC Simple Matrix Encryption Scheme.

seem to allow much greater freedom in selecting secure injective functions— we observe that essentially none of the recent such proposals have attained their claimed level of security after scrutiny. Perhaps there is a fundamental barrier ensuring that any efficiently invertible function must have some exploitable property, such as low rank, preventing the advantage of privileged information of the legitimate user from dramatically separating the complexity of that efficient inversion from the adversary's task. It seems that multivariate encryption is an area still in need of significant development.

***Abstract*—In the era of the Internet of Things, botnet threats are rising, which has prompted many studies on botnet detection. This study aims to detect the early signs of botnet attacks such as massive spam emails and Distributed Denial-of-Service attacks. To that end, this study develops a practical method for measurement, labeling, and classification of botnet Command and Control (C2) for predicting attacks. The focus is on C2 traffic and measurement of the comprehensive metrics studied in previous works. The data is labeled based on the result of the correlation analysis between C2 metrics and spam volume. Then, a special type of recurrent neural network, i.e., Long Short-Term Memory, is applied to detect an increase in spam by a botnet. The proposed method managed to detect it with an accuracy of 0.981.**

I. Introduction

A botnet is still a serious threat to cybersecurity as it controls a massive number of compromised hosts to conduct various attacks such as sending email spam or launching a Distributed Denial-of-Service (DDoS) attack. A Command and Control (C2) server plays a significant role in a botnet: it sends commands to bots and receives outputs of bots while hiding a botmaster behind it. Despite many previous attempts at botnet measurement [6], [8] and botnet detection [4], [5], [7], [10], to the best of our knowledge, there is no study that *detects the early signs of botnet attacks*. According to the botnet communication patterns [11], once a bot infection occurs, the bot registers itself to C2 and the keep-alive communication between the bot and C2 starts periodically. A botmaster issues a command to bots for launching an attack through C2, and then an attack is launched. The key idea in this study is that traffic patterns from or to C2 will be changed before the attack. For example, a botmaster would prefer more bots to launch an attack effectively, and then the bot register may increase before the attack. A command contains some data such as the target and parameter, and will be sent to numerous bots in parallel so that the size of the packet may be increased before the attack. Such predictive threat intelligence is crucial for an internet service provider (ISP) for prioritizing C2s and cutting off communication between C2 and bots in advance in crisis situations or at customers' requests.

This poster presents a method for effective measurement, labeling, and classification of botnet C2s for predicting attacks. In the measurement phase, various metrics of C2 are computed with flow data collected with a certain sampling rate by an ISP for network management. Next, a set of C2 metrics is labeled for a certain period based on 1) the gradient of spam volume and 2) the result of the correlation analysis between the moving average of each C2 metric and the volume of spam email associated with C2 as attack data. For the classification, a recurrent neural network is used to train and test the labeled dataset. The following sections describe each phase of the method and preliminary experimental results.

II. Methodology

A. Measurement

The 17 metrics listed in TABLE I are defined for measuring C2 activity, which is a compilation of various metrics studied in previous works [4], [10]. All metrics are computed with flow data for every three hours. Because the used flow data has a unidirectional format, IP addresses of C2 will be observed in the source or destination field. The metrics can be computed using three patterns: C2 in source, C2 in destination, and C2 in either source or destination. Finally, because the 17 metrics are multiplied by the three patterns, it is possible to use 51 metrics. The lists of C2s are retrieved from websites [1], [3] and provided by a reliable research institution once daily.

TABLE I. C2 Metrics

Category	Metrics
Size	1) # of bots
	2) # of bots observed multiple flows
Volume	3) Average, 4) standard deviation and 5) sum of bytes
	6) Average, 7) standard deviation and 8) sum of packets
Frequency	9) # of flows
	10) # of flows with few packets (less than three packets)
	11) # of flows with short duration (less than one s)
	12) # of flows with small bytes (less than 500 bytes)
Load	13) Average, 14) standard deviation and 15) sum of duration
Lifetime	16) # of days flow was observed in the last seven days
	17) # of days flow was continuously observed in the last seven days

B. Labeling

Spam reputation data [2] is retrieved as attack data once daily. It includes information such as the IP address of the spam sender and spam volume in the last day. The total spam volume associated with C2 can be added up by associating an IP address of C2 and an IP address of the spam sender in flow data. As a preliminary experiment, it was analyzed whether the metrics could be useful for predicting the increase in spam during a week. At that time, the moving average of each C2 metric was taken with a one-day time window. This time window represents how far in advance a sign can be detected. To align the number of data elements with the

Hatada, Mitsuhiro; Scholl, Matthew. "Method for Effective Measurement, Labeling, and Classification of Botnet C2s for Predicting Attacks." Paper presented at 27th Annual Network and Distributed System Security Symposium (NDSS), San Diego, CA, US. February 23, 2020 - February 26, 2020.

C2 metric, spam volume was padded with the same value as the previous data. According to the result of the correlation analysis between each C2 metric and spam volume for each botnet, a different botnet tends to show different correlation and there are metrics with a high positive correlation. Based on this observation, it was decided to use all metrics and the following two criteria were set for labeling: 1) there is at least one metric with a high correlation greater than or equal to 0.3; 2) there is a positive gradient of the spam volume. With these criteria, C2 with the increasing spam for one week can be set as a *True* label. These steps are repeated for the entire period while shifting the starting point by one day.

C. Classification

Long Short-Term Memory (LSTM) [9] was applied for binary classification. LSTM is a recurrent neural network capable of learning long-term dependencies. To apply LSTM, each C2 metric is scaled between 0 and 1, and then the time series data of each C2 metric is laterally shifted. Finally, it becomes 2,856-dimensional data. Various models have been tried, but a model of stacked LSTMs was selected because of its high accuracy. The model has a layered structure comprising LSTM, dropout, LSTM, dropout, and dense. A dropout layer is used for the regularization that randomly sets some of the dimensions of the input vector to zero at each update during training time, which helps prevent overfitting. The dense layer represents matrix vector multiplication. The values in the matrix are the trainable parameters that get updated during backpropagation. The model is configured using binary cross-entropy for the loss function, Adam as the optimization algorithm, and Sigmoid as the activation function.

III. Evaluation

A. Dataset

TABLE II describes the dataset used in the evaluation, which was generated between August 3, 2019 and November 1, 2019 (90 days) and labeled as described in Section II-B with a different time window of the moving average. The number of true and false data is unbalanced, so false data are randomly sampled to align with the number of true data for experiments.

TABLE II. Dataset

Time Window (hours)	# of True	# of False	# of C2s
12	1,893	8,641	234
24	2,291	8,154	234
48	2,423	7,888	233

B. Experiment

The proposed method was evaluated with respect to accuracy as well as computational time. Using Python 3.6.9 with Keras 2.2.4 on top of TensorFlow 1.14.0, experiments were performed for training and testing with 10-fold cross-validation on the *Enki* which is the High Performance Computing cluster at the National Institute of Standards and Technology. TABLE III demonstrates the average results of the 10-fold cross-validation. The highest accuracy is 0.981, when the time window of the moving average is 48 and the number of hidden units is 100. By increasing the number of hidden units, both training time and testing time almost linearly increased as expected. The effect of the time window is not noticeable because all data might have been properly learned.

TABLE III. Results of binary classification

(batch=128, epoch=200, dropout=0.3, learning rate=0.01)

Time Window (hours)	Units	Train (s)	Test (s)	Accuracy	Recall	Precision
12	100	2,201.90	2.37	0.923	1.000	0.883
	200	3,186.01	3.71	0.929	0.956	0.918
	300	4,256.90	5.93	0.938	1.000	0.902
	400	5,566.59	9.39	0.898	0.994	0.859
	500	7,037.26	13.69	0.934	0.999	0.890
24	100	2,658.80	2.98	0.956	0.998	0.923
	200	3,817.19	4.20	0.926	1.000	0.881
	300	4,976.25	6.98	0.921	0.998	0.882
	400	6,730.17	11.15	0.966	1.000	0.939
	500	8,535.01	16.35	0.955	0.986	0.931
48	100	2,830.37	2.97	0.981	1.000	0.966
	200	4,050.56	4.56	0.881	1.000	0.829
	300	5,354.73	7.21	0.805	0.642	0.968
	400	7,138.42	11.92	0.918	0.963	0.897
	500	9,056.58	17.29	0.939	0.906	0.973

IV. Conclusions and future work

By focusing on C2 traffic, the proposed method managed to detect an increase in spam email by a botnet with an accuracy of 0.981. The next challenge is how far in advance to predict the increase in spam email. It is necessary to extract C2 communication appropriately because C2 metrics are computed including legitimate flow if a legitimate server is compromised and used as C2. It is also essential to accurately track a C2 IP address because C2 changes the IP address to avoid detection. Although the method can be further improved, the method would also be applicable to the prediction of attacks such as DDoS if the data that associates bots with C2 is available.

Method for Effective Measurement, Labeling, and Classification of Botnet C2s for Predicting Attacks

Mitsuhiro Hatada and Matthew Scholl, Computer Security Division

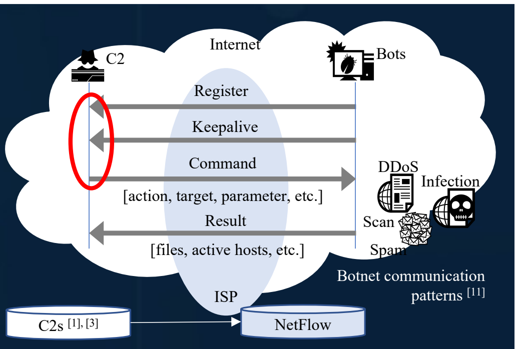
Motivation

- Botnet is still a serious threat to cybersecurity as it controls a massive number of compromised hosts to conduct various attacks such as sending email spam or launching a Distributed Denial-of-Service (DDoS) attack.
- Command and Control (C2) server plays a significant role in a botnet: it sends commands to bots and receives outputs of bots while hiding a botmaster behind it.
- Despite many previous attempts at botnet measurement [6], [8] and botnet detection [4], [5], [7], [10], to the best of our knowledge, there is no study that **detects the early signs of botnet attacks**.

Key Idea

Traffic patterns from or to C2 will be changed before the attack.

- Botmaster would prefer more bots to launch an attack effectively, and then the bot register may increase before the attack.
- Command contains some data such as the target and parameter, and will be sent to numerous bots in parallel so that the size of the packet may be increased before the attack.



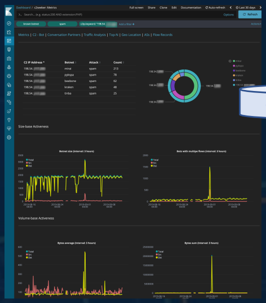
Botnet communication patterns [11]

Measurement

- All metrics are computed with flow data for every three hours and can be computed using three patterns: C2 in source field, C2 in destination field, and C2 in either source or destination field of unidirectional NetFlow.
- Finally, it is possible to use 51 metrics.

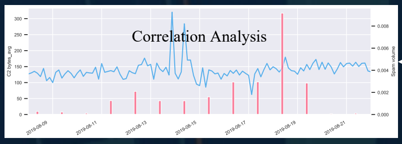
TABLE I. C2 METRICS

Category	Metrics
Size	1) # of bots
	2) # of bots observed multiple flows
Volume	3) Average, 4) standard deviation and 5) sum of bytes
	6) Average, 7) standard deviation and 8) sum of packets
Frequency	9) # of flows
	10) # of flows with few packets (less than three packets)
	11) # of flows with short duration (less than one s)
	12) # of flows with small bytes (less than 500 bytes)
Load	13) Average, 14) standard deviation and 15) sum of duration
Lifetime	16) # of days flow was observed in the last seven days
	17) # of days flow was continuously observed in the last seven days



C2 Metrics

Spam Vol. [2]



Preliminary Analysis

Could the metrics be useful for predicting the increase in spam during a week?

- The total spam volume associated with C2 can be added up by associating an IP address of C2 and an IP address of the spam sender in flow data.
- The moving average of each C2 metric was taken with a one-day time window. This time window represents how far in advance a sign can be detected.
- According to the result of the correlation analysis between each C2 metric and spam volume for each botnet, *a different botnet tends to show different correlation* and *there are metrics with a high positive correlation*.

Labeling

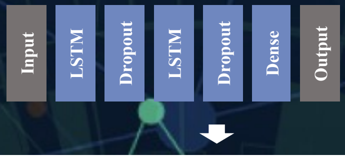
- Criteria
  1) There is at least one metric with a high correlation greater than or equal to 0.3
  2) There is a positive gradient of the spam volume
- C2 with the increasing spam for one week can be set as a True label. These steps are repeated for the entire period while shifting the starting point by one day.

C2	Time	Metric A	Metric B	…	Label	2) Gradient
198.51.100.22	8/3 00:00-03:00	133.45	1872.10	…	True	0.02
	8/3 03:00-06:00	664.87	3606.19	…		
	:	:	:	…		
	8/9 21:00-24:00	293.42	18,341.22	…		
	1) Correlation	0.11	0.42	…		

Dataset

Classification

- Long Short-Term Memory (LSTM) [9], a recurrent neural network capable of learning long-term dependencies, was applied for binary classification.
- The model is configured using binary cross-entropy for the loss function, Adam as the optimization algorithm, and Sigmoid as the activation function.
- Each C2 metric is scaled between 0 and 1, and then the time series data of each C2 metric is laterally shifted. Finally, it becomes 2,856-dimensional data.



Evaluation

- Dataset was generated between August 3, 2019 and November 1, 2019 (90 days) with a different time window of the moving average.
- The number of true and false data is unbalanced, so false data are randomly sampled to align with the number of true data for experiments.
- Experiments were performed for training and testing with 10-fold cross-validation on the Enki which is the High Performance Computing cluster at the NIST.
- By focusing on C2 traffic and using LSTM for the time series data of comprehensive metrics, the proposed method managed to detect an increase in spam email by a botnet with an accuracy of 0.981.

Key Considerations for Microbial Viability Measurements

Making reliable measurements of antimicrobial killing efficacy requires careful consideration of the sources of biological variability, measurement bias and error throughout the entire workflow. For ultraviolet-C (UV-C) disinfection, killing efficacy is most commonly measured using plate counting where the $\log_{10}$ reduction in colony forming units (CFUs) is calculated using the inoculum CFU count before and after UV-C exposure. Although CFU counting is not a rapid diagnostic, it is fit-for-purpose for testing UV-C sources and establishing room disinfection protocols. Best practices for minimizing biological and technical error in plate counting have been established [1]. Careful consideration of sources of variability during all experimental stages can help minimize error propagated to the final $\log_{10}$ reduction value. Instrument calibration, sample preparation, counting and viability measurements performed at NIST provide insights that could further improve confidence in killing efficacy results.

Samples for UV-C killing efficacy testing are prepared using bacteria at a target concentration, which is measured using a spectrophotometer and converted to bacterial concentration using an OD_{600} -bacteria concentration calibration curve. Characterization of spectrophotometer performance for linearity and offset against OD standards is an essential first step for accurate and comparable measurements. Figure 1 shows an example spectrophotometer calibration, where the linear operating range is only up to ≈ 0.9 OD, illustrating that high OD cultures should be diluted to the linear range for accurate measurement.

The OD-bacterial concentration calibration curve is typically based on CFU counts. The use of counting devices such as a Coulter (impedance) counter, flow cytometer or optical microscope can improve calibration reliability by providing an object count rather than a culturable cell count. These types of calibration curves must be collected for each strain and culture condition being studied, as the relationship between OD and concentration will vary. For instance, *E. coli* cultures diluted to the same cell concentration had very different OD readings when they were grown either in rich or in minimal media. Using alternate counting methods helps in understanding how well CFUs compare with maximum attainable count.

Microbe aggregation contributes to counting error, so disaggregation while maintaining viability can improve viable cell counts accuracy. In one approach, a focused ultrasonic instrument is used to break microbial aggregates into single cells to improve counting accuracy. *A. naeslundii*, an aggregated facultative anaerobe, is highly disaggregated after focused ultrasonic treatment optimization (Figure 2). Comparison of CFU count and Coulter counter count as a function of ultrasonic treatment time showed that an optimum treatment time can maximize viable counts of disaggregated *A. naeslundii*.

Dunkers, Joy; Da Silva, Sandra M.; Servetas, Stephanie; Filliben, James J.; Pinheiro, Guilherme; Lin, Nancy. "Key Considerations for Microbial Viability Measurements." Paper presented at Workshop on Ultraviolet Disinfection Technologies & Healthcare Associated Infections: Defining Standards and Metrology Needs, Gaithersburg, MD, US. January 14, 2020 - January 15, 2020.

The accuracy and precision of CFU measurements is also dependent on microorganism size, concentration and morphology (chain vs single). Comparison of CFUs to Coulter counter results has been performed using *S. cerevisiae* (spherical yeast), *B. thuringiensis* (spores), *B. thailandenis* (short rods), and *S. mutans* (chains). A 2 µm bead concentration standard was used for absolute count. Agreement between CFU and Coulter counter results varied by microorganism, although there was very good counting agreement between known bead concentration and Coulter counter results. *B. thailandenis* had lower precision for both CFU and Coulter counter compared to the other organisms. For *S. mutans*, plate counting had much lower precision than the Coulter counter. The addition of Coulter counter data aids in evaluating robustness in plate counting.

Orthogonal methods for viability provide independent results, albeit with different caveats. Orthogonal methods are not meant to be run regularly, but as a check on the primary method. A desirable orthogonal method to CFUs would allow for increased throughput and more robust statistics. Flow cytometry and automated optical microscopy are two high throughput methods that both rely on fluorescent probe intensity as a surrogate for viability. In selecting a fluorescent probe, the mechanism of cell death should be considered. For UV-C killing, DNA strand breakage and base rearrangement have been identified as the main killing mechanisms [2]. Membrane integrity fluorescent probes have been used as viability markers [3] but may not be suitable for testing UV-C killing efficacy. Loss of membrane potential may be considered independent of killing method, and membrane potential fluorophores as viability markers have been studied in bacteria [4] and yeast [5].

Robust measurement methods and technology innovation for cell count and viability are needed to improve confidence in plate counting as a measure of UV-C killing efficacy.

***Abstract*—In recent years, combinatorial testing methods have been successfully applied to test systems with a large number of input parameters. Generating combinatorial test sets for such complex systems is still a challenging task as it requires a lot of time and computing power. To tackle that issue, high performance tools are required. In this work, we present the combinatorial test set generation tool CAgen. It is capable of generating combinatorial test sets significantly faster than other state-of-the-art tools, such as ACTS, and contains various features such as constraint handling and higher-index arrays. It is highly compatible with other combinatorial testing tools and is available as CLI and Web-GUI. CAgen aims to make combinatorial testing more efficient and more accessible and user-friendly.**

I. INTRODUCTION

Due to the reduction in the number of tests necessary when using combinatorial testing methods, it has become possible to test larger systems within reasonable time and resources, while maintaining certain coverage guarantees. At the same time, the generation of combinatorial test sets with a small number of tests becomes increasingly difficult as the systems under test become larger [1]. To counteract this, tools are necessary that are both fast and memory-efficient. Even for smaller systems, faster generation times can lead to reduced testing cycle durations. Furthermore, in order for combinatorial testing to be adopted by a wider set of software testers and developers, the tools necessary to edit, generate and inspect combinatorial test sets need to be user-friendly, enabling a quick development cycle. Both these properties aim at lowering the entry barrier to people unfamiliar with combinatorial testing. However, presently there is a distinct gap in the space of combinatorial testing tools making a wide-spread adoption harder than necessary. In the following, we will outline a few problems of the current state-of-the-art and then propose a new tools to bridge this gap.

One of the largest problems hindering adoption is the way in which different tools are distributed. Classic software distribution via pre-compiled binaries or bundles has the drawbacks of having no easy way to implement software updates by the vendor and placing a high maintenance burden on the provider depending on the number of supported platforms. Therefore, System as a Service (SaaS) solutions are becoming a more and more popular way to bring a software product to the end user with control remaining at the side of the vendor. In case of defects, bug fixes can quickly be deployed to the service and new versions are immediately available to all users without. Recently, the authors in [2] surveyed existing combinatorial test generation tools which are available via the web. However, their analysis concludes that many of these tools have deficiencies which prevent their use in many testing scenarios. Most are commercial and thus not readily available to entry-level testers, students or academic users. Furthermore, some tools only offer limited support for higher strength test generation with three out of five tools only supporting pair-wise test generation and only one with support for 6-way coverage. As a response, in the same paper, they proposed a new tool named CTWEDGE which offers free test set generation with either ACTS or CASA accessible via a web frontend. Furthermore, in [3] a tool for automated combinatorial test generation and fault characterization was intruduced, where the algorithm underlying CAgen was used for initial test set generation.

In this work, we present CAgen[1], a fast, efficient and user-friendly combinatorial test generation tool. To evaluate its features and performance, we will draw comparisons with the following tools: for GUI functionality, we consider ACTS [4], which comes as a command line tool as well as a GUI version, and the publicly available service CTWedge [2] that offers free test set generation using ACTS or CASA. Further, we will analyze the performance of our tool against the state of the art test set generation tools ACTS and PICT.

The paper is structured as follows. Section II gives an overview about algorithms used in test set generation and constraint handling. The architecture of CAgen is explained in detail in Section III and Section IV introduces the various features of CAgen and compares them with other generation tools. Section V provides benchmarks for various different instances of covering arrays, including models from real world applications, and compares them with ACTS and PICT, while Section VI concludes our work and discusses potential future work.

II. BACKGROUND AND RELATED WORK

The efficient generation of *covering arrays* (CAs), the mathematical construct underlying combinatorial test sets, is a highly researched topic. Various generation methods, such

Kacker, Raghu N.; Kuhn, D. Richard. "CAgen: A fast combinatorial test generation tool with support for constraints and higher-index arrays." Paper presented at IEEE International Conference on Software Testing, Verification and Validation ICST 2020 Workshops, Porto, PT. March 23, 2020 - March 27, 2020.

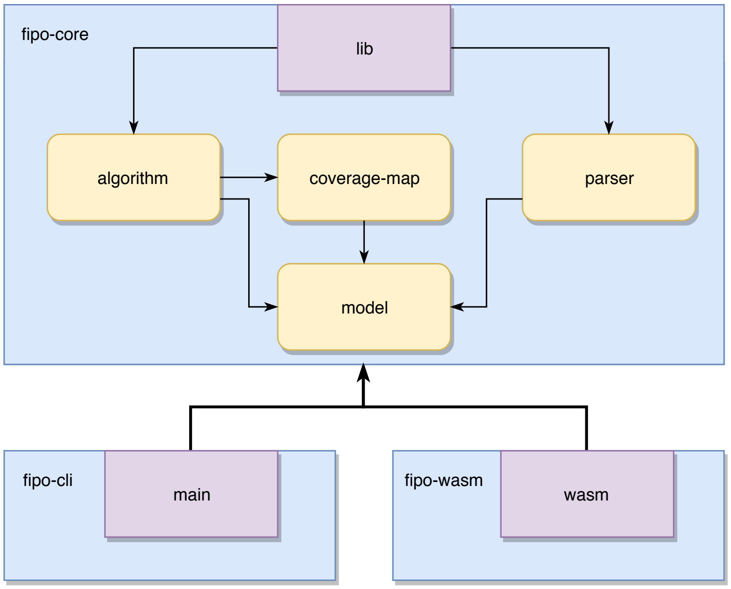

Fig. 1. Rust project structure of CAgen tool

as mathematical and algebraic constructions, exact methods or metaheuristic approaches, have been successfully applied to generate covering arrays [5], but due to the need for flexibility, constraint handling and speed of generation, greedy approaches have proven the most versatile when are applied to real world applications. A popular generation strategy is the one-test-at-a-time approach, where a test set is built by adding one test at a time until all desired t-way interactions are covered. The tests can either be constructed using random methods, as used by AETG [6], or deterministically, such as in the deterministic density algorithm [7] and the algorithm underlying the tool PICT [8]. Another efficient generation strategy is the In-Parameter-Order (IPO) strategy [9]. The strategy starts with a $t \times v^t$ array containing all possible t-way combinations of the first t parameters and continues expanding the array incrementally. In every extension, a horizontal extension is used to add columns (parameters) to the array, while a vertical extension step ensures that the coverage property remains satisfied, adding additional rows (tests) if necessary. While the initially proposed IPO algorithm assigned the values in appended columns greedily from top to bottom, two new variants of the horizontal extension were introduced later on in [10]. The IPOG-F algorithm greedily selects the order in which values are assigned to rows, while the IPOG-F2 algorithm makes use of a heuristic to estimate the gains of selecting a value. All three of these algorithms are available in the ACTS tool as well as in CAgen.

Support for constraints in combinatorial test generation algorithms has been studied intensively [11]. Constraints are a crucial feature for combinatorial test set generation when applied to real-world testing scenarios. The integration of constraints into the test generation process using IPO has been studied previously in [12], [13] and [14]. Currently, two approaches are used in practice: SAT-based and forbidden tuples. The constraint handling techniques used in CAgen are discussed in more detail in Section IV and are based on the forbidden tuples approach, also discussed in [8].

III. Tool Architecture

The tool architecture is based on the core algorithm implementations described in [15]. The algorithms are implemented in Rust[2], a fast and safe system-level programming language. The implementation is fast and exhibits a low memory footprint. The basic structure of the project can be found in Figure 1. It is structured into three crates (Rust terminology for package). fipo-core is the library implementing the core algorithms which is further divided into modules. The model module contains common data structures for `Parameter` and `Value` types, the parser module is responsible for parsing common input formats into internal representations. coverage-map and algorithm provide the core data structure and implementations of different IPO algorithms respectively.

Listing 1 shows the interface of the core FIPO algorithm. Two methods for the horizontal and vertical extension can be implemented by different implementations depending on the underlying algorithm. Note that they are parameterized by a generic type T which represents the strength parameter t. Since t is usually a small integer [16], we can instantiate different versions of the algorithm at compile time with constant values for T (e.g., for $t \in \{2, 3, 4, 5, 6, 7, 8\}$) and the compiler can then treat the strength as a constant and perform many useful optimizations such as

[2] https://www.rust-lang.org/en-US/

```
trait CoreIpoAlgorithm {
    fn extend_horizontal<T>(&mut self, column: usize)
        where T: Unsigned;

    fn extend_vertical<T>(&mut self, column: usize)
        where T: Unsigned;

    // non-generic
    fn generate_array(&mut self, strength: usize) {
        // select implementation with given strength
        // -> strength becomes part of the type
        match strength {
            1 => self.generate_with_strength::<U1>(),
            2 => self.generate_with_strength::<U2>(),
            [..]
            _ => panic!(
                format!("t={}␣not␣implemented", strength)
            ),
        };
    }

    fn generate_with_strength<T>(&mut self)
        where T: Unsigned
    {
        // from here on, the strength is part of the type
    }
}
```

Usage: fipo-cli

Options:
    -h, --help          send help
    -t, --strength      Strength
    -l, --index         Index of the covering array to generate (default 1)
    -i, --instance      Instance to generate an array for. Can be a path to a
                        ACTS configuration file or a textual representation in
                        either linear form (e.g., 2,2,3,2,4,5), exponential
                        notation (e.g., 2^3,3,4,5) or in named notation (e.g.,
                        param1:0,1;param2:true,false;param3:TLS,SSL,none).
    -a, --algorithm     Algorithm to use. Values: ipog, ipog-f, ipog-f2
    -c, --constraint <constraint-spec>
                        Add a constraint
    -p, --print         Print CA
    -q, --quiet         Print nothing except size
    -r, --header        Output a header row
        --randomize     Randomize don't-care values.
```

Fig. 2. Command-line arguments for fipo-cli

]

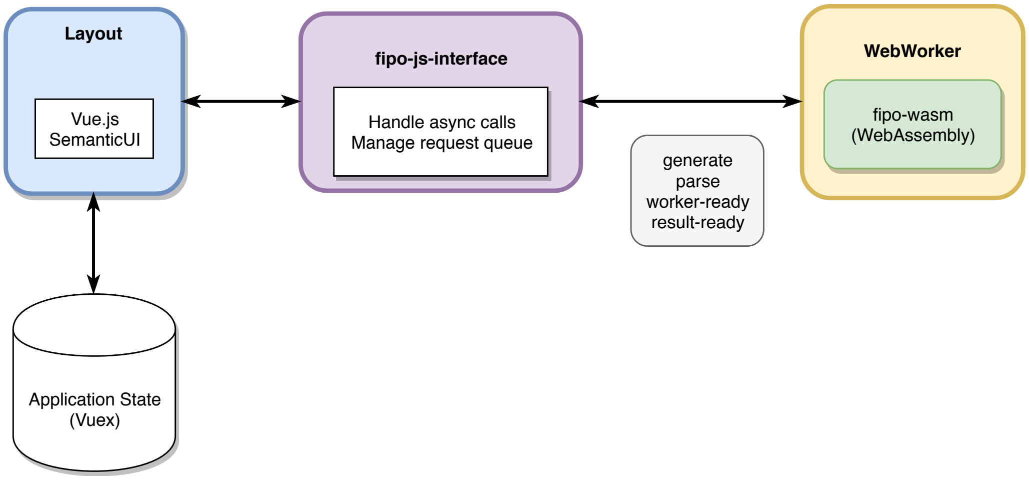

Fig. 3. Architectural overview of CAgen

1) **Compile-time sized t-selections**: t-selections are represented by a constant amount of space in memory and can be tightly packed in an array without necessary meta-data to store the size
2) **Constant iteration bounds**: The loop computing indices for tuples (see definition of *pack* in [15]) can be unrolled, eliminating the inner-most loop of the algorithm altogether

The non-generic `generate_array` method will at run-time select the corresponding generic instantiation of the algorithm based on the strength passed as the argument. As Rust does not yet posses the capability of representing compile-time integers, a type-level encoding using the `typenum`[3] crate is used instead.

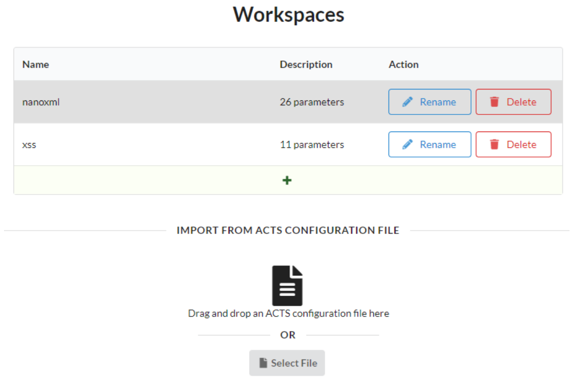
The core of fipo is exposed in two separate frontends.

A. Command-line interface

The command-line interface is implemented using a separate crate (Rust terminology for module) named `fipo-cli`. It is responsible for parsing the given command-line arguments and invoking the desired test generation algorithms for the given configurations. The resulting test sets are then printed to the console according to the formatting wishes of the user. Figure 2 displays all available command line options for `fipo-cli`.

The command-line interface's main use-case is to use it in a broader testing workflow where the tool can be dropped-in to perform (abstract) test case generation.

The main use-case for the command-line interface is to use it as a test generation service which can be embedded into a larger testing work-flow. The interface is kept simple and only allows for the generation of mixed-level covering arrays (MCAs). As such, no explicit test translation (i.e., using model values from an IPM) is provided by `fipo-cli`, but



Workspaces

Fig. 4. Workspaces manages your IPMs and allows you to import models from config files.

this is trivial to implement by any simple substitution. As test translation often requires additional steps to convert abstract (CA-level) test sets into concrete test sets it makes sense to separate these two parts.

B. Web Application

The web frontend is named CAgen and is a web application bundling the core algorithms of fipo into a user-friendly interface. The general architecture can be found in Figure 3. The most important design decision is the non-requirement of a backend service as the application is completly client-side. It can be hosted on a simple web space and does not require the operator to invest in many computational resources. It is freely available at https://matris.sba-research.org/tools/cagen. The application is a single-page application built with Vue.js[4]

Fig. 6. In Input Parameter Model, new parameters can be added easily.

and SemanticUI[5] as the layout framework. The state is managed by Vuex[6]. This state consists mainly of the IPMs managed by the user which are called workspaces in CAgen, see Figure 4. IPMs can be created, edited or uploaded from ACTS files directly in the application and configuration files can even simply be dragged and dropped into the website.

The IPM editor, shown in Figure 6 provides convenience functions for adding boolean, enumeration and range parameters and also supports the addition of parameters given in exponential notation. Further, it is possible to specify and edit constraints for the model.

Lastly, Figure 5 depicts the generate tab, where you can choose between three different algorithms and specify a desired strength and index. Upon clicking the generate button, the tool will generate a covering array for the selected workspace with the specified parameters. Finally, post processing options such as randomizing Don't-Care values as well as an option export the array to different environments are available. For more detailed information and examples, we refer the interested reader to the User Guide in the Help section of our tool.

Providing backend-free test generation: The core of fipo is written in Rust and the language ecosystem has support for the compilation of Rust projects to WebAssembly. WebAssembly is a standardized binary format for executable code supported by all major browsers. It can be used as a common compilation target for different source languages and programs written in these languages can then directly be executed in the browser. Fipo exposes the core algorithms as a separate crate (c.f. Figure 1) which is compiled to WebAssembly and a small JavaScript interface. The web application uses these exposed routines inside a WebWorker which allows for parallel execution (i.e., without blocking the interface with a synchronous call). A small Javascript runner is used to abstract away the worker internals, handle test generation requests asynchronously and also implements queuing.

IV. Main Features

A. *Fast combinatorial test set generation*

A fast run time and low memory usage can play important role in test set generation, as they allow for the generation of test sets for models with a higher number of parameters and values or with higher interaction strength. As an example, CAgen has been one of the key factors for the generation of test sets for testing large-scale data processing at Adobe [1]. In [15], various improvements to the existing IPO algorithms were introduced on the algorithmic as well as on implementation level, briefly summarized as follows. First, it was proposed to compute the coverage gain for same-prefix

[5] https://semantic-ui.com

[6] https://vuex.vuejs.org/en/intro.html

tuples simultaneously, which reduces the reduces the number of operations needed to encode a tuple. Due to the how often this operation is needed, this seemingly small optimization has a significant impact on the run time of the algorithm. Further, storing the number of t-way interactions covered by every column selection in the coverage map makes it possible to exclude fully covered selections from any further considerations. A possible memory optimization is to only keep the currently relevant parts of the coverage map in memory, while the redundant information of the partial CA with $i-1$ columns can be discarded at the begin of the ith horizontal extension step. Another implementation-level optimization is the use of a more efficient vector representation of the array that gets constructed. Lastly, as already mentioned in Section III, the interaction strength can be turned into a compile time constant, enabling various compiler optimizations such as unrolling the loops used to encode tuples.

Section V showcases the speedup these optimizations provide compared to other state-of-the-art tools for the generation of various uniform and mixed level covering arrays.

B. Higher-index CAs

Sometimes it can be desirable that all interactions are covered multiple times instead of at least once, e.g. when multiple activations of an interaction are needed to trigger a fault. With CAgen, it is possible to specify an index λ, where $\lambda = 1$ is equivalent of a traditional covering array. In the generated array, every possible combination is covered at least λ times. We would like to remark, that while this could also be achieved by using the same covering array λ times, our experiments showed that the number of tests needed to cover all interactions at least λ times is usually significantly less than $\lambda \times N$, where N refers to the number of rows in a CA with $\lambda = 1$. For example, for a uniform covering array with 100 columns, $v = 5$ and strength $t = 3$, using IPOG-F, we can construct a $\lambda = 4$ covering array with only 1367 rows, while a normal covering array using the same algorithm has 744 rows.

C. Constraints

CAgen supports user-specified constraints via forbidden tuples. The approach has been described in prior work, however we detail some implementation aspects that have not been covered thus far in the literature in more detail. Specifically we propose a simple way of deriving an initial set of forbidden tuples from arbitrary logical formulas without the need to embed any kind of complex SAT solving mechanism.

The approach is separated into three major steps:

1) Parse user-specified constraints (arbitrary logic formula) into an abstract syntax tree (AST)
2) Visit the AST in post-order to derive an initial set of forbidden tuples
3) Compute minimal forbidden tuples

a) Parsing: The grammar used to parse user-specified constraints can be found in Grammar 1. It allows for arbitrary nesting of formulas using the most commonly used logic operators `or`, `and`, `implication` and `not`. The resulting list of constraints are formulas which must be satisfied by each test in the combinatorial test set. The parser will also check the constraints against the given IPM to make sure that the parameters used in the constraint are part of the model and comparisons with parameter values are with values from the corresponding parameter's domain.

```
⟨constraint-list⟩ ::= ⟨constraint-list⟩ ‘,’ ⟨expr⟩ | ⟨expr⟩

⟨expr⟩ ::= ⟨and-expr⟩
  |  ⟨and-expr⟩ (‘||’ ⟨and-expr⟩)+

⟨and-expr⟩ ::= ⟨impl-expr⟩
  |  ⟨impl-expr⟩ (‘&&’ ⟨impl-expr⟩)+

⟨impl-expr⟩ ::= ⟨unary-expr⟩
  |  ⟨unary-expr⟩ ‘=>’ ⟨unary-expr⟩

⟨unary-expr⟩ ::= ⟨primary-expr⟩ | ‘!’ ⟨unary-expr⟩

⟨primary-expr⟩ ::= ⟨term⟩ | ‘(’ ⟨expr⟩ ‘)’

⟨term⟩ ::= ⟨parameter⟩ ‘=’ ⟨literal⟩
  |  ⟨literal⟩ ‘=’ ⟨parameter⟩
  |  ⟨parameter⟩ ‘!=’ ⟨literal⟩
  |  ⟨literal⟩ ‘!=’ ⟨parameter⟩
  |  ⟨parameter⟩ ‘!=’ ⟨parameter⟩

⟨parameter⟩ ::= r‘[a-zA-Z][a-zA-Z0-9]*’

⟨literal⟩ ::= r‘[0-9]’
  |  ⟨quote⟩ r‘[a-zA-Z0-9_-]+’ ⟨quote⟩
```

Grammar 1. Grammar for user-specified constraints

1) Initial forbidden tuple derivation: Since the constraints are written as positive constraints, i.e. specifying valid configurations, they first need to be converted into a negative representation: forbidden tuples. This step can easily be implemented by visiting each node in the parsed abstract syntax tree in post-order fashion and is defined in Figure 7. Note that p and q represent parameters and v and w corresponding parameter values. $values(p)$ denotes the set of values of the parameter p. Note that in the grammar, the `and` and `or` operators are n-ary instead of binary, but the derive procedure is trivially extendable to handle the $n > 2$ case as well.

Equations (1) - (4) specify base rules to derive forbidden tuples from terms. The resulting set of forbidden tuples for each term is simply the set of all tuples involving the occurring parameters whose value assignments would violate the equation. The remaining rules define the derivation of forbidden tuples for composed expressions. Rules (7) - (11) are simple rewrite-rules for interpreting implications using the `or` and `not` operators as well as pushing negations further down the tree (ending in the negation of a term which is simple to handle according to the first four base rules). This leaves us just with the additional need to handle `or` (5) and `and` (6) operators on the semantic level.

$$\begin{aligned}
derive(p = v) &= \{(p = v') \mid v' \in values(p) \setminus \{v\}\} && (1)\\
derive(p \neq v) &= \{(p = v)\} && (2)\\
derive(p = q) &= \{p = v, q = w) \mid (v, w) \in values(p) \times values(q), v \neq w\} && (3)\\
derive(p \neq q) &= \{p = v, q = w) \mid (v, w) \in values(p) \times values(q), v = w\} && (4)\\
derive(e_1 \,||\, e_2) &= tuple\_product(derive(e_1), derive(e_2)) && (5)\\
derive(e_1 \,\&\&\, e_2) &= derive(e_1) \cup derive(e_2) && (6)\\
derive(e_1 \Rightarrow e_2) &= derive(!e_1 \,||\, e_2) && (7)\\
derive(!!e) &= derive(e) && (8)\\
derive(!(e_1 \,\&\&\, e_2)) &= derive(!e_1 \,||\, !e_2) && (9)\\
derive(!(e_1 \,||\, e_2)) &= derive(!e_1 \,\&\&\, !e_2) && (10)\\
& && (11)
\end{aligned}$$

Fig. 7. Rules for initial tuple derivation

a) and: The formula $e_1 \,\&\&\, e_2$ is not valid if any of the subexpressions e_1 or e_2 are not valid. Thus, any forbidden tuple derived from e_1 and e_2 will be a forbidden tuple for the whole expression and we can just compute the union of the two.

b) or: The formula $e_1 \,||\, e_2$ is not valid if both of the subexpressions evaluate to false. To this end, we must compute the product (`tuple_product`) obtained by joining each tuple from $derive(e_1)$ with all other tuples from $derive(e_2)$ since each tuple derived this way will falsify the entire expression. Note that some tuples can be inconsistent, i.e. contain the same parameter more than once for different value assignments. Such tuples can be discarded since they would not violate the constraint.

2) Minimal Forbidden Tuples Computation: The initial forbidden tuples derived in the previous step are then used to compute the set of minimal forbidden tuples. They are minimal in the sense that removing any parameter value assignment from the tuple will make it valid. This is an important property for test set generation since this means that any test which does not contain a forbidden tuple can be extended without violating any constraint. For more details about the procedure to compute the set of minimal forbidden tuples we refer the reader to [14].

D. Compatibility and Export

CAgen provides a large potential to be used with other combinatorial testing tools by providing different means of exporting both IPMs and generated arrays. IPMs can be exported into formats interpretable by ACTS, CITLAB, PICT and fipo-cli. Arrays can be exported as a comma-separated file (csv) or can directly be exported to Matlab or Python by copying the array into a data structure for the desired target into the users clipboard.

E. Comparison with other GUI tools

Last, we want to compare the feature set provided by the Web-GUI of CAgen with the GUI version of the ACTS tool as well as the service CTWedge. The features of the three test generation tools are summarized in Table I.

a) Features: All three tools support the generation of combinatorial test sets with constraints and provide a way to edit the input parameter models, although CTWedge only provides this in form of a text editor. While the CLI version of ACTS also supports higher strengths, the GUI version is limited to a maximum interaction strength of 6. CAgen supports generation of arrays with strength 8 in both the Web-GUI and the CLI version. As CTWedge is a wrapper around the tools ACTS and CASA, its maximum strength is only limited by the selected tool. Both CAgen and ACTS allow for export of the results and input parameter models into various formats, while CTWedge only supports array exports as .csv files with various seperators. Lastly, only ACTS supports mixed-strength covering arrays and the extension of existing test sets to combinatorial ones, while only CAgen can generate arrays of higher-index and allows you to freely switch between the array with parameter values and the mathematical object underlying it.

b) Distribution: The largest difference between the three tools is the way in which they are distributed. ACTS is, at the time of writing, only available as a pre-compiled Java binary (.jar file) upon request, while both CTWedge and CAgen are accessible via the browser. However, while CTWedge performs the calculations on the server side, CAgen works entirely on the client side using WebAssembly.

c) Privacy: Software testing, by nature, can expose internal details of the system under test and so it might be necessary to keep all testing activity and the produced artifacts in-house. In the case of combinatorial testing, the model might reveal trade-secrets or expose the SUT in other ways so that the chosen testing tool should not share these details with third parties. Both ACTS and CAgen run locally and perform their computations on the users machine. Due to the architecture of CTWedge, the IPM is sent to the server before a test set is returned and thus no such privacy guarantee can be made.

TABLE II
RESULTS FOR AN TEST SET WITH CONSTRAINTS.

V. PERFORMANCE BENCHMARKS

To evaluate the performance of the IPOG algorithm implementation of CAgen, we compare its CLI version against the implementation of the same algorithm in the CLI version of ACTS, as well as with Microsoft's pairwise testing tool PICT. For each considered instance, we report the run time as well as the size of the generated arrays. Note that, while ACTS and CAgen use the same algorithm, the size of the resulting arrays varies slightly due the tie breaker selection. For an in-depth analysis of tiebreakers for algorithms of the IPO family, we refer the interested reader to [17]. For CAgen and PICT, the Linux time command was used for measuring the run times, while for ACTS we used the run time reported by the tool, as the overhead produced by java would not allow an accurate algorithmic comparison for smaller instances. All experiments were conducted on a server equipped with 64 GB of RAM and an Intel Xeon E3 processor.

First, we tested the generation of uniform CAs with 10 columns, strengths $t = 2$ to $t = 4$ and values arising from an alphabet with cardinality between 10 and 100. The results of our experiments are depicted in Table III. For strength two, CAgen seems to achieve a consistent speedup between 20 and 30 compared to ACTS, while producing slightly smaller arrays on average. For higher strengths, we can notice the run time difference increase with higher alphabets, with CAgen generating the desired CAs more than 100 times faster for high alphabets. The algorithm underlying PICT seems to scale even worse with bigger instance sizes, which made it impossible to generate arrays for many of the tested instances within reasonable time.

Afterwards we generated test sets for models from real world applications, also used in [18] and [19] , shown in Table IV. Once again, all instances report a significant speed up compared to ACTS, while generally generating slightly smaller arrays. PICT seems to be competitive in terms of speed for smaller $t = 2$ instances, but once the strength is increased, it becomes too slow for practical use.

Lastly, we tested a model for exploiting web application security vulnerabilities (XSS) that contains various constraints. The model and it's application is explained in detail in [20] and the results are depicted in Table II. For smaller strengths, CAgen still finishes significantly faster than ACTS, while for high strengths, ACTS manages to generate CAs slightly faster, suggesting that our constraint implementation still leaves room for improvement.

VI. CONCLUSION AND FUTURE WORK

In this work we presented CAgen, a tool for generating combinatorial test sets. It comes as a Web-GUI or a command line interface and contains various features necessary for combinatorial testing, such as support for higher strengths, constraints and covering arrays of higher-index. Our benchmarks show that CAgen can construct covering arrays significantly faster than other state-of-the-art tools such as ACTS or PICT, without compromise in the number of test cases needed. In the future, we want to increase the number of features CAgen supports even further, by enabling an option to extend existing test sets to combinatorial ones. Furthermore, in [21], better support for negative testing was suggested, which can be done to some degree manually, using constraints, but is still something we want to include in future releases of the tool. Lastly, in addition to the currently provided efficient greedy algorithms, we want to extend CAgen by adding support for various metaheuristic approaches [22] and hybrid heuristics [23] as well as algorithms based on learning methods [24]. Thus, we envision that in the future CAgen will become an all-around framework useful to developers as well as researchers.

ABSTRACT

The ASME 2020 Manufacturing Science and Engineering Conference (MSEC) is the 15th annual meeting organized by the Manufacturing Engineering Division (MED) of ASME. MED and ASME MSEC focuses on manufacturing sciences, technology, and applications, including machining, materials processing, sensing, robotics, manufacturing system dynamics, and production optimization. As the conference has grown and evolved from its inception, it can be difficult to intuitively visualize and discuss the broad range of research topics covered by the MSEC community or to intuitively ascertain their evolution throughout time. This paper discusses a methodology to quantitatively model research communities within bodies of literature—specifically, the relative change of relevant topics within AMSE MSEC conference papers through time, from 2006 through 2018. The goal of this work is to not only present how research in MSEC has shifted over time, but in a broader sense to provide a discussion on how others can interpret results so that similar analysis can be produced within other research communities. This methodology can be used to identify overlap of communities, monitor growth or stagnation within the communities, to aid in developing new symposiums and communities of interest, or even to dictate future standards needs by looking at research trends and subsequent standard development.

1 INTRODUCTION

In 2020, the Manufacturing Engineering Division (MED) in ASME (The American Society of Mechanical Engineers) will observe its 100 year anniversary [1]. MED focuses on “the knowledge base of manufacturing sciences and technology and its applications for improved production performance that is economically viable and meets industrial health, safety, and resource conservation legislation” [2]. In conjunction with its 100 year anniversary, MED will hold the 15th annual Manufacturing Science and Engineering Conference (MSEC) in Cinncinati, OH. Traditionally, MED and MSEC have covered a wide array of manufacturing topics, including: machine tools, materials processing, sensors and controllers, computer integrated manufacturing and robotics, manufacturing systems management and optimization, and emerging areas of manufacturing engineering [2].

As published research in manufacturing evolves, a method is needed to quantitatively evaluate the research topics within communities and interpret their evolution over time. This paper uses established statistical modeling and natural language processing (NLP) techniques, such as topic modeling and document cluster tracking, with papers from ASME MSEC on 1) the topics of discussion within ASME MSEC, and 2) how related research efforts have evolved over time within those topics. The goal of this paper is to not only discuss interesting trends in ASME MSEC, but more importantly to provide a detailed process for obtaining and interpreting these results. The larger goal is to ensure that the developed procedure can be replicated for other research collec-

Sexton, Thurston; Brundage, Michael; Dima, Alden A.; Sharp, Michael. ”MSEC: A Quantitative Retrospective.” Paper presented at MSEC: Manufacturing Science and Engineering Conference, Cincinnati, OH, US. June 22, 2020 - June 26, 2020.

tions, providing needed insights for other communities and domains. This quantitative method for evaluating and interpreting the evolution of research communities and their primary topics of interest can be used to identify success stories in areas of rapid growth or movement, new and developing thrusts that may be worthy of additional attention, stagnant topics in need of revitalization, as well as predicting future needs and next steps. Information gained through these types of analysis within a specific domain could even be used to help describe future conference tracks or symposiums, highlight standards needs, and provide justification for potential future research funding areas.

The rest of the paper is structured as follows. Section 2 discusses background on topic modeling, document cluster tracking, and other literature discussing research paper trends. Section 3 illustrates the methodology used to create the topics and document shift results. Lastly, conclusions and future work are presented in Section 4.

2 PROBLEM CONTEXT

With the rapidly expanding volume of available documents in a given research area, it is nearly impossible for a single person to manually survey and synthesize a full community of research. Evolution of language usage as well as changes in interest and focus through time can make identifying and evaluating groups of common research difficult. This paper presents a method to quantitatively assess and follow groups of semantically similar documents to create a timeline of research thrusts that identifies progressive changes in interest, and the relative interplay between thrust areas. Additionally, results are presented to gain a more global view of the intrinsic topic areas that arise through time and how different ideas will come in and out of vogue across the corpus of documents.

2.1 Data Acquisition

The quality of any analysis is directly related to the quality of the data used in the analysis, in this case the presented data relates a sampling of the available MSEC documents from 2006 to 2018. Information contained in the ASME Digital Collection web pages was used to identify and download MSEC conference papers as individual PDF files using the workflow created by the authors, shown in Fig.1. This step produced the data set used in our analysis by extracting and processing their text from the pdfs. However, due to a lack of a standardized storage and access format, the number of papers available for this research between 2006 and 2012 is significantly lower that the full number of papers identified by citation, as shown in Fig. 2. The work presented in Section 3 still includes these years for completeness and for demonstration of the method, but any conclusions drawn from this region must be regarded as highly uncertain due to the low number of full text papers that could be obtained for this work.

The top-level conference-related pages list conference papers by track and symposium. Starting from a list of manually collected top-level URLs, the data gathering workflow used a combination of common Unix command-line tools and established Python libraries to download the top-level conference papers (Fig. 1: Web Page Downloader). The downloaded pages were processed to extract the article metadata directly from the page HTML (Fig. 1: Metadata Extraction) including: the conference name, the PDF URL, and the article ID, DOI, Date, and URL. Each article's track and symposium was then extracted from the structural information of the conference proceedings webpage (Fig. 1: Track & Symposium Extraction). Using the extracted data, we identified a total of 2267 articles and were able to download 1457 MSEC-related PDFs from the ASME Digital Collection (see Fig. 2 and Fig. 1: PDF Downloader). We extracted their text, including titles, table and figure captions, and metadata, via the pdftotext command-line tool (Fig. 1: Text Extraction).

Though there are software tools that can be used to automate portions of the data acquisition, the general form of the task of obtaining and collating a collection of documents will still require human supervision and intervention at each stage. Various factors like the form and location of the publications, possibly Web site structure, document layout, and file naming conventions all affect the ability to automate the discovery and extraction of articles. There is also strong possibilities of desirable tacit information being encoded that is incredibly difficult for an automated algorithm to address without special considerations being made.

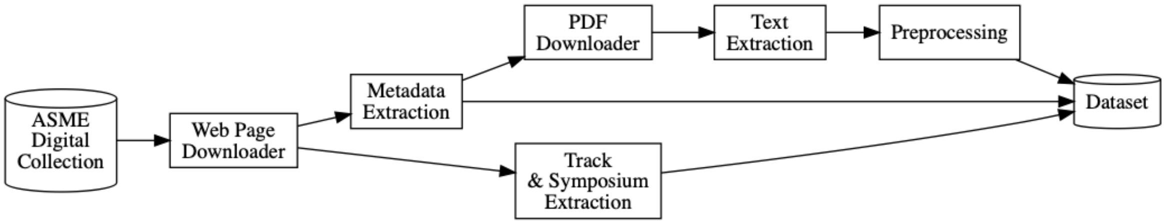

FIGURE 1. *Workflow used to acquire and process ASME MSEC articles.*

During our study, important information about the relationship between articles and symposia were encoded structurally in the Web pages and required human inspection and analysis to write the custom code for its extraction. Though each instance of acquiring data to process will have unique eccentricities, the most important aspects of collection for our pipeline are to ensure that each document with computer interpretable text is accessible, and their associated publication date are linked to them. Any additional meta data about locations, tracts, authorship, etc. can be useful for additional analyses, or may facilitate the data acquisition, but are not critically needed for the described analysis.

2.2 Data Preparation

Even in digital form, text is not amenable to direct analysis, especially by mathematical techniques based on linear algebra, which are typical of many NLP algorithms. Preprocessing is necessary to convert the text into a more suitable representation. We will discuss text preprocessing in the following two sections. Section 2.2.1 will give an overview of the different facets of text preprocessing. Section 2.2.2 will describe how we prepared our text for the analyses described in Section 3.

2.2.1 Overview of Text Preprocessing

Text is often preprocessed before analysis, with one goal being to simplify the data for analysis without losing necessary information [3]. This simplification can be thought of as sharpening the desired "signal" while reducing "noise". Another simultaneous goal is to structure the data in a manner that facilitates the analysis [4]. This restructuring is often designed to emphasize certain features that are important to the analysis and algorithms at the expense of others that may be less important. Examples of typical preprocessing beneficial to these types of analysis include:

Extraneous Metadata Removal: The removal of unwanted template text [5] that add "noise" to analyses. For example, each page contained text such as:

> Downloaded from https://asmedigitalcollection.asme.org
> /MSEC/proceedings-pdf/MSEC2008/48517/1/2715771
> /1_1.pdf by NIST user on 18 September 2019

This unwanted text can be identified for removal using technologies such as regular expressions, a mathematical language for describing text patterns used by text processing software to identify specific text [6].

Stop Word Removal: The elimination of many common words such as *this, that,* and *the* that convey little semantic meaning to an analysis [7]. Preassembled *Stop Lists* can be used to identify and remove them from text prior to analysis [7, 8].

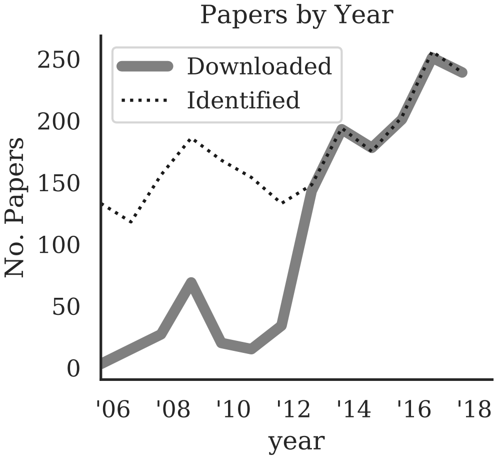

FIGURE 2. *Papers identified and downloaded from the ASME Digital Collection by year using our workflow*

Lemmatization: The reduction of inflected words via linguistic techniques into their dictionary forms [9], for example:

$$\{\text{boat, boats, boat's, boats'}\} \Rightarrow \text{boat} \tag{1}$$

By mapping all of the variants of a word into its base form, lemmatization can be seen as a way to increase the "signal" associated with that word.

Cleaning: The removal of characters and tokens, such as punctuation, numbers, and email addresses as well as low-frequency words, from the text to reduce noise features in the data that can negatively impact analysis [3, 9]

Tokenization: The process of separating text into its smallest meaningful units such as words and numbers [4, 7]. Because it identifies individual words, tokenization is a fundamental process that serves other downstream preprocessing and analysis tasks.

Sentence Segmentation: The identification of sentence boundaries in a text [4, 8]. Sentence segmentation plays a key role in supporting lemmatization by providing the input for the linguistic analyses required for lemmatization.

Bag of Words (BOW): A method for representing the contents of documents by identifying their words and counts without any ordering information [9]. For example:

$$\text{“Jack has a blue hat and Jill has a red hat”} \Rightarrow \{(\text{“Jack”},1),(\text{“Jill”},1),(\text{“a”},2),(\text{“and”},1), (\text{“blue”},1),(\text{“has”},2),(\text{“hat”},2),(\text{“red”},1)\} \quad (2)$$

Vectorization: In the presence of a dictionary to assign unique integers to each word, BOW can also be represented as vectors. For example, assuming that the previously used sentence was the first sentence in a text collection then the dictionary would contain the following information:

$$\text{dict} = \{(0,\text{“Jack”}),(1,\text{“has”}),(2,\text{“a”}),(3,\text{“blue”}), (4,\text{“hat”}),(5,\text{“and”}),(6,\text{“Jill”}),(7,\text{“red”})\} \quad (3)$$

The integers serve as word ids and as subscripts to the vector representations for the BOW. The first example now becomes:

$$\text{“Jack has a blue hat and Jill has a red hat”} \Rightarrow (1,2,2,1,2,1,1,1,0,\ldots) \quad (4)$$

where $0,\ldots$ represents positions associated with other words in the text collection not found in the first sentence. In practice, these vectors are sparse; for a typical text collection, zeros account for about 98% of the vector elements [10].

Considerations Text preprocessing is a form of analysis on its own, where typically the actual analysis is hidden from the user and performed in preexisting libraries and frameworks. For example, lemmatization requires the identification of the parts of speech that also depend on the identification of individual sentences. These operations are implemented by the NLP framework (Section 2.2.2) and involve commonly available statistical and neural-network language models whose full descriptions are outside the scope of this paper. However, interested readers can refer to books such as Krohn et al [11] and Rao and McMahon [12] and articles such as those by Young et al [13] and Akbik et al [14]. The ultimate text analysis performed thus rests upon the these hidden analyses.

While it is convenient to visualize text preprocessing as a pipeline in which raw text flows in and is replaced with refined text for analysis, it is better to initially consider it as a series of stages in an converging iterative process. Ideally, the entire output of each stage should be available for inspection and analysis; “sanity checks” are crucial. The pipeline perspective makes the most sense at the end when all of the issues discovered during development have been resolved.

2.2.2 Text Preprocessing Used

Our final data set contained the following preprocessing steps. First, filenames were standardized to contain both the year and a unique paper ID for easy of storage, indexing, and retrieval. We then filtered the extracted text from each document using Python’s regular expression library to remove headers and extraneous metadata that can negatively impact the subsequent text analysis. For example, each PDF file contained text identifying its source URL, the account that downloaded it, and the date and time that it was downloaded; none of which is relavant to the subject of the document. The text was then segmented into individual sentences and tokenized words. *Stop words* were discarded and the remaining tokens were lemmatized using established procedures found in `spaCy`[1]. Special word/number occurrences were replaced with unique text-only aliases prior to the removal numeric entities. For example:“1D”, “2D”, and “3D” were replaced with “oned”, “twod”, and “threed”, respectively. The text was then scrubbed using the `clean-text` library[2] to reduce it to lower case and to remove URLs, email addresses, phone numbers, currency symbols, punctuation, and numbers. At the end of this phase of data preparation, each downloaded PDF document had a corresponding text file that contained a single processed sentence per line.

We then used gensim[3] to build a look up table style dictionary that relates individual tokens to a unique numerical identifier and converted each text file into a BOW represented by gensim’s sparse vector format [15]. These processes have allowed the data to now be ingested and analyzed by modern mathematical analysis techniques.

The presence of semantically interesting non-word tokens (such as “3D” and its replacement with “threed”) highlights that text preprocessing is transformative in nature. While it may be intuitive that some text should be removed as being not relevant, it may be less obvious that text analysis relies on the translation of the original text, for example the use of lemmatization, substitutions, and bags of words. Text preprocessing should not be seen as the rote application of recipes to the original text. Instead analysts must inspect the intermediate results while considering their ultimate goals. For a discussion of how preprocessing can alter analysis, see Denny and Spirling [3].

3 ANALYSIS WORKFLOW & RESULTS

To streamline analysis and interpretation of collections of research documents, this paper presents a workflow for deriving useful insights from raw text, not only from the collections gathered at MSEC, but in other domains as well. Many options exist for the mechanical implementation of each of the steps in the process, but the choice of specific algorithms or combinations of algorithms has the potential to greatly influence the quality and

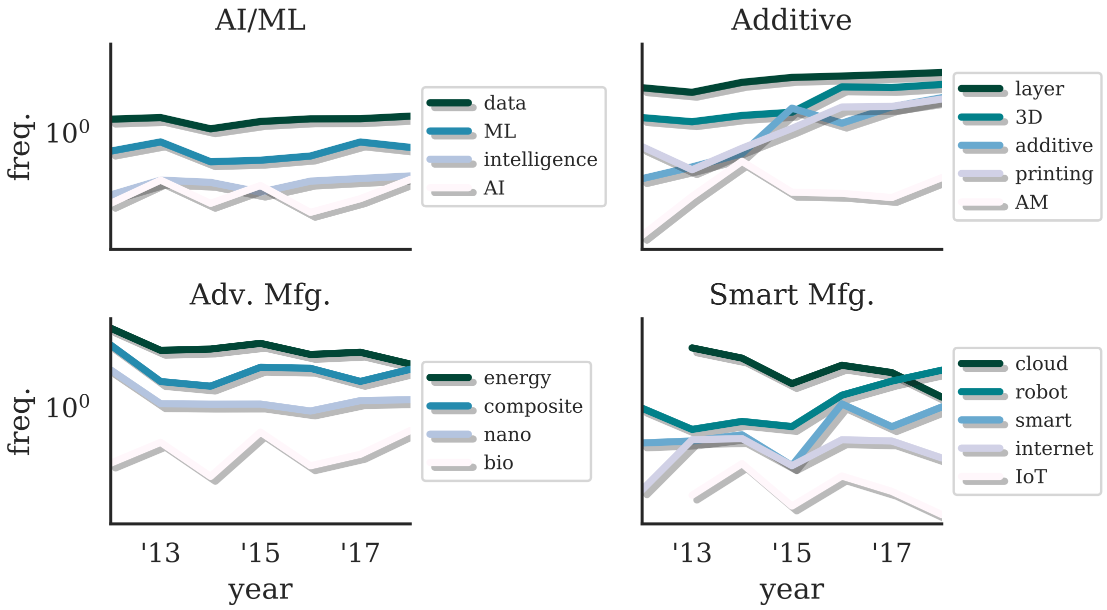

FIGURE 3. Keyword occurrences per document (log-scale) over time, for documents submitted after 2012. Each figure shows the top most-frequent terms occurring within the author-determined research areas. Darker color represents higher all-time occurrence.

outcome of the end analysis. This section discusses the benefits and difficulties of choices made at each step of the process to develop a guideline and philosophical approach for readers wishing to apply the procedure to better understand their own domain.

3.1 Keyword Trends

One *direct* way to access trends in a domain over time is to observe how keyword usage evolves within the documents that make up the domain. Given a frame of reference, such as a defined area of interest (*e.g.* , guiding documents from steering committees) we can categorize keywords by their relevant topic and observe the relative frequency of these keywords within.

For example, ASME defined several key research areas[4] that may define the coming decade in engineering research. Several of these are highly relevant to manufacturing specifically. By selecting keywords typically associated with each area, whether from anecdotal experience or expertise, we can observe high-level trends in the focus each area has over time.

Figure 3 illustrates an example selection of these key research areas identified from ASME with several terms the authors deem as relevant to those areas. Each term is reported for the years in which a significant fraction of total papers were recovered to avoid bias. Importance is compared through total expected occurrences *per paper*.

Note that this analysis only shows general trends over time– whether a word is used more or less frequently at a global scale. In *AI/ML* we see a slight increase in “data” over time with “Machine Learning” displaying an earlier surge than “Artificial Intelligence”, which surged recently after a slight down-turn in use in 2015-2016. *Additive* sees a steady increase across all major keywords, likely due to an overall increase of total interest (paper submissions) in the topic. Although a fairly broad topic scope, *Advanced Manufacturing* is seeing continued research in nano-scale and composites fabrication. A long-term decline in “energy” interest is being met with a rise in “bio-manufacturing” interest. Finally, *Smart Manufacturing* is showing a marked increase in “robot” use, while words like “Internet of Things” and “cloud” seem to be declining from a peak near 2014.

While this may present an excellent first-look into the trends within a community-of-interest, the actual “dynamics” here can be difficult to parse. Despite the apparent correlation between certain keywords, the same could be said about terms across topics. This is problematic if one wishes to make quantitative generalizations about topics overall, or even how well individual terms reflect the state of a topic. Do these “areas of interest” constitute an efficient snapshot of the community as a whole, and the trends hidden within?

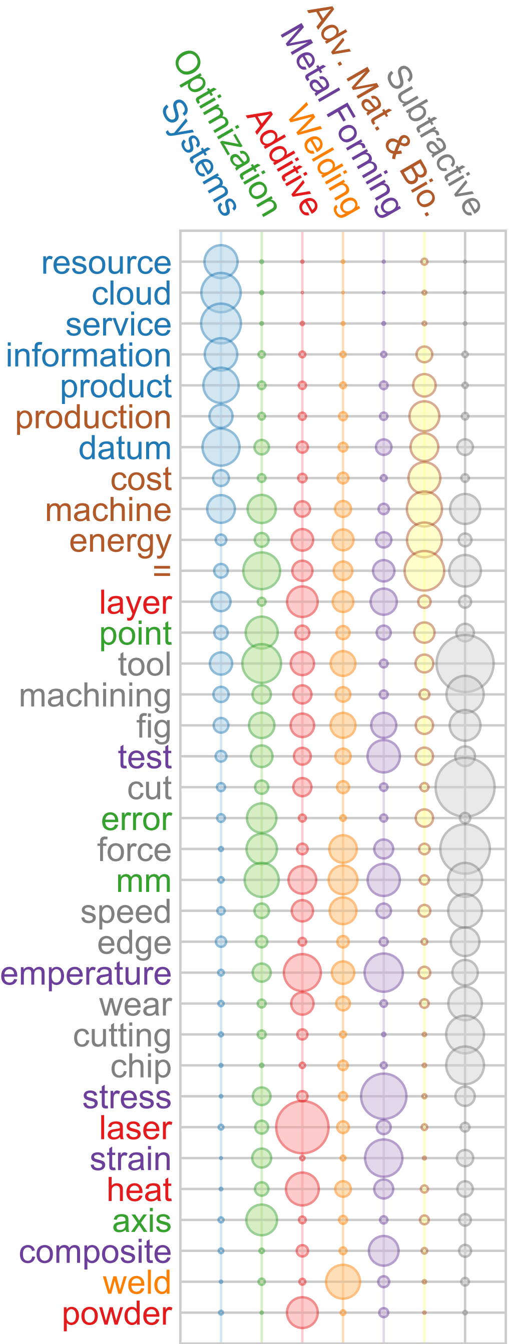

FIGURE 4. Term probabilities within each of 7 topics, as named by the authors. Showing top 35 terms having the highest probability in any topic. Rows are sorted to group terms occurring within similar contexts together. [16, 17] For instance, the top rows are all tightly related to the "Systems" topic, though they are increasingly linked to the "Advanced Materials and Bio-manufacturing" topic.

3.2 Topic Model

One mechanism to answer questions such as "what topics are contained within my documents," or, "what terms are most associated with a topic" is to infer patterns from the computational distribution of the documents. Doing this without directly labeling or classifying the documents beforehand constitutes *unsupervised learning* and is called topic modeling.

Topic modeling is a group of unsupervised natural language processing methods that can identify topics in large text collections [18, 19]. These topics are weighted sets of words that imply the overall semantics of the collection and its documents. The words weights in a topic tend to represent important concepts for that topic. The overall set of topics computed for a collection of documents can serve as an interpretable decomposition that summarizes its overall content.

Latent Dirichlet Analysis (LDA) is a topic modeling approach that uses a Bag of Words representation of each document (Section 2.2.1) to infer topics from a corpus. Being a generative technique, it assumes that documents are generated from two distributions: a per-document topic distribution that assigns topic weights to documents and a per-topic word distribution that assigns word weights to topics [15]. The goal of LDA then is to recover these distributions from the data in the form of the most likely allocation of term probabilities into discrete distributions of terms, called *topics*. So, if we observe terms as collections of words within documents, using an LDA model directly assumes that each observed document is generated from some set of topics each of which have a likelihood of "emitting" any of the terms in our corpus. Estimating those probabilities and the topic mixtures that make up each document involves training on a Bag of Words representation of each document in the entire corpus simultaneously. Note that the number of topics is an important parameter that must be passed before training has begun. It determines the number of possible "types of things" any given paper can draw upon, but allows the algorithm to determine an optimal distribution of term probabilities among them.

While it is theoretically possible to determine an "optimal" number of topics given a measure of topic quality such as coherence [20], in practice this parameter should be selected carefully to aid in communication and decision making. In the case of this analysis, AMSE MSEC accepts approximately seven submission tracks per year. Perhaps as a result of this, seven topics corresponding to a seven-dimensional space was found to result in more stable results for later analytics (see below) than all other parameter values tested by the authors ($5 \leq n \leq 15$). Similarly, as LDA merely defines n distributions over terms, it is necessary for *the analyst* to interpret each distribution of terms, estimating whatever latent groupings are being detected – i.e., to *name* the topics. This is a highly subjective process, even commonly called *"reading tea leaves"* in natural language processing [21]. Naming each topic, therefore, should constitute an iterative process of design, preferably among multiple stakeholders that carefully balances interpretations with defensible data-driven justifications.

Figure 4 illustrates how a topic model allocates term probabilities from the conference to each of seven latent topics. This is trained across the entirety of the corpus (all the papers from Fig. 2). In this plot, called a "termite" visualization[5] [16], rows correspond to terms and columns to topics that have been named through an iterative process by the authors. The probability that a term is generated by a topic corresponds to the size of each circle. Rows have been sorted by the method of *spectral seriation*, such that similar rows are grouped together as much as possible. [17]

This analysis provides some interesting insights into the topics of discussion at ASME MSEC. For example, the majority of submissions to MSEC have been historically related to manufacturing *process* research. This trend can be seen in the four topics: 1) *Subtractive*, 2) *Metal Forming*, 3) *Welding*, and more recently 4) *Additive Manufacturing*. Manufacturing Systems research is also a relevant topic as shown in the *Systems* topic. The *Advanced Materials and Bio-Manufacturing* topic captures another topic of research that has recently become prevalent at the conference. Lastly, the *Optimization* topic is often cross cutting, as deals with research relevant in each of the other topics as well. This type of trend can be seen in Fig. 4 as the *Optimization* terms of importance also appear in other topics (e.g., tool is more prevalent in *Subtractive*, despite being a core term in *Optimization*).

Figure 4 provides some other interesting results allowing experts to see terms relevant across multiple topics versus terms relevant only in one topic. For example, "cloud" is highly prevalent in *Systems*, but no where else, while "=" and "mm" are cross cutting in all topics except *Systems*[6]. Terms such as "cut" or "cutting" or "chip" are most important in *Subtractive*, while "temperature" is important to both *Additive* and *Metal Forming*. While these types of insights might seem obvious to some experts, this analysis and subsequent visualization provides a quantitative look at the conference and can be used to confirm or reject inferred perspectives to further more informed discussions. It provides a quick overview of the entire conference and the topics and related terms of discussion.

Although Figure 4 only tells a *static* story, we would also like to quantify the dynamic importance of terms, similar to what was done in our keyword frequency analysis (Fig. 3) while incorporating knowledge found within a topic modeling framework. For example, "cloud" was not discussed in retrieved documents prior to 2013, as shown in Fig. 3, and yet is a major term within the *Systems* topic. Surely that topic of interest had related terms that organized around the same themes prior to the introduction of cloud computing. As such, it would be helpful to see the evolution of each *topic* over time.

3.3 Topic Term Evolution

The naïve approach to temporal topic modelling would be to partition a corpus by date before creating separate LDA models for each piece and analyzing them each individually. Unfortunately, this drastically reduces the amount of data available to train each LDA instance. In addition, the process of "reading tea leaves" implies a complete lack of consistency from year-to-year as to which topics correspond to which preceding or following year's topics, let alone global-level topics as in Fig. 4.

Instead of creating topic models for each individual year, we can instead directly model the term evolution in each topic over time. This is called Dynamic Topic Modeling, as proposed by Blei et al.[7] [22]. Analyzing terms in each topic provides the necessary context that is missing in the analysis for Fig. 3, while enabling analytics and decisions based on trends over time — a dimension missing from Fig. 4. This topic term evolution analysis can help discover the most important terms in each topic *as they age*: how they ebb and flow over time.

As opposed to the general term trend analysis in Fig. 3, Figure 5 gives insights into term usage of importance within each topic individually. For instance, an expert can identify the trends from individual terms within a topic to better discover research trends. In the topic referred to as *Advanced Materials & Biomanufacturing*, a large overarching trend in consistent use of the word "energy" in the years 2011-2016 likely reflects strong incentive in the community to investigate energy consumption and sustainability. As of 2018, the topic is now dominated by composites and fiberous materials. This indicates what would otherwise be hidden dynamics between the two, having been aligned with the same topic.

Similarly, term coupling can provide useful insights. Using "cloud" as a continuing example, the same peak occurs in 2013 as in Fig. 3, but now it is possible to analyze the other important terms that are tightly coupled within that same topic, i.e., namely, "service" and "resource". These appear to rise and fall together. However, other terms are becoming more indicative of this topic in the past few years, with "datum" and "robot" growing significantly of late.

Finally, identifying how terms are distributed across topics over time can, for example, indicate the context where a technology is most "in vogue" at a given time. "Laser" is a key defining term in the *Additive* topic until 2014-15 where laser-based *Welding* appears to be not only important but dominant in that topic. Instead, keywords like "3D printing" are more indicative of *Additive* research with lasers serving as an enabling technology,

[5] Seriation as suggested by Chuang [16] achieved via spectral method proposed by Fogel [17], as implemented in the package `Textacy` (`https://github.com/chartbeat-labs/textacy`).

[6] The term "=" was left in the analysis to provide an approximation of the importance of equations in papers, while "mm" remains to illustrate the importance of dimensions/measurements.

[7] This is accomplished by assuming that the topic distributions for documents are sampled directly from the parameters of corresponding topic distributions in the previous time slice, thus achieving smooth, contiguous topic evolution.

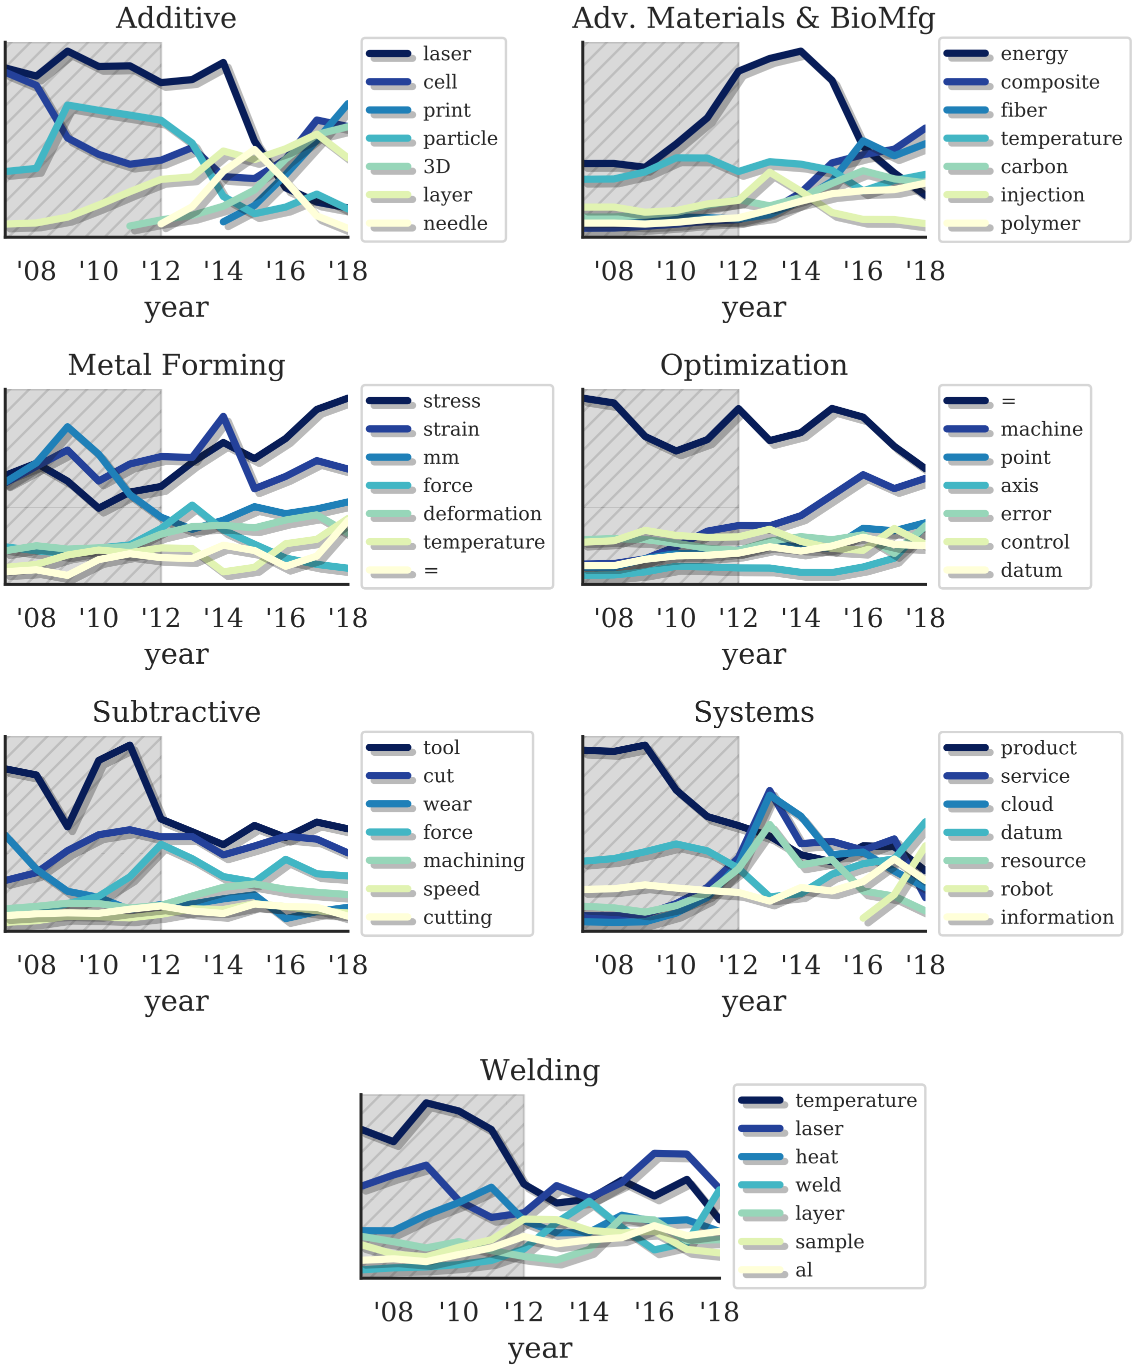

FIGURE 5. Dynamic term *importance*, i.e., relative term probabilities within dynamic topics, normalized by total topic occurrence in each year. Darker color means higher peak importance since 2012. Shaded region indicates years 2012 and before, for which downloaded document collection was incomplete.

Sexton, Thurston; Brundage, Michael; Dima, Alden A.; Sharp, Michael. "MSEC: A Quantitative Retrospective." Paper presented at MSEC: Manufacturing Science and Engineering Conference, Cincinnati, OH, US. June 22, 2020 - June 26, 2020.

These patterns let us quantify the degree to which specific topics of interest shift from one key idea to the next while maintaining an underlying connection and a more consistent relationship with the rest of the topics as a whole.

While this analysis provides a glimpse at how relevant research areas evolve over time, it is important to note that it says very little about how groups of individuals and/or papers *coalesce* around these areas through time. “Cloud” may be falling out-of-vogue within the topic overall, but ostensibly the community of researchers contributing to that body of work moved on to other relevant terms. Although terms like “robot” and “datum” are growing within their respective topic (*Systems*), this does not tell us whether they arising from the same community of interest; what are the original “cloud” researchers presenting on now? The next subsection presents a method to utilize topic modeling in conjunction with particle swarm tracking, to find and track clusters of actual documents–as opposed to topic mixtures – as they occur and migrate within the space of topics. This analysis has potential to provide a glimpse into the mixture of topics that individual communities of researchers are discussing, and how this mixture evolves over time.

3.4 Document Cluster Evolution

The idea of particle swarm tracking is not a novel one. The basic concept is to define the center of a group of similar entities (or entities that share a local region of some data space) as a swarm and track its movement through time. The number of particles that make up a group may shift over time, but so long as the local region defined by the swarm maintains a defined region and sensible movement criteria, then this local cluster can be monitored as a single entity.

As applied to this work, once a vector representation of a series of documents—i.e., conference papers—has been made, those documents can be thought to exist together somewhere in this semantic space. Using these locations, collections of proximity- or density-based clusters can be established that each contain a minimum number of documents. Labeling this group of documents as a single entity with volume and location, any number of particle tracking algorithms may then be applied to derive relative movement and interactivity of naturally occurring research efforts within the semantic document space.

In this work, a hierarchical density-based cluster approach was chosen to create the research document group instances. The specific tool used in this work is HDBSCAN from Rahman et al. [23]. This tool allowed for natural development of differing numbers of document groups, intuitively leading to new research thrust arrivals or merging or splitting of existing thrusts through time. Other clustering methods such as k-means, which specify a required number of clusters, makes such dynamic generation of topics less intuitive and forces prior assumptions upon the data.

The final step in the document group tracking is to connect the document groups to corresponding groups through time, thus making temporal traces of research thrusts. While there are many methods to accomplish this connection, for simplicity the intuitive method of requiring significant overlap across time of the document groups was selected. This method required the minimum number of assumptions and allowed for the method to be generalized to any selected characterization of the document-group space. In this work, the groups were represented as Gaussian-based N-dimensional fuzzy hyper-cubes. This allowed for rapid calculation of overlap in infinite space. With this, groups of different years can be checked for sufficient enough overlap between them to justify inclusion as a temporal trace. Although overlap was chosen as the connectivity metric here, any metric which captures significant semantic commonality between the clusters can be used to connect a cohesive trace through time.

Building each trace was performed as a single directional pass starting at 2018 and creating or extending traces one year at a time towards the beginning of the document. This single backwards stepping approach ensures that each termination point is unique for every particle trace. At each step backwards through time, the earliest point of each existing trace checks for the the document group with the most overlap (if any exist) to add as the new earliest entry. After all traces have claimed groups, any unclaimed particles are then defined as the terminal point of a new trace. Note that a single document group could be claimed by multiple traces as during their initial creation (while moving backwards in time). Subsequently, this will be shown as a split in research thrusts after construction when interpreting them forwards through time. This comparatively simple process of extending traces back through time accounts for expected behaviors of research efforts to die, merge, split, or even jump years if, for example, some new technology revitalizes some dormant research topics from the past.

There are other possibilities for creating particle traces of document clusters that may provide comparable results. The selections for this process were made to minimize the number of a priori assumptions and complex calculations to allow this process to be easily extended to higher-volume processing.

As presented in Figure 6, a total of ten different research thrusts were discovered and trended as document swarms through time. Labeled generically A through J, Fig. 6 shows that while each of the major topic areas (the colored ribbons) have one research thrust that mostly centered in it over time, there also exist several thrusts that cross cut these seven topics. Also, the focus of some of the long running thrusts seems to shift over time.

Trace A captures the primary research thrust concerning *Advanced Materials and Bio-Manufacturing*. We can see that there is a constant contribution of optimization to this research thrust, which is intuitive given that part of advanced materials research is to optimize some need via the materials or to opti-

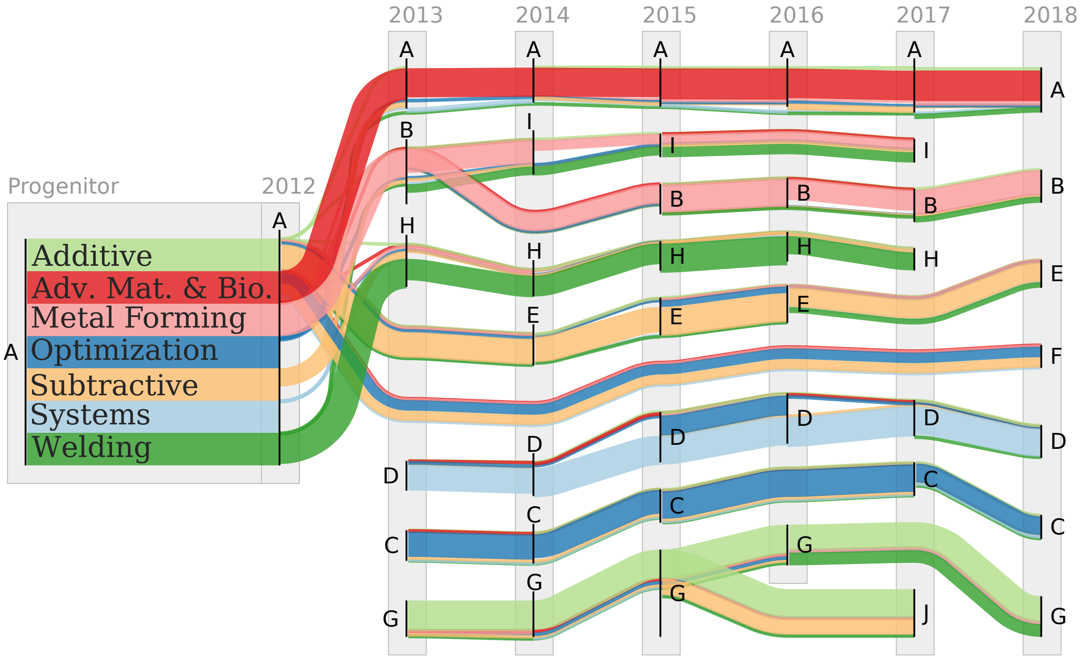

FIGURE 6. Sankey Diagram of document cluster alignment with LDA topics. Color indicates topic, while band thickness indicates proportion of that topic's global occurrence happening solely within each cluster. A trace is a presumed evolution of a persistent cluster. For example, if you look at the *Additive* topic, it is predominately in trace G until 2015 when it splits into a mixture of trace G and trace J. The key difference is the contributions from the *Subtractive* versus the *Welding* topic areas. This can be interpreted by thinking of G as a persistent research thrust that dominates the *Additive* topic until a new area splits apart form it in the form of trace J that focuses more on research related to the *Subtractive* domain while G moves into *Welding*.

mize construction methods for said material. Additionally, there are occasional spikes of interest in types of processing for this topic, namely *Subtractive* and *Welding*, which can relate again to both the use and creation of such materials. This research thrust remains the most focused through time as no other thrust has a major contribution from *Advanced Materials and Bio-Manufacturing* and no other topics contribute strongly to this thrust.

Although not as pure as A, traces B, C, D, E, H, and G each represent the central or dominate research thrust for one of the seven semantic topics. With rare exception, each of these are easy to interpret as analogs to the main topic with only slight leanings towards other topics through time. Notably, there seemed to be a brief, but strong shift towards *Optimization* in the *Systems* dominating research thrust (D) during 2015. This temporary shift may have precipitated from a shift in directives from industry drivers or some new technology hype that ultimately did not remain relevant in this research thrust community.

Some notable splits in related research can also be seen in Figure 6. For example, the divergence of I in 2014 shows that unique interest area revolving specifically around *Metal Forming* and *Welding*. This reflects a growing interest in general production methods as opposed to specific individual methods. Soon after, this area picks up a noticeable contribution from *Advanced Materials and Bio-Manufacturing*, indicating that the growing interest in use of advanced materials.

The research thrust J splits off from the *Additive* dominated thrust G in 2015 by gaining significant contributions from the *Subtractive* topic area. This research thrust would seem to again be a leaning towards more general manufacturing techniques by investigating complementary methods. Even the minor contribution from *Welding* seems to confirm this. Both major splits from the single topic dominated thrusts seems to be a step in interest towards higher-level investigations.

The only thrust area to have significant contributions from multiple topics from inception is F. Relating to mostly to *Sub-*

tractive, *Optimization*, and to a smaller degree *Advanced Materials and Bio-Manufacturing*, this thrust is likely characterizing research on the manufacturing process itself. Interest in optimizing the manufacturing process has understandably been a consistent research area in this community.

Obviously the labels and insights related to each of the thrusts are framed through the lenses of the established semantic topics. Were different numbers of semantic topics chosen, or different methods for creating these topics used, this may have lead to capturing slightly different research-thrust traces over time. With any methods of data collapse and visualization some nuance and specific information will be lost. Even so, the basic trends and results from this analysis can shed interesting insight into both trends and overall focus of research efforts.

Other revealing metrics useful for characterizing the overall research efforts in a set of documents relate to the movement and size of each of the identified document swarms. Looking at relative movement can help to estimate progress and the existence of common driving forces or technologies between efforts. On the other hand, swarm volume or counts of included documents could be used to estimate interest and participation by communities, based on the intuition that more interest will produce more publications within the trace clusters (i.e. swarms). Although omitted for space in this paper, these metrics are simple to calculate and monitor for each identified trace via the process described above.

The major pitfall of this or any particle swarm tracking method is that it must be performed with a number of entities both large enough to successfully group and distributed in such a way to characterize the behavior you wish to capture. Due to the low fraction of retrieved documents prior to 2013, any trends or insights derived are hugely unreliable during those years. As shown in Figure 6, all discovered traces (A through J) derive from a single progenitor. This is strictly due to the low number of retrieved documents for that time frame only being able to produce a single cluster. With access to more of the published documents, it is expected that multiple progenitor or initiating research points would be discovered.

4 CONCLUSIONS & FUTURE WORK

This paper discusses a methodology to determine topic trends and evolution for bodies of research publications, with a specific case study of the AMSE MSEC conference. The paper provides the steps needed to repeat the process and interpret the results in the hopes that others will use this method for quantitatively analyzing new research areas throughout time.

One important takeaway from this paper is the need for multidisciplinary teams when analyzing these results. Merging domain expertise and NLP knowledge while interpreting these topics is key when using this analysis for decision making purposes. Another important takeaway is the necessity of consulting multiple visualizations when analyzing this data; no single metric or visualization can completely describe the complex interplay of research thrusts within a community. At various times while interpreting the results for this paper, the authors simultaneously consulted multiple visualizations to get the “big” picture. For example, by looking at Fig. 3, we noticed that that the term “cloud” started to appear in 2013. We were then able to consult Fig. 4 and further analyzed it place in the topic space. Once we discovered that “cloud” appears predominantly in the *Systems* topic, we could then use Fig. 5 to analyze other important terms from that topic. Finally, Fig. 6, allowed us to analyze the evolution of clusters of papers through time.

A key improvement for this analysis pipeline would be to better facilitate the iterative, collaborative process between research domain experts and the NLP algorithms or analysts (assuming they are not the same). For instance, allowing a mixture between domain expertise-driven topic definitions and latent-topic discovery would improve interpretability and understanding for the domain experts and ensure patterns recovered by the NLP algorithms and analysts are more likely to be useful. Future work should investigate various tools for continual human-NLP collaboration, taking cues from models like Anchored Correlation Explanation [24], which allow users to guide topics toward more human-readable distributions.

An application using the method presented in this paper could be adapted to automatically predict paper placement in symposiums or to help define research sub-communities of interest within a larger community, such as a conference. Other future work could be predicting research effort movement to anticipate future interests and create topics to allow conference planners to better organize current community interests. For example, given the trends in MSEC, optimization topics with advanced materials or additive manufacturing seem to be gaining momentum and may produce a unique research thrust centered in those topics soon. Lastly, this type of analysis could be used to better predict standards needs by studying the lag time between surges in academic publications in a space (e.g., additive manufacturing) and the first mentions and development of standards in the same space. This would allow standards organizations to better adapt to high velocity technical research and start analyzing standards needs more efficiently.

Abstract— **In this paper we describe the application of high-frequency electromagnetic wave (in microwave frequency / radio frequency (RF in the range, i.e., 3 kHz – 300 GHz) based techniques to probe material and structural changes that occur in integrated circuits. These techniques fall under the general area of "Broadband Dielectric Spectroscopy". In this paper, we describe corrosion of the redistribution layer (RDL), required for the implementing 3-D integrated circuits (3D-ICs), during high-temperature storage. As an illustration of our techniques, we use the RF signal loss between ports 1 and 2 on a typical vector network analyzer (i.e., RF insertion loss, S21), to monitor the oxidation of the RDL copper interconnects. We compare the RF signal loss results to the direct current-resistance that was measured simultaneously with the S21. Using electrodynamic simulations, partition the RF signal loss in corroded copper interconnects, and discuss the significance of the roughness at the air-copper oxide interface.**

I. Introduction

Recent advances in technology and materials innovations have shifted the architecture of integrated circuits from two-dimensional planar to three dimensional (3D) systems, for example, as in stacked three-dimensional integrated circuits (3D-ICs). However, the performance demands of these 3D-ICs conflict with the reliability needs of these devices. That is, the 3D-IC devices are expected to operate at higher current densities but have lower voltage tolerances at higher electric fields. Thus, with 3D-ICs, the reliability of the electronic circuitry has shifted from being transistor-dominated to interconnect-dominated. These reliability issues are mostly materials related and include such effects as resistivity change, stress-induced unexplained early failures, corrosion, electromigration, etc. The traditional metrology techniques, such as DC resistance, have been unable to adequately address the measurement needed to characterize in-situ the underlying failure mechanism.

In this paper, we describe how appropriate test structures can be used in conjunction with broadband radio frequency dielectric spectroscopy (BDS)-based metrology to fill some of these metrology gaps. Specifically, we describe how we have used BDS to study the corrosion of the redistribution layer (RDL), required for the implementing 3-D integrated circuits (3D-ICs), during high-temperature storage. The redistribution layer (RDL) allows for circuitry fan-out and allows for lateral communication between the chips [1]. Figure 1 shows the basic elements of 3D-ICs, of which the interposer is arguably the most critical. Here, we use the RF signal loss between ports 1 and 2 on a typical vector network analyzer (i.e., RF insertion loss, S21), to monitor the oxidation of the RDL copper interconnects.

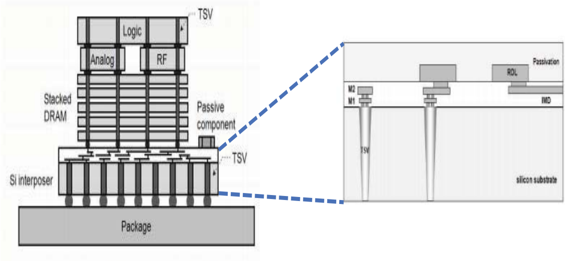

Fig. 1. Essential components of 3D stacked IC using TSV and a silicon interposer. The exploded area shows the elements within the interposer layer, pay attention to the passivation layer encapsulating the RDL (Adapted from [4])

II. Results

In a common implementation of the RDL, polymers are used as passivation and Cu-plating is used to make the metal layer. Unfortunately, in this integration scheme, the polymer passivation limits the thermal budget of the back-end of line process flow. At temperatures above the glass-transition temperature (T_{gt}) of the passivating polymers, dimensional changes expose the copper material to ambient air, resulting in spontaneous oxidation of the metal. Figure 2 compares electron micrographs of the (A) 'as-received' and (B) oxidized RDL copper metal feature. The extent of copper oxidation increases with increasing temperature and time at temperature.

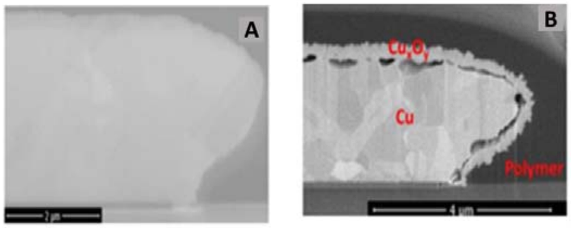

Fig. 2. Micrographs showing the development of copper oxide films around RDL feature: (A) “as-received” and (B) after 4 days at 200°C.

Figure 3 shows the microwave insertion loss (S21 at 100 MHz) as a function of the extent of corrosion of the copper RDL metallization (i.e., copper oxide film thickness measured by SEM, as in Figure 2) [2].

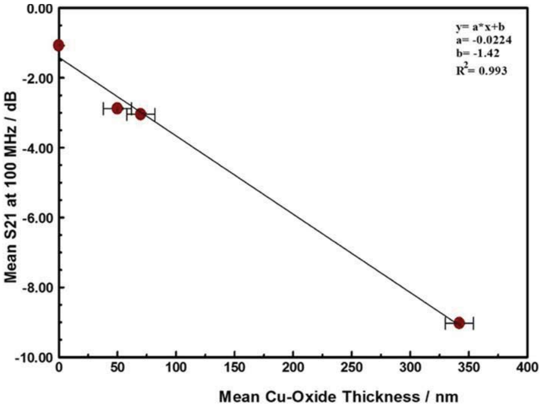

Fig. 3. Correlation between the Copper Oxide Film Thickness and the Insertion Loss (S21) at 100 MHz (Adapted from [2])

The changes in the electrical properties of the copper metal due to the oxidation are readily observed with BDS, as shown in Figure 4. In our experimental setup, we were able to monitor the direct current resistance (RDC) of the device under test (DUT). Figure 5 compares the RF signal loss results (at a single frequency (1 GHz) to the direct current-resistance that was measured simultaneously with the S21. The insertion losses increase dramatically with increasing DUT resistance (R_{DC}), suggesting that S21 may be a more sensitive measure of material changes (e.g., RDL corrosion).

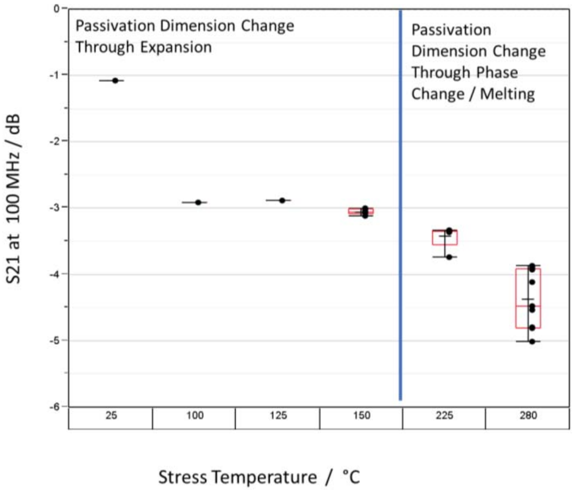

Fig 4: A comparison of the extent of oxidation (as indicated by S21) as a function of storage temperature. The data segments into two domains gated by the physico-chemical changes in the polymer passivation layer on the RDL

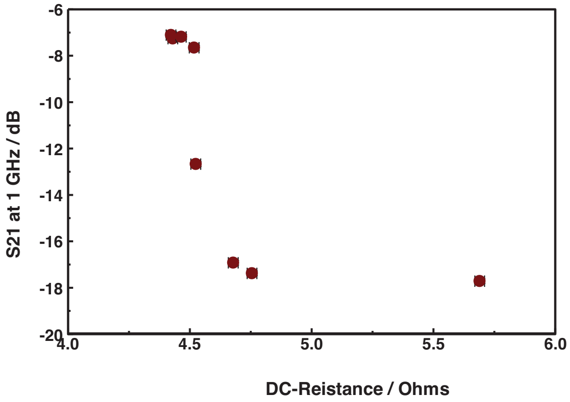

Fig 5: A comparison of the DC-resistance to the microwave insertion loss (S21) at 1GHz

Close analysis of the BDS data also provides information about the chemistry of the oxidation process, a product that techniques such as DC resistance (R_{DC}) cannot afford. For example, COMSOL Multiphysics (Burlington, MA, USA) electrodynamic modeling of the microwave signal loss (S21) through the corroded RDL required accounting for the roughness seen in Figure 2B. It turns out that the roughness of the copper oxide-air interface is attributable to the formation of electrically conductive polycrystalline copper oxide nanostructure mixtures (i.e., ranging from nanowires to nanotubes of Cu_2O and CuO) due to the thermal oxidation of crystalline copper nanowires at BEOL processing temperatures (200 to 300 °C) [3]. Figure 6, shows the simulated S21 spectrum as a function of the roughness of the oxidized RDL Cu.

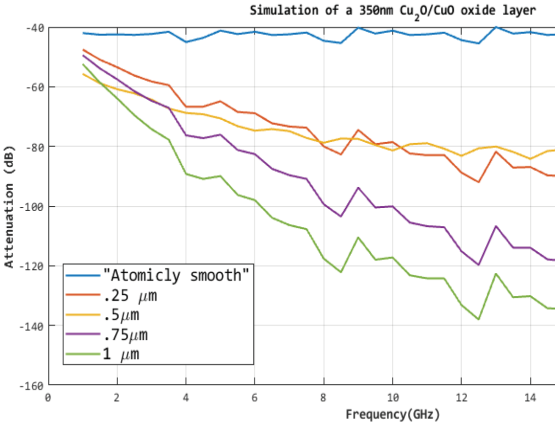

Fig. 6. Electrodynamic simulation, showing the impact of interfacial nanostructures, that manifest as roughness, on the microwave signal loss in the oxidized redistribution layer due to polymer passivation failure.

III. Discussions/Conclusions

The traditional metrology techniques, such as DC resistance, have been unable to adequately address the measurement needed to characterize in-situ the underlying failure mechanism. In this paper we have shown that the broadband radio frequency dielectric spectroscopy (BDS)-based metrology allows us to monitor the material changes in real-time, as well as extract mechanistic information from appropriately designed test structures.

Standards, Metrology and Technology to Minimize Healthcare-Associated Infections: Novel approaches to measure efficacy[#]

Healthcare-associated infections (HAIs) impose great burdens on public health, making HAIs the strongest contender as the most pressing healthcare problem in acute-care hospitalization. Ultraviolet-C illumination effectively decontaminate surfaces to reduce the population of many HAI-inducing microbes. Unfortunately, no industry-accepted standards exist for evaluating the decontamination efficacy, largely due to a paucity of measurements. Ideally, technology to detect microbial populations on surfaces will be sensitive, rapid, and efficient to maintain the high turnover required by hospitals. In this paper, we discuss some recent advances in UV-antimicrobial metrology focused on underpinning the development of standards through a collaborative effort involving NIST, the ultraviolet industry and the Yale School of Medicine.

Ultraviolet-C (UV-C) irradiation decontaminate surfaces by the photodegradation of of DNA and RNA through absorption of photons resulting in formation of pyrimidine dimers from thymine and cytosine, killing a variety bacterial species, including spores [1]. The killing efficacy is most commonly quantified using basic microbiology where the number of colony-forming units (CFUs) is determined from growth plate counts of a known CFU inoculum before and after UV-C exposure. Best practices for minimizing biological and technical error in plate counting have been established [2]. Current decontamination indicators include (i) biological indicators (BI) that directly determine survivability of the most resistant microorganisms (e.g., *Geobacillus stearothermophilus*), (ii) mechanical indicators (gauges and digital displays) and (iii) chemical indicators (e.g., autoclave tape) which do not ensure sterilization but indicate that autoclaving conditions have been met. Although none of these are rapid diagnostic techniques, they are they are currently the only available metrology for evaluating UV-C decontamination and establishing room disinfection protocols [3].

Dielectric spectroscopic investigations examine and explain different molecular dynamic processes of dielectric systems in response to rapidly changing magnetic fields. In this paper, we introduce a solid-state broadband dielectric spectroscopic (BDS, 10^{-5} -10^{10} Hz) method to rapidly and nondestructively indicate decontamination of DNA containing targets on inoculated surfaces (Figure 1A), and contrast it to the UV-C induced photodecomposition of pure protein (Figure 1B). The BDS technique is predicated on detecting photoinduced changes in the electrical properties (possibly due to a reduction of the

cytoplasm conductance and permittivity) of DNA containing moieties [4]. Mechanistically, the observed changes in electrical properties due to UV-C exposure are the result of an eventual disruption in the semipermeable cell membrane, allowing ions and molecules to leak out of the cytoplasm, as observed with membrane-potential fluorophores in bacteria [5] and yeast [6]. The loss of cellular integrity is measurable with microwave evanescent sensors. Indeed, the changes in the electrical properties may be independent of killing method. We expect our technique to detect and quantify bacterial populations on surfaces for rapid point-of-use diagnostics, and to provide a metrology for assessing the efficacy of decontamination processes [4].

Abstract. As smart home technology is becoming pervasive, smart home devices are increasingly being used by non-technical users who may have little understanding of the technology or how to properly mitigate privacy and security risks. To better inform security and privacy mitigation guidance for smart home devices, we interviewed 40 smart home users to discover their security and privacy concerns and mitigation strategies. Results indicated a number of concerns, but a general willingness to accept risk in lieu of perceived benefit. Concern was sometimes, but not always, accompanied by users taking mitigating actions, although most of these were simplistic and not technical in nature due to limited options or lack of user technical knowledge. Our results inform how manufacturers might empower users to take protective actions, including providing security tips and more options for controlling data being collected by devices. We also identify areas that might benefit from third-party involvement, for example by providing guidance to manufacturers on minimum privacy and security standards or developing a security and privacy rating system to aid users in selecting devices.

Keywords: smart home · internet of things · security · privacy · usability.

1 Introduction

As Internet of Things (IoT) smart home technology is becoming pervasive, smart home devices are increasingly being used by non-technical users [10] who may have little understanding of the technology or awareness of the implications of use, including considerations for privacy and security. Since their inception, smart home devices have become the target of security attacks, placing consumers' data, privacy, and safety at risk [13, 16]. In addition, concerns about the privacy and protection of potentially sensitive consumer data are surfacing [6, 12]. In fact, the U.S. Federal Bureau of Investigation (FBI) recently issued security and privacy warnings about smart televisions and other IoT devices [18, 19]. Therefore, it is critical that users are provided with the means to safeguard

Haney, Julie; Furman, Susanne M.; Acar, Yasemin. "Smart Home Security and Privacy Mitigations: Consumer Perceptions, Practices, and Challenges." Paper presented at International Conference on Human-Computer Interaction, Copenhagen, DK. July 19, 2020 - July 24, 2020.

their information and households while still enjoying the convenience of these devices.

Unfortunately, smart home device manufacturers may not provide privacy and security protections and configuration options [4], or, if they do, these options may not be transparent to the user. In addition, smart home users may not be knowledgeable enough to discern which mitigations would be most effective, or may only implement simplistic mitigations that might be inadequate [1, 26, 11, 15]. This inadequacy was demonstrated by recent stories of weak user-configured passwords being responsible for parents and children being surveilled and terrorized after their smart home devices were exploited [13].

Understanding consumers' interactions with smart home devices and their current privacy and security mitigation strategies is a first step towards developing guidance for manufacturers and third-party organizations to aid consumers. We sought to gain this understanding via an in-depth interview study of 40 smart home consumers to discover their overall experiences with, perceptions of, and challenges regarding their smart home devices. This paper addresses a subset of research questions (RQs) from the broader study that were focused on security and privacy:

RQ1: What are smart home users' privacy and security concerns, if any?

RQ2: What mitigation actions, if any, do users take to address their concerns?

RQ3: What are the factors affecting users' implementation (or lack of implementation) of privacy and security mitigations?

RQ4: What do users want (actions to take on their own or from others) in order to feel like their privacy and security are adequately protected?

We found that many users have privacy and security concerns but are mostly implementing simplistic mitigations to counter those concerns. However, some smart home users displayed a lack of concern or failed to take mitigation actions even if they do have concerns. The interviews revealed several challenges to the implementation of effective security mitigations, including users having incomplete threat models, privacy resignation, lack of transparency, poor usability of privacy and security-related device features, and lack of user technical knowledge to discern or implement appropriate mitigations. Our study makes several contributions:

– We confirm and expand upon prior studies that investigated smart home users' privacy and security concerns and mitigations [3, 20, 26] with a larger, more diverse participant sample.
– We identify several mitigations not previously described in the literature, including a more in-depth examination of smart home device updates.
– We distill participants' privacy and security "wishlist," which provides insight into potential areas for improvement in smart home device design and data handling.

– Our results inform how manufacturers and third-party evaluators might provide a more usable security and privacy experience.

2 Related Work

Prior work has examined perceptions of smart home privacy and security. Security and privacy concerns can be barriers to adoption of smart home devices. Lau et al. find that some non-users are privacy conscious and distrustful of privacy and security of smart home devices and their manufacturers, and that smart home devices generally cross these non-users' perceived privacy thresholds [11]. This finding is corroborated by Parks Associates [14], Worthy et al. [25], Emami-Naeini et al. [3], and Fruchter and Liccardy [7], who find that a lack of trust in vendors to properly safeguard personal data is a major obstacle to adoption of smart home technology. From a broader IoT perspective, Williams et al. [24] found that IoT is viewed as less privacy-respecting than non-IoT devices such as desktops, laptops, and tablets.

Adopters were found to share the same concerns, and often expressed a lack of agency in the control of their data [11]. However, they generally have higher tolerances for privacy violations, and willingly or reluctantly accept the trade-off in exchange for the convenience and utility offered by smart home devices [11]. They are generally more trusting towards well-known manufacturers and often express that they have "nothing to hide" [11, 20]. They also have complex, but incomplete threat models, which includes a general sense of being surveilled by manufacturers or the government, and the possibility of being attacked by hackers, but a lack of awareness of botnets and the sale of inferred data [1, 3, 27]. A main security concern was the possibility of a breach in the cloud that would expose user data [20].

Multiple studies discovered both technical and non-technical mitigations to address security and privacy concerns, for example passwords, secure configurations for the home network, and altering behavior around the devices [1, 11, 15, 20, 26]. However, they also identified lack of action. Reasons may be lack of awareness and availability of these options, privacy resignation, trust in the manufacturers, and assignment of responsibility to entities other than the users themselves [11, 20, 26].

Our study confirms many of the findings identified in prior literature while identifying additional mitigations such as device selection, access control, and updates. In addition, unlike other studies, we collected a wish list of mitigations that can help inform manufacturers and other entities in making privacy and security protections for smart home devices more usable for consumers.

3 Methods

We conducted semi-structured interviews of 40 smart home consumers to understand their perceptions of and experiences with smart home devices from purchase decision, to implementation, to everyday usage. The in-depth interviews

Haney, Julie; Furman, Susanne M.; Acar, Yasemin. "Smart Home Security and Privacy Mitigations: Consumer Perceptions, Practices, and Challenges." Paper presented at International Conference on Human-Computer Interaction, Copenhagen, DK. July 19, 2020 - July 24, 2020.

afforded more detailed data than could be collected via anonymous surveys and the ability to ask follow-up questions to explore responses [2]. To protect participants' confidentiality, data were recorded with generic identifiers (such as P10) and not linked back to individuals. The study was approved by the National Institute of Standards and Technology (NIST) research protections office.

We hired a consumer research company to recruit 33 general public participants, and identified seven participants via professional contacts. To determine study eligibility, adult participants interested in the study completed an online screening survey about their smart home devices, role with the devices (i.e., decision maker, purchaser, installer, administrator, troubleshooter, or user), professional background, basic demographic information, and number of household members. To ensure information-rich cases, we then purposefully selected participants who had two or more smart home devices for which they were active users.

The interview protocol addressed the following areas: understanding smart home terminology, purchase and general use, likes and dislikes, installation and troubleshooting, privacy, security, and physical safety. Interviews lasted an average of 41 minutes. Prior to the interviews, we informed the participants about the study and how we would protect their data by not recording any personal identifiers that could be linked back to the participant. All interviews were audio recorded and transcribed. General public participants were compensated with a $75 gift card.

Using widely-accepted qualitative data analysis methods [9], all three authors individually coded a subset of four interviews, then met to develop and operationalize a codebook to identify concepts within the data. Based on the codebook, we then performed iterative coding on the remainder of the interviews, with two coders per transcript. Each pair of coders met to discuss and resolve areas of difference in code application. As a group, we then progressed to the recognition of relationships among the codes and examined patterns and categories to identify themes. In this paper, we focus on themes related to privacy and security mitigations and concerns.

4 Participant Demographics

We interviewed 40 participants, 32 of whom were the installers and administrators of the devices (indicated with an A after the participant ID) and eight who were non-administrative users of the devices (indicated with a U). 55 % were male, and 45 % were female. Multiple age ranges were represented, with the majority (70 %) between the ages of 30 and 49. Overall, participants were highly educated with all but one having at least a bachelor's degree and almost half (45 %) having at a graduate degree. Table 1 shows participant demographics.

All but one participant had three or more individual smart home devices, with 34 (85 %) having three or more different types of devices. Figure 1 shows the general categories of smart home devices in participants' homes. Represented categories, along with examples of devices in that category, were:

Table 1. Participant Demographics. ID: A - smart home administrators/installers, U - smart home users; Education: M - Master's degree, B - Bachelor's degree, C - some college, H - High school.

Smart security: security cameras, motion detectors, door locks
Smart entertainment: smart televisions, speakers, streaming devices, other connected media systems
Home environment: smart plugs, energy monitors, lighting, smoke and air quality sensors, thermostats
Smart appliances: refrigerators, coffee pots, robot vacuums, washers
Virtual assistants: voice-controlled devices such as Amazon Echo (colloquially called Amazon Alexa) and Google Home.

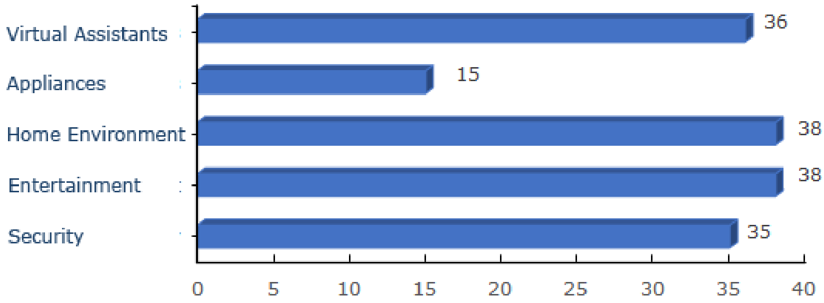

Fig. 1. Types of Smart Home devices owned by participants.

5 Results

In this section, we report results from a subset of the interview data specific to privacy and security concerns, mitigations, and mitigation wish lists. Counts of the number of participants mentioning various concepts are provided in some cases to illustrate weight or unique cases and are not an attempt to reduce our qualitative data to quantitative measures.

5.1 Concerns

We present an overview of concerns identified in our study to provide context for what our participants believe might need to be addressed by mitigations. Participants' privacy and security concerns are summarized in Table 2. For each concern in the table, we include whether the concern was discussed in a privacy or security context (or both), the number of participants mentioning each concern, and an example participant quote to illustrate the concern.

The most frequently mentioned concerns that were discussed within both the privacy and security contexts included: audio and video access via smart

	Concern	#	Example Participant Quote
Security and Privacy	Audio/video access	34	*“I was reading some article where [a virtual assistant] listens in on some of the conversations we have in our house without it being awake... That kind of freaks me out in the sense that we could be talking about something, and they have that information.” (P21_U)*
	Data breaches	17	*“Manufactures can say they can protect things, but in reality, if someone wants something bad enough, I don’t know if they really can.” (P33_A)*
	Government access	12	*“I would hate to sound like a conspiracy theorist, but I’m pretty sure the government and places like that can actually see what you do.” (P14_U)*
	Exposure of financial information	8	*“I wouldn’t want anybody committing fraud and taking my credit card information to do things they shouldn’t be doing.” (P37_A)*
Privacy	Household profiling	19	*“If someone was in control of this [device], they might be able to know what my schedule is, when I’m usually home, when the house is empty.” (P34_A)*
	Selling data	17	*“That’s what I’m really afraid of, is them packaging my information to get trends and marketing it.” (P13_A)*
	Unknowns of data collection	16	*“I’m concerned because I think we’re unaware of the types of information that these smart devices store of us or have of us.” (P21_U)*
Security	Device hacking	22	*“There’s some just people who are really smart and they’re sitting somewhere, all they’re thinking about is how to get into stuff... And if people could hack into the Department of Defense, they can hack into yours.” (P28_A)*
	Safety	17	*“It could be life threatening... If you rely on the smart device to keep your home locked,... if it does misfunction, there could be extreme circumstances. ” (P19_U)*
	Gaining Wi-Fi access	6	*“Many of these devices, you’re giving it your network password, so it has full access to everything on your network.” (P11_A)*
	Linked accounts	4	*“If you use a password commonly across different accounts, the same password, if that gets hacked... If I log into my Google account they might be able to get in because I might use the same exact password and user name.” (P2_A)*
	Poor default security settings	2	*“I would be disturbed if I saw a device that, for example, had a password you couldn’t change or restricted you to something like a 4-digit key code that’s more easily hacked.” (P15_A)*
	Update issues	2	*“I guess one area where I would be worried about would be adding features that may threaten my privacy and security.” (P15_A)*

Table 2. Smart Home Privacy and Security Concerns. # - number of participants mentioning the concern

Haney, Julie; Furman, Susanne M.; Acar, Yasemin. ”Smart Home Security and Privacy Mitigations: Consumer Perceptions, Practices, and Challenges.” Paper presented at International Conference on Human-Computer Interaction, Copenhagen, DK. July 19, 2020 - July 24, 2020.

home devices such as virtual assistants and cameras; data breaches of the manufacturer; foreign and domestic government access to data; and exposure of financial information via smart home device credentials and apps. Participants talked about the following privacy-specific concerns: household habit profiling; the selling of data and targeted ads; and unknowns about what data is being collected and how it is being used. Security-specific concerns included: general exploitation/hacking of devices; physical security/safety; gaining access to the Wi-Fi network and other devices on that network via smart home devices; gaining access to linked accounts (e.g., email or social media accounts) by exploiting device apps; poor default security settings (e.g., default passwords); and updates potentially having harmful consequences.

We also found examples of various levels of lack of concern, with seven participants having neither privacy nor security concerns. In 24 cases, participants did not think that the information collected by smart home devices was valuable or interesting to others. For example, one participant commented, *"I live a life that you could probably watch. I could probably have cameras in my house, and I wouldn't feel guilty about that... That's a concern I know some people have. But I didn't have an issue with that" (P2_A).* We also identified evidence of participants exhibiting privacy and security resignation [11, 17] (8 participants). They are of the opinion that, since so much of their data is already publicly available via other means (e.g., social media, data breaches), smart home devices pose no additional risk. One smart home user said, *"I do dislike having all of my information out there, but I think that, regardless of these smart devices, it's already out there" (P17_A).* Finally, five participants viewed exploitation of devices (hacking) as a low-probability event. This feeling was often tied to them not valuing information collected by smart home devices: *"Somebody would have to pluck us at random to really be at risk" (P25_A).*

Ultimately, even if they had concerns, participants were more than willing to accept privacy and security risks because of the perceived benefits. One participant commented, *"It's an acceptable risk if you don't think you're doing anything that's illegal or bad. It's not like I do anything weird in front of the TV besides exercise, and nobody wants to see that" (P14_U).* Another said, *"It makes my life easier, so I will continue to do it unless I have a major security concern that comes up" (P17_A).*

5.2 Mitigations

Our study discovered a variety of mitigations that participants or others in their household implement to address privacy and security concerns. All mitigations were mentioned in both the privacy and security contexts. Figure 2 shows the number of participants mentioning each mitigation. We describe the mitigations in more detail below.

Authentication. Participants mentioned using various forms of authentication (e.g., passwords, face recognition, two-factor) when asked what actions they

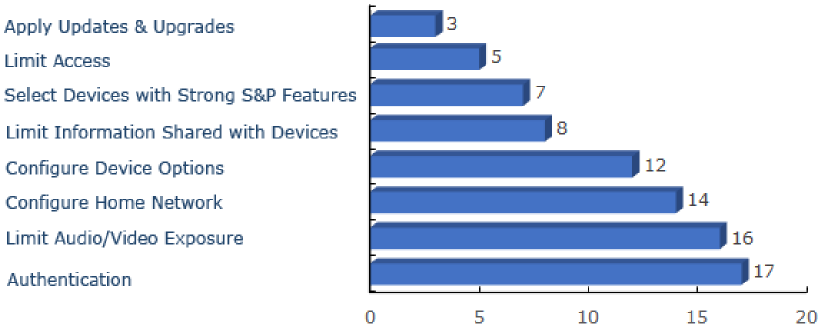

Fig. 2. Security and Privacy mitigations mentioned by participants.

take to address their concerns. However, this action was typically not a user choice, but rather prompted during installation. Authentication was most often referenced with regards to the device companion apps, which are often controlled via a cellphone.

Passwords were the most common authentication mechanism afforded by device companion apps, and often the only mitigation mentioned. One participant said that he addressed his concerns by *"password protecting the devices so nobody can connect to them... It's not very convenient, but... that's what I need to do" (P20_A)*. Several participants specifically discussed their attempts at having strong passwords: *"I have my own unique passwords that aren't dictionary words, so that's how I mitigate" (P10_A)*. Another participant used a password manager for her smart home device apps. Two others said that they made sure that they change any default passwords during installation.

Only one participant mentioned two-factor authentication in the context of mitigations: *"If I know that I can do two factor authentication for something, I'll do that" (P2_A)*. When asked about how they authenticate to their devices in a later, separate question, only one additional participant mentioned two-factor authentication, which was an option offered by his smart thermostat.

Limiting Audio and Video Exposure. To address concerns about audio and video being exposed to manufacturers or unauthorized users, study participants mostly mentioned non-technical mitigations. They were careful about where they placed cameras and virtual assistants, avoiding more private rooms in the house. For example, one participant talked about the location of his virtual assistant: *"Bedrooms are just a little more personal. I make sure not to keep it there because... if it does record, I don't want maybe those conversations and things that happened in the bedroom to be on there" (P32_A)*. Several participants were also cognizant of not having sensitive conversations in the vicinity of listening devices: *"I try to keep [my virtual assistant] in a central location and kind of avoid being close to it when having certain conversations" (P22_A).* Others covered cameras not being used. For instance, a participant remarked that her husband took action: *"The [virtual assistant] device has a video camera that you can use, but he's taped it over" (P1_A).* Finally, several users turned off devices in certain circumstances. One user talked about how her husband unplugs their virtual assistants when he is teleworking to guard against potentially sensitive conversations being recorded. Another said, *"With the security camera, sometimes I switch it off... It's when I'm really like out of town, that's when I like to switch it on back again" (P34_A).*

Network Configuration. The security and privacy of smart home devices can be contingent on the security of the home network. There were a few advanced users that mentioned more sophisticated network security mitigations, for example, segmenting their home network, installing virtual private networks (VPNs), or monitoring network traffic. For example, a do-it-yourselfer who customizes his smart home devices was diligent in securing his home network: *"I have a protective network where all these devices live in, and you can't get to it from the outside. I can get to it from within my house, and if I have to I can get to it via a VPN from the outside" (P16_A).* Another also made use of VPNs *"to mask the IP address. It's not that I'm doing anything illegal... It's just I don't feel like being tracked" (P20_A).*

However, most participants' extent of network security configuration was to password-protect their Wi-Fi. One participant commented, *"When it comes to my internet that I use to connect a lot of them, you know, it is password protected. So you know, it's not like anyone can just log on and use my network" (P32_A).* Another said, *"I'm always switching passwords with my Wi-Fi" (P34_A).*

Option Configuration. Twelve participants configured options that were at least loosely related to privacy and security. This mostly entailed disabling default functionality. For example, one participant disabled online ordering on her virtual assistant: *"We have cut off some functionality just to prevent the $400 order of mystery items" (P1_A).* A tech-savvy participant mitigated his concerns by *"turning off certain features that I think might share more information or provide more access to the device than is necessary" (P15_A)*, giving the example of how he had disabled the microphone in his smart TV. Another participant was one of the few who knew about options in virtual assistants to limit audio recording usage: *"For the [virtual assistant], it records everything. But I did see one of the options was to regularly delete it every day or something, so that kind of took the concern off the table" (P27_A).*

Limiting Shared Information. Eight participants mentioned limiting the information they share with device manufacturers, mostly when setting up companion apps. A participant said, *"I have my email address that I use for signing* *up for accounts that I'm never going to check and email address that I use for signing up for things that I actually care about. The latter is a very small number" (P17_A).* Another remarked, *"When it comes to, especially I think my [virtual assistant], I don't keep certain information stored on it. Like, I know some people will keep their actual address or even sometimes even credit card information to be able to buy things right away" (P32_A).* One participant discussed using false information when setting up her smart home device app accounts: *"I always put in fake birthdays... You need to know I'm eighteen, but you don't need to know everything" (P37_A).*

Device Selection. Some participants were proactive in their mitigation efforts by considering security and privacy in their purchase decisions. One participant remarked that, prior to selecting devices, he *"paid a lot of close attention to the security of those devices and what's happening with the data, what sorts of data they might record, how others might be able to access the system" (P15_A).* Another commented on the importance of buying secure devices: *"Even if you have to spend more money to get more into that security, we would definitely do that as we are so much dependent on this. We have to protect ourselves" (P9_A).* Others made decisions based on whether or not they trusted particular manufacturers to provide secure products. For example, a participant commented, *"I'm looking for devices that, if they're going to communicate with a cloud service, they use a well-known cloud service" (P11_A).* One made the conscious choice to buy products from well-known, larger companies: *"These are pretty big companies... We're paying money for the brand itself... Maybe that's why I'm feeling a little more secure than not... If something happens, hopefully, they have the money to figure it out" (P6_U).*

Limiting Access. Five participants made a variety of attempts to limit access to smart home devices and their apps. Three discussed limiting access of devices by visitors and service providers entering the house. One discussed making decisions on which device to use for potentially sensitive tasks, for example, *"I don't place orders via [my virtual assistant]... I do everything mostly on my computer, which has a VPN on it" (P14_U).* Another mentioned securing access to her cellphone (which contained device companion apps) as a mitigation:

> *"I'm very secure with my phone. I make sure that it's not easily accessible... I keep my phone right on me, I don't set it down, I don't let people look at stuff, I don't access the [public Wi-Fi] internet in other areas when I'm using those apps" (P37_A).*

Updates. Although updates can be a powerful mitigation against device vulnerabilities, only three participants mentioned updates or upgrades in the context of mitigations. A user said, *"I found that I'm updating everything a lot more... just kind of keeping up with the technology because it is so important" (P31_A).* A do-it-yourselfer purchased a smart camera with dubious ties to a foreign government, so he *"modified the firmware so it's no longer using the [untrusted] web service or cloud service" (P11_A).*

Prior to the security and privacy portions of the interviews, we asked participants about their experiences with device updates. Participants rarely associated updates with security or privacy and mentioned that they often do not know whether updates are available or have been installed due to inconsistent notifications and user interfaces. While updates are often viewed as potentially being security-related with traditional IT products (e.g., Microsoft's "Patch Tuesday'), we did not find that same association in our study. In addition, users often do not apply updates if they feel their devices are still working without issue. These findings indicate both a usability problem and a perception that updates are only functionality-based and not related to security.

Lack of Mitigations. We also discovered reasons for participants not implementing mitigations. Several participants cited a lack of privacy/security options or them not being aware of available options: *"Usually the description of the controls aren't specific enough... They're like, 'Check this for our privacy settings,' and sometimes the description of the settings aren't very specific" (P13_U).* Similar to reasons behind lack of concern, users often exhibited resignation and feelings of lack of control: *"I wish we could [limit data collection], but I don't think there'll ever be a way to control it" (P12_U).* Others cited a lack of knowledge or skill, especially with respect to cybersecurity: *"I'm not going to educate myself on network security... This stuff is not my forte. I'm very accepting to the fact that it is what it is" (P8_A).* Of course, some participants were simply not concerned enough to take any kind of action: *"I go on faith that they don't find me interesting enough. I guess that's it" (P23_A).*

5.3 Mitigation Wish List

Even though users have ultimately accepted privacy and security risks by introducing the devices into their homes, we found that they still desire greater control, especially with respect to privacy. We asked participants what they would like to do to protect their smart home privacy and security but are not doing, cannot do, or do not know how to do. Examination of the participant "wish list" provides insight into what would make users feel more empowered to take mitigating action and what options or instructional information they think manufacturers should provide.

Data Collection Transparency. Users desire manufacturers to be more forthcoming about what data is being collected, where it is going, and how it is being used (mentioned by 12 participants). Manufacturers claim that user level agreements provide this information. However, participants said that they rarely read the long agreements and generally do not find those useful because they are in *"lawyer speak. You don't really know what they're collecting because they can use* *language to mislead you" (P31_U).* The lack of transparency leaves users wanting more: *"At least give us notice in terms of who has access to it... We would appreciate that and make us feel more comfortable around the security behind it" (P21_U).* One user desired a more concise, clear statement of data usage: *"if these companies provided a manifesto of what information they're interested in or how they use information and how they're collecting information and provide that - a one pager - that would be great" (P2_A).* Realizing that it might not be in manufacturers' best interest to clearly disclose data usage, P31_A saw the government as having a role since *"we've got to do something to protect people's information, or at least make them more aware of what exactly is being utilized and sold."*

Privacy and Security Controls. Ten participants would like more control over the devices and data. This includes the ability to opt in/out of various data collections, limit how data is shared, and configure security and other privacy options. For example, a participant remarked, *"there would be some of these products that I have been avoiding purchasing that I might purchase if they provided more granular control over... all aspects of the security and privacy" (P15_A).* Another participant said he would like to be able to use two-factor authentication for his devices' companion apps: *"There would be features that would be nice to have, I guess one being a two-factor authentication. If my phone is close to my thermostat, that's my second factor" (P10_A).* Options should also be easy-to-configure, as mentioned by one participant: *"I think the ability to control that data should be simpler than a multi-step process" (P29_A).*

Technically advanced users were more specific about what they would like to do and wanted granular controls. A computer scientist said, *"I would really be happy actually if a lot of them had APIs [application programming interfaces] that I could use to directly program their behavior and get more control over them programmatically" (P15_A).* An electrical engineer commented:

> *"I'd like to have the ability to potentially allow or disallow the functionality of all these devices, maybe at given times. I'd like to be able to define what are allowable communications or protocols" (P11_A).*

Five participants wished that they had the ability to keep smart home data on their local network when possible instead of the common business model of data being sent to manufacturers or their cloud services. A participant said, *"If I could not have accounts and just have it on my own home network, I would prefer that" (P17_A).* P15_A commented that he wished *"some of these devices used the voice control features locally only rather than sending clips of your voice over the Internet to be analyzed."*

Security Feature Transparency. Four participants would like to know the level of security provided by the devices. One stated, *"it would be nice to know what security features are already there because they're not advertised or transparent at all. And maybe to have an option to get some kind of enhanced security if you wanted to" (P24_A).* Wishing to know if he needed to bolster the security of his home network to counter potentially weak smart home security, another participant said, *"I wish I knew more about what kind of encryption they use" (P3_A).*

Assistance for Users. Within the security context, four participants expressed their desire to be provided with suggestions and instructions on how to better secure their devices. A participant unfamiliar with security best practices commented, *"I think I need to be advised on good practices that I could take... And then I probably would implement them" (P35_A).* Another suggested, *"maybe the apps that I have could throw out reminders in a more frequent manner that says are you doing something like this to protect yourself?" (P19_A).* A heavy user of smart home devices said that he would like to know how best to protect his devices against vulnerabilities: *"I would like the vulnerability identified well enough so I know what it is and then some directions on how to solve it" (P13_A).*

6 Implications

The users we interviewed were diverse in their mitigation approaches to smart home devices. Some were proactive from a privacy and security perspective and knowledgeable about the technology. Others had very little understanding of the technology and implications of use. Our results suggest that users do the best they can with the skills and the options available to them.

Most of the mitigations identified in our study were simplistic (e.g., setting passwords) or not technical in nature (e.g., placement of devices). From a privacy perspective, participants expressed the desire to be able to control what happens to their data but do not know what options are available, or, in many cases, no options exist. Security concepts and implications were more difficult for participants to grasp, with many lacking the knowledge to implement effective mitigations, for example, by properly securing their home networks. Overall, we observed that many of the participants were left with a feeling of discomfort because they had privacy and security concerns but felt powerless to address those.

Based on study results, we describe possible ways in which manufacturers could empower users to make appropriate security choices through usable interfaces and where further research may be helpful. We also identify areas that could benefit from third-party evaluation and guidance.

6.1 Considerations for Usable Security and Privacy Options

Participants' current mitigation strategies (or lack thereof) and their wish lists for privacy and security can inform what additional options manufacturers could provide and other areas where they might alleviate user burden by defaulting to strong privacy and security.

Note that since our interview study was broader than privacy and security, we had the opportunity to delve into users' installation and administration experiences with their smart home devices. Participants revealed that they rarely change settings after initial setup. Therefore, additional research may be warranted to investigate if installation is the best time to prompt users on security and privacy options.

Secure and private by default: As revealed in prior usable security research, people are often reluctant to change default security settings [28, 29]. Therefore, to alleviate undue burden on users, there may be settings which manufacturers could configure to be the most secure/private by default. However, more research should be conducted to understand how setting defaults to the most secure/private options may contribute to or detract from usability.

Opt in/out: Currently, opting out of data collection and various uses may not be possible or may be burdensome. For example, P17_A said that one manufacturer required a letter be mailed requesting to limit data sharing. Based on participants desiring more control on data usage, more research is needed regarding how manufacturers could offer easy-to-configure opt in/out options.

Data usage transparency: Device privacy policies and user agreements are rarely read and difficult to understand, leaving users uninformed about data collection practices. Manufacturers could provide greater transparency about what data is collected, where the data goes, how long it is stored, and who it is shared with.

Data localization: Our participants were often concerned about manufacturer profiling of their households, selling of their data, and possible data breaches of manufacturer data storage. To counter these concerns, manufacturers could provide options to localize whatever data processing can be localized instead of sending everything to the manufacturer's cloud.

Securability: In situations where security settings might be dependent on user context, there could be a focus on "securability," which is the "ability and knowledge to enable and configure the appropriate security features" [23]. To achieve product securability, manufacturers could facilitate secure use by providing users with real-time assistance, such as configuration wizards, to help them set the level of security appropriate for their situation. For example, users might be given the option of configuring low, medium, and high levels of security based on clear criteria (e.g., network environment, context of use, risk tolerance) gleaned through a security configuration wizard. The securability concept can also be applied to privacy settings.

Granular options for advanced users: We interviewed several advanced users who were well-versed in technology and security. These users wanted more control over security settings. Therefore, in addition to supporting less technical users with guided wizards and instructions, manufacturers could offer more granular security controls for those who want them. We acknowledge that striking the right balance between an abundance of granular options and a minimal set for less-technical users may be difficult. Therefore, we recommend additional research into interface solutions that may attempt to balance these considerations.

Update transparency: Updates are especially important as they might be the only mitigations for certain kinds of smart home device vulnerabilities (e.g., those in the code). In line with the NIST Interagency Report 8267 (Draft) Security Review of Consumer Home Internet of Things (IoT) Products [5] recommendation that users receive update notifications in a timely manner, manufacturers might either provide an option for automatic updates or push notifications to users with clear installation instructions and descriptions of the importance of applying the update.

Network security tips: Home networks need to be secured to protect smart home devices. However, people often lack the knowledge and motivation to take action. For example, the FBI recommends that users segment their network [13] even though few participants in our study had the technical knowledge to be able to do so. Several of our study participants said they would like manufacturers to provide step-by-step tips on home network security (e.g., setting up secure Wi-Fi, password-protecting all devices on the network) that complement the security options provided by the devices themselves.

6.2 Third-party Opportunities

Our results suggest that users may be open to third-party organizations (e.g., government agencies, industry groups, standards organizations) playing a bigger role in suggesting guidance for manufacturers concerning the usability of smart home security and privacy features and options. For example, the guidance produced by NIST [4, 5] provides recommendations but emphasizes that these should be tailored to specific contexts of use while not placing undue burden on the user.

The wide variety of mitigations mentioned by participants may also indicate a need for more standardization of privacy and security best practices for smart home users by trusted third parties (e.g., government agencies or an IoT industry consortium). To help users understand privacy and security implications of smart home devices, we also recommend exploring the usability considerations of having an independent, third-party ratings system similar to that which has been proposed by the Canadian Internet Society [21] and the U.S. Government Departments of Commerce and Homeland Security [22]. This ratings system would help consumers to make informed decisions about which devices to bring into their homes.

7 Limitations

In addition to typical limitations of interview studies (e.g., recall, self-report, and social desirability biases), our study may be limited in generalizability. The small sample of participants, the majority of whom were well-educated individuals living in a high-income metropolitan area, may not be fully representative of the U.S. smart home user population. However, our study population appears to mirror early adopters of smart home devices, which have been characterized in prior industry surveys [8]. We also recognize that smart home users in the U.S. may have different privacy and security attitudes from users in other countries because of political or cultural factors, for example those related to privacy expectations. Finally, our study does not capture perceptions of those choosing not to adopt smart home technologies or limited adopters (those with only one device). Non-adopters' and limited adopters' perceptions of privacy and security could shed light on additional areas needing improvement. However, even given the limitations, our exploratory study is a solid step in investigating smart home users' perceptions and practices and can inform subsequent surveys of broader populations, for example via quantitative surveys distributed in multiple countries.

8 Conclusion

We interviewed 40 smart home users to discover their security and privacy concerns and mitigation strategies. Results indicated a number of concerns, but a willingness to accept risk in exchange for perceived benefit. Concern was sometimes, but not always, accompanied by users taking mitigating actions, although most of these actions were simplistic due to limited options or lack of user technical knowledge.

Improving the security and privacy of smart home devices will be critical as adoption of these technologies increase. Efforts should be joint between consumers, manufacturers, and third-party organizations with special consideration made for designing usable interfaces that empower users to take protective actions while not overburdening them.

Abstract

The classical seismic design procedure uses a force-based approach where reduced seismic force demands are evaluated and compared to the corresponding seismic capacities. An improved performance-based design procedure recently developed uses the displacement-based approach to ensure that structures with nonlinear deformations perform within acceptable limits. However, neither of these procedures considers the effect of cyclic behavior that is typically observed in the seismic response of nonlinear structures.

On the other hand, energy is the product of force and displacement, which captures both monotonic and cyclic behavior of structural response. At the same time, structures suffering damage from a major earthquake participate in an energy transfer process. Earthquake ground motion transfers energy to individual structures as input energy that induces vibrations in the structure and its contents, resulting in response in terms of potential energy, kinetic energy, and damping energy. Quantifying these energy demands is often difficult, particularly in the calculation of potential energy, where earthquake often causes both material and geometric nonlinearities in the structure. Since the potential energy relates to the stiffness of the structure, it consists of three parts: (1) Strain energy associated with the elastic portion of the material; (2) Higher-order energy associated with geometric nonlinearity of the structure; and (3) Plastic energy associated with material nonlinearity of the structural components.

In this research, an analytical derivation is used to quantify the energy demand in fully nonlinear framed structures using an energy balance approach. A moment-resisting steel frame is used to verify the method by evaluating the energy response and the transfer among different energy forms throughout the dynamic analysis. The result shows that plastic energy dissipated at each plastic hinge is a positive, scalar quantity that can be calculated uniquely, and the sum of individual plastic energy at each plastic hinge is exactly equal to the overall plastic energy of the structure. Once energy demand is quantified uniquely, structural performance and damage can be assessed more easily via comparison of the energy demand with the corresponding energy capacity. Through this process of quantifying the seismic performance of structures, higher level of confidence can be achieved in the design over the current force-based or displacement-based methods.

Keywords: Energy demand; Energy capacity; Plastic energy; Material nonlinearity; Geometric nonlinearity

Wong, Kevin K F; McCabe, Steven. "Quantification of Seismic Energy Demand in Nonlinear Structures Through Analytical Derivations."
Paper presented at 17th World Conference on Earthquake Engineering, Sendai, JP. September 13, 2020 - September 18, 2020.

1. Introduction

Current seismic design procedures use either a force-based or displacement-based approach to ensure that structures can perform adequately during major events. However, neither of these procedures considers the effect of cyclic behavior that is typically observed in the seismic response of nonlinear structures. Accumulation of damage as a function of the number of inelastic cycles has been recognized in laboratory as well as post-earthquake reconnaissance. The question often raised is how to relate maximum responses with some measure of damage. Recognizing this shortcoming in the current procedure, energy, as a product of force and displacement, can capture both monotonic and cyclic behavior. Therefore, a study on how energy can be used in structural design is worthwhile, particularly how energy demand and capacity are quantified.

Research on seismic energy began in the 1980s when it was recognized that significant cumulative damage can occur in structures without large global displacement responses in long-duration earthquake ground motions [1-4]. However, these studies focused on evaluating the hysteretic energy by calculating the enclosed area in a force-deformation curve of single degree of freedom systems. In 1990, an analytical procedure was developed to clearly define different forms of energy for linear multi-degree of freedom structures [5], and this procedure is later extended in 2002 to define energy due to inelastic deformation [6]. However, these studies did not consider the reduction of lateral stiffness by axial load due to geometric nonlinearity, which can lead to considerable error in the energy calculations.

In this research, an analytical method for calculating energy considering both geometric and material nonlinearities is derived to investigate the energy of framed structures responding nonlinearly to earthquakes. In particular, the potential energy that is directly related to nonlinear stiffness of the structure is investigated, and a step-by-step analysis of a one-story frame is used to verify that input energy is balanced by potential energy throughout the static loading and unloading phases. This potential energy consists of three parts in a fully nonlinear system: (1) the stored linear elastic "strain energy"; (2) the "higher-order energy" associated with geometric nonlinearity; and (3) the "plastic energy" dissipated by material nonlinearity. Finally, four-story frame is used to verify energy balance can also be achieved in a dynamic context.

2. Inelastic Displacement for Material Nonlinearity

The derivation on the use of inelastic displacement for analyzing structures with material nonlinearity has previously been published [6-7] and is briefly summarized here with an extension to include geometric nonlinearity. Consider a framed structure having a total of n degrees of freedom (DOFs) and m plastic hinge locations (PHLs). Let the $n \times 1$ total displacement $\mathbf{x}(t)$ at each DOF be represented as the summation of the $n \times 1$ elastic displacement $\mathbf{x}'(t)$ and the $n \times 1$ inelastic displacement $\mathbf{x}''(t)$:

$$\mathbf{x}(t) = \mathbf{x}'(t) + \mathbf{x}''(t) \tag{1}$$

Similarly, let the $m \times 1$ total moment $\mathbf{m}(t)$ at the PHLs of a moment-resisting frame be separated into the $m \times 1$ elastic moment $\mathbf{m}'(t)$ and the $m \times 1$ inelastic moment $\mathbf{m}''(t)$:

$$\mathbf{m}(t) = \mathbf{m}'(t) + \mathbf{m}''(t) \tag{2}$$

This inelastic moment $\mathbf{m}''(t)$ is often known as the "residual moment" that is caused by material nonlinearity in the structure. The displacements in Eq. (1) and the moments in Eq. (2) are related by the equations:

$$\mathbf{m}'(t) = \mathbf{K}'(t)^T \mathbf{x}'(t) \quad , \quad \mathbf{m}''(t) = -\left[\mathbf{K}''(t) - \mathbf{K}'(t)^T \mathbf{K}(t)^{-1} \mathbf{K}'(t)\right] \mathbf{\Theta}''(t) \tag{3}$$

where $\mathbf{\Theta}''(t)$ is the $m \times 1$ plastic rotation at each PHL, and $\mathbf{K}(t)$, $\mathbf{K}'(t)$, and $\mathbf{K}''(t)$ are time-varying stiffness matrices due to geometric nonlinearity in which columns are subjected to time-varying axial compressive forces $P(t)$. Since the total axial force in all columns within a single floor remains constant, software developers generally assume that all stiffness matrices remain constant throughout the duration of the earthquakes to simplify the calculations without losing accuracy. Doing so, Eq. (3) becomes

$$\mathbf{m}'(t)=\mathbf{K}'^{T}\mathbf{x}'(t) \quad , \quad \mathbf{m}''(t)=-\left[\mathbf{K}''-\mathbf{K}'^{T}\mathbf{K}^{-1}\mathbf{K}'\right]\boldsymbol{\Theta}''(t) \tag{4}$$

The relationship between the plastic rotation $\boldsymbol{\Theta}''(t)$ and inelastic displacement $\mathbf{x}''(t)$ can be written as

$$\mathbf{x}''(t)=\mathbf{K}^{-1}\mathbf{K}'\boldsymbol{\Theta}''(t) \tag{5}$$

Substituting both equations in Eq. (4) into Eq. (2) and then making use of Eqs. (1) and (5) gives the governing equation for calculating the plastic hinge responses for any total displacement pattern $\mathbf{x}(t)$:

$$\mathbf{m}(t)+\mathbf{K}''\boldsymbol{\Theta}''(t)=\mathbf{K}'^{T}\mathbf{x}(t) \tag{6}$$

3. Dynamic Equilibrium Equation of Motion

For a moment-resisting framed structure modeled as an n DOF system and subjected to earthquake ground motions, the dynamic equilibrium equation of motion can be written as

$$\mathbf{M}\ddot{\mathbf{x}}(t)+\mathbf{C}\dot{\mathbf{x}}(t)+\mathbf{K}\mathbf{x}'(t)=-\mathbf{M}\ddot{\mathbf{g}}(t)-\mathbf{F}_a(t) \tag{7}$$

where $\mathbf{M}$ is the $n\times n$ mass matrix, $\mathbf{C}$ is the $n\times n$ damping matrix, $\dot{\mathbf{x}}(t)$ is the $n\times 1$ velocity vector, $\ddot{\mathbf{x}}(t)$ is the $n\times 1$ acceleration vector, $\mathbf{K}$ is the same $n\times n$ stiffness matrix presented in Eq. (4), $\ddot{\mathbf{g}}(t)$ is the $n\times 1$ earthquake ground acceleration vector corresponding to the effect of ground motion at each DOF, and $\mathbf{F}_a(t)$ is the $n\times 1$ vector of additional forces imposed on the structure due to geometric nonlinearity accounting for all the gravity columns in the structure (mainly the P-Δ effect). In a two-dimensional analysis, the relationship between this lateral force $\mathbf{F}_a(t)$ and the lateral displacement $\mathbf{x}(t)$ can be written as

$$\mathbf{F}_a(t)=\mathbf{K}_a\mathbf{x}(t) \tag{8}$$

where $\mathbf{K}_a$ is an $n\times n$ stiffness matrix that is a function of the gravity loads on the leaning column and the corresponding story height, which can be written in the form:

$$\mathbf{K}_a=\begin{bmatrix} -Q_1/h_1-Q_2/h_2 & Q_2/h_2 & 0 & \cdots & 0 \\ Q_2/h_2 & -Q_2/h_2-Q_3/h_3 & \ddots & \ddots & \vdots \\ 0 & \ddots & \ddots & Q_{n-1}/h_{n-1} & 0 \\ \vdots & \ddots & Q_{n-1}/h_{n-1} & -Q_{n-1}/h_{n-1}-Q_n/h_n & Q_n/h_n \\ 0 & \cdots & 0 & Q_n/h_n & -Q_n/h_n \end{bmatrix} \tag{9}$$

Here, Q_i is the total axial force due to gravity loads acting on the leaning column of the i^{th} floor, and h_i is the story height of the i^{th} floor. Now substituting Eq. (8) into Eq. (7) and rearranging terms gives

$$\mathbf{M}\ddot{\mathbf{x}}(t)+\mathbf{C}\dot{\mathbf{x}}(t)+\mathbf{K}\mathbf{x}'(t)+\mathbf{K}_a\mathbf{x}(t)=-\mathbf{M}\ddot{\mathbf{g}}(t) \tag{10}$$

Since $\ddot{\mathbf{y}}(t)=\ddot{\mathbf{x}}(t)+\ddot{\mathbf{g}}(t)$ where $\ddot{\mathbf{y}}(t)$ is the $n\times 1$ absolute acceleration vector, substituting this equation into Eq. (10) gives the governing equation of motion for energy balance:

$$\mathbf{M}\ddot{\mathbf{y}}(t)+\mathbf{C}\dot{\mathbf{x}}(t)+\mathbf{K}\mathbf{x}'(t)+\mathbf{K}_a\mathbf{x}(t)=\mathbf{0} \tag{11}$$

4. Energy Balance

To evaluate seismic energy, integrating Eq. (11) over the path of displacement response gives

$$\int_0^t \ddot{\mathbf{y}}(t)^T\mathbf{M}d\mathbf{x}+\int_0^t \dot{\mathbf{x}}(t)^T\mathbf{C}d\mathbf{x}+\int_0^t \mathbf{x}'(t)^T\mathbf{K}d\mathbf{x}+\int_0^t \mathbf{x}(t)^T\mathbf{K}_a d\mathbf{x}=0 \tag{12}$$

Note that $d\mathbf{x}(t)=d\mathbf{y}(t)-d\mathbf{g}(t)$, where $\mathbf{y}(t)$ is the $n\times 1$ absolute displacement vector and $\mathbf{g}(t)$ is the $n\times 1$ earthquake ground displacement vector. Substituting this equation into the first integral of Eq. (12) gives

$$\int_0^t \ddot{\mathbf{y}}(t)^T \mathbf{M} d\mathbf{y} + \int_0^t \dot{\mathbf{x}}(t)^T \mathbf{C} d\mathbf{x} + \int_0^t \mathbf{x}'(t)^T \mathbf{K} d\mathbf{x} + \int_0^t \mathbf{x}(t)^T \mathbf{K}_a d\mathbf{x} = \int_0^t \ddot{\mathbf{y}}(t)^T \mathbf{M} d\mathbf{g} \tag{13}$$

In addition, the incremental displacement $d\mathbf{x}(t)$ can be separated into elastic displacement and inelastic displacement as $d\mathbf{x}(t) = d\mathbf{x}'(t) + d\mathbf{x}''(t)$. Substituting this equation into the third integral of Eq. (13) gives

$$\int_0^t \ddot{\mathbf{y}}(t)^T \mathbf{M} d\mathbf{y} + \int_0^t \dot{\mathbf{x}}(t)^T \mathbf{C} d\mathbf{x} + \int_0^t \mathbf{x}'(t)^T \mathbf{K} d\mathbf{x}' + \int_0^t \mathbf{x}'(t)^T \mathbf{K} d\mathbf{x}'' + \int_0^t \mathbf{x}(t)^T \mathbf{K}_a d\mathbf{x} = \int_0^t \ddot{\mathbf{y}}(t)^T \mathbf{M} d\mathbf{g} \tag{14}$$

Each integral in Eq. (14) is considered separately in the following sub-sections.

4.1 Kinetic Energy (*KE*)

The first integral on the left-hand side of Eq. (14) represents the absolute kinetic energy (*KE*) and can be evaluated using the absolute velocity of the structure as:

$$KE(t_k) = \int_0^{t_k} \ddot{\mathbf{y}}(t)^T \mathbf{M} d\mathbf{y} = \frac{1}{2}\dot{\mathbf{y}}(t_k)^T \mathbf{M}\dot{\mathbf{y}}(t_k) - \frac{1}{2}\dot{\mathbf{y}}(0)^T \mathbf{M}\dot{\mathbf{y}}(0) = \frac{1}{2}\dot{\mathbf{y}}_k^T \mathbf{M}\dot{\mathbf{y}}_k \tag{15}$$

where $\dot{\mathbf{y}}(t)$ is the $n \times 1$ absolute velocity vector, $\dot{\mathbf{y}}_k$ represents the discretized form of $\dot{\mathbf{y}}(t_k)$, and t_k represents the k^{th} time step at which the energy value is calculated. The structure is assumed to be at rest when the earthquake begins, and therefore $\dot{\mathbf{y}}(0) = \mathbf{0}$. Due to the squaring of the absolute velocity vector in Eq. (15) and a positive definite **M** matrix, the kinetic energy is always positive.

4.2 Damping Energy (*DE*)

The second integral on the left-hand side of Eq. (14) represents the damping energy (*DE*), which is the energy dissipated via viscous damping mechanism within the structure. The integrand is always positive, and therefore damping energy always accumulates over time. In terms of numerical simulation, the integral can be numerically approximated by evaluating the area underneath the curve using the trapezoidal rule:

$$DE(t_k) = \int_0^{t_k} \dot{\mathbf{x}}(t)^T \mathbf{C} d\mathbf{x} = \sum_{k=1}^{t_k} \frac{1}{2}\left(\dot{\mathbf{x}}_{k-1}^T + \dot{\mathbf{x}}_k^T\right) \mathbf{C} \left(\mathbf{x}_k - \mathbf{x}_{k-1}\right) \tag{16}$$

where $\mathbf{x}_k$ represents the discretized form of $\mathbf{x}(t_k)$ and $\dot{\mathbf{x}}_k$ represents the discretized forms of $\dot{\mathbf{x}}(t_k)$.

4.3 Strain Energy (*SE*)

The third integral on the left-hand side of Eq. (14) represents the strain energy (*SE*) of the moment-resisting frame and can be evaluated as:

$$SE(t_k) = \int_0^{t_k} \mathbf{x}'(t)^T \mathbf{K} d\mathbf{x}' = \frac{1}{2}\mathbf{x}'(t_k)^T \mathbf{K}\mathbf{x}'(t_k) - \frac{1}{2}\mathbf{x}'(0)^T \mathbf{K}\mathbf{x}'(0) = \frac{1}{2}\mathbf{x}_k'^T \mathbf{K}\mathbf{x}_k' \tag{17}$$

where $\mathbf{x}_k'$ represents the discretized form of $\mathbf{x}'(t_k)$. The structure is again assumed to be at rest when the earthquake begins, and therefore $\mathbf{x}'(0) = \mathbf{0}$. Due to the squaring of the elastic displacement vector in Eq. (17) and a positive definite **K** matrix, the strain energy is always positive.

4.4 Plastic Energy (*PE*)

The fourth integral on the left-hand side of Eq. (14), which is associated with inelastic displacements, represents the plastic energy (*PE*) dissipated by the permanent deformations of the structure. Rewriting Eqs. (4) and (5) in the forms:

$$\mathbf{K} d\mathbf{x}'' = \mathbf{K}' d\mathbf{\Theta}'' \quad , \quad \mathbf{x}'(t)^T \mathbf{K}' = \mathbf{m}'(t)^T \tag{18}$$

Then substituting Eq. (18) into the fifth integral of Eq. (14) gives

$$PE(t_k) = \int_0^{t_k} \mathbf{x}'(t)^T \mathbf{K} d\mathbf{x}'' = \int_0^{t_k} \mathbf{x}'(t)^T \mathbf{K}' d\mathbf{\Theta}'' = \int_0^{t_k} \mathbf{m}'(t)^T \, d\mathbf{\Theta}'' = \sum_{i=1}^{m} \int_0^{t_k} m_i'(t) d\theta_i'' = \sum_{i=1}^{m} PE_i(t_k) \tag{19}$$

where PE_i represents the plastic energy dissipation at the i^{th} plastic hinge, $i = 1,...,m$. Through this analytical derivation, it is proven in Eq. (19) that the overall plastic energy dissipation $PE(t_k)$ is exactly equal to the sum of plastic energy dissipation in all the plastic hinges $PE_i(t_k)$.

The term PE_i in Eq. (19) can be numerically approximated by evaluating the area underneath the curve using the trapezoidal rule:

$$PE_i = \int_0^{t_k} m_i'(t) d\theta_i'' = \sum_{k=1}^{t_k} \frac{1}{2}\left(m'_{i,k-1} + m'_{i,k}\right)\left(\theta''_{i,k} - \theta''_{i,k-1}\right) \tag{20}$$

where $m'_{i,k}$ and $\theta''_{i,k}$ represent the discretized forms of $m_i'(t_k)$ and $\theta_i''(t_k)$, respectively. Note that PE_i is computed by integrating the product of elastic moment m_i' and the change in plastic rotation $d\theta_i''$. A positive change in plastic rotation is always caused by a positive moment, and a negative change in plastic rotation is always caused by a negative moment. Therefore, PE_i is always positive and accumulates over time.

4.5 Higher-order Energy (*HE*)

The fifth integral on the left-hand side of Eq. (14) represents higher-order energy (*HE*) due to gravity loads on the structure itself. It is of higher-order because the energy comes from the large *P*-Δ effect, where gravity in the vertical direction is producing energy while going through movement in the horizontal direction. This energy is calculated as follows:

$$HE(t_k) = \int_0^{t_k} \mathbf{x}(t)^T \mathbf{K}_a d\mathbf{x} = \frac{1}{2}\mathbf{x}(t_k)^T \mathbf{K}_a \mathbf{x}(t_k) - \frac{1}{2}\mathbf{x}(0)^T \mathbf{K}_a \mathbf{x}(0) = \frac{1}{2}\mathbf{x}_k^T \mathbf{K}_a \mathbf{x}_k \tag{21}$$

where the structure is again assumed to be at rest when the earthquake begins, and therefore $\mathbf{x}(0) = \mathbf{0}$. Due to the squaring of the total displacement vector in Eq. (21) and a negative definite $\mathbf{K}_a$ matrix as presented in Eq. (9), the higher-order energy is always negative and varies with time.

4.6 Input Energy (*IE*)

Finally, the integral on the right-hand side of Eq. (14) represents the absolute input energy (*IE*) due to the earthquake ground motion, and this integral can be numerically approximated by evaluating the area underneath the ground motion curve using the trapezoidal rule:

$$IE(t_k) = \int_0^{t_k} \ddot{\mathbf{y}}(t)^T \mathbf{M} d\mathbf{g} = \sum_{k=1}^{t_k} \frac{1}{2}\left(\ddot{\mathbf{y}}_{k-1}^T + \ddot{\mathbf{y}}_k^T\right) \mathbf{M} \left(\mathbf{g}_k - \mathbf{g}_{k-1}\right) \tag{22}$$

where $\ddot{\mathbf{y}}_k$ represents the discretized form of $\ddot{\mathbf{y}}(t_k)$ and $\mathbf{g}_k$ represents the discretized form of $\mathbf{g}(t_k)$.

In summary, substituting Eqs. (15), (16), (17), (19), (21), and (22) into Eq. (14), the energy balance equation becomes

$$KE + DE + SE + HE + PE = IE \tag{23}$$

5. Energy Balance Verification

To verify the energy is balanced in Eq. (23), consider a one-story one-bay frame as shown in Fig.1a. Assume an elastic modulus of $E = 200$ GPa and a moment of inertia of $I = 4.16 \times 10^8$ mm^4 for both the beam and columns. Also let the gravity load be $P = 5340$ kN acting on each column, which is equivalent to 13.6 % of the critical buckling load (i.e., $P/P_{cr} = 0.136$). Finally, six plastic hinges are included in the model as shown in Fig.1a with labels from #1 to #6. Assume material exhibits elastic-perfectly-plastic behavior with moment capacities $m_c = 3909$ kN·m for the columns and $m_b = 3130$ kN·m for the beam.

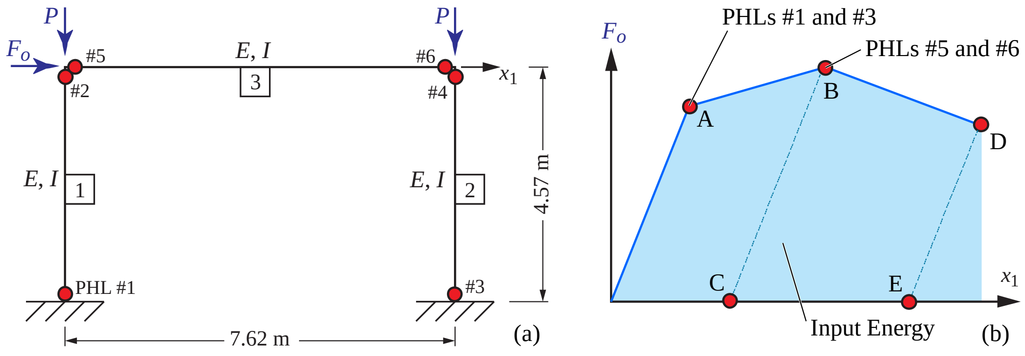

Fig. 1 – One-story one-bay moment resisting frame

No leaning column is used in the model, and therefore $HE = 0$. Now consider a static horizontal load F_o is incrementally applied to the frame. A typical pushover curve for the frame is shown in Fig.1b, where Point A shows the yielding of PHLs #1 and #3, and Point B shows the yielding of PHLs #5 and #6. Input energy (*IE*) is calculated by determining the area underneath the curve as highlighted in blue. With static load being applied, $KE = DE = 0$. Therefore, the energy balance equation in Eq. (23) becomes

$$SE + PE = IE \tag{24}$$

5.1 Loading Up to Point A

First consider Point A shown in Fig.1b, where the moments in PHLs #1 and #3 are exactly equal to the maximum moment capacities. At this point, the applied force is $F_o = 2289$ kN, and the resulting displacement is $x_1 = 0.229$ m as shown in Fig.2a. This gives an elastic stiffness of the frame of $K = F_o / x_1 = 9996$ kN/m. The resultant forces of each member are shown in Fig.2b, and Fig.2c shows that PHLs #1 and #3 are at yield, while PHLs #5 and #6 are below yield. The energy quantities are calculated as:

$$SE = \frac{1}{2}(9996)(0.229)^2 = 262 \text{ kJ} \quad , \quad PE = 0 \text{ kJ} \quad , \quad IE = \frac{1}{2}(0.229)(2289) = 262 \text{ kJ} \tag{25}$$

Therefore, from Eq. (25), $SE + PE = IE$, and Eq. (24) is satisfied.

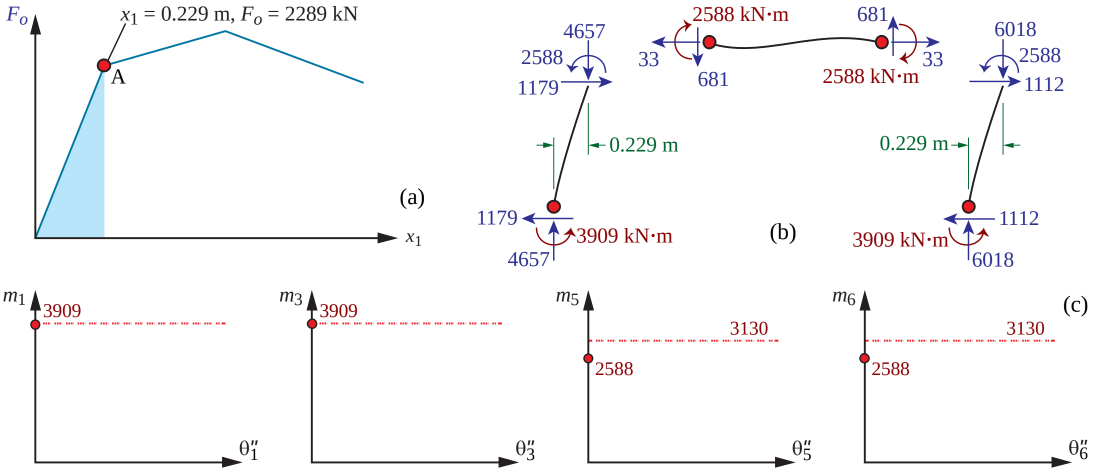

Fig. 2 – State of structure at Point A

5.2 Loading Up to Point B

Now let the applied force be increased up to Point B shown in Fig.1b, where the moments in PHLs #5 and #6 are exactly equal to the moment capacities. At this point, the applied force is $F_o = 2326$ kN, and the resulting displacement is $x_1 = 0.316$ m as shown in Fig.3a. The resultant forces of each member are shown in Fig.3b, and Fig.3c shows that PHLs #5 and #6 are at yield, while PHLs #1 and #3 are beyond yield with plastic rotations of $\theta_1'' = \theta_3'' = 0.0245$ rad. Note that the moments m_1 and m_3 are below the moment capacity of the columns due to axial force and yield moment interactions. Corresponding to the plastic rotations in PHLs #1 and #3, the elastic moments are calculated to be $m_1' = 3923$ kN·m and $m_3' = 2924$ kN·m, and therefore the inelastic moments are $m_1'' = -40$ kN·m and $m_3'' = -62$ kN·m. The energy quantities are calculated as:

$$PE_1 = \frac{3883 + 3923}{2}(0.0245) = 96 \text{ kJ} \quad , \quad PE_3 = \frac{3862 + 3924}{2}(0.0245) = 95 \text{ kJ} \tag{26a}$$

$$SE = \frac{1}{2}\frac{(2326)^2}{9996} = 271 \text{ kJ} \quad , \quad IE = 262 + \frac{(2326 + 2289)}{2}(0.316 - 0.229) = 462 \text{ kJ} \tag{26b}$$

$$PE = PE_1 + PE_3 = 191 \text{ kJ} \tag{26c}$$

Therefore, from Eqs. (26b) and (26c), $SE + PE = IE$, and Eq. (24) is satisfied.

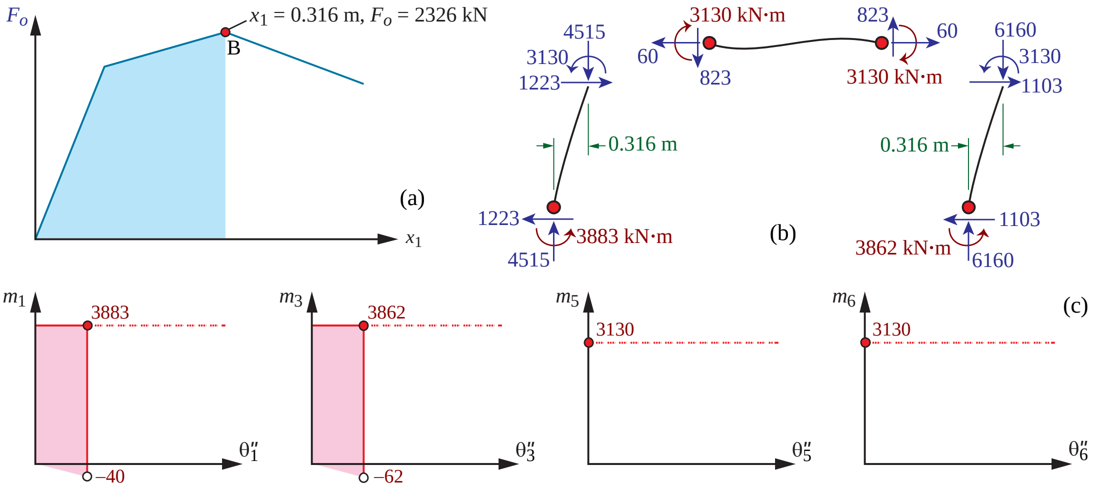

Fig. 3 – State of structure at Point B

5.3 Unloading to Point C

Now let the applied force be completely removed to reach Point C shown in Fig.1b. At this point, the applied force is $F_o = 0$ kN, and the resulting displacement is $x_1 = x_1'' = 0.084$ m (i.e., the elastic displacement $x_1' = 0$) as shown in Fig.4a. The resultant forces of each member are shown in Fig.4b, and Fig.4c shows that PHLs #5 and #6 are elastic, while PHLs #1 and #3 unload to negative moments of $m_1 = m_1'' = -40$ kN·m and $m_3 = m_3'' = -62$ kN·m (i.e., the elastic moments $m_1' = m_3' = -40$). Since plastic energy remains the same during unloading, i.e., $PE_1 = 96$ kJ and $PE_3 = 95$ kJ, the energy quantities are calculated as:

$$SE = 0 \text{ kJ} \quad , \quad PE = PE_1 + PE_3 = 191 \text{ kJ} \quad , \quad IE = 462 - \frac{1}{2}\frac{(2326)^2}{9996} = 191 \text{ kJ} \tag{27}$$

Therefore, from Eq. (27), $SE + PE = IE$, and Eq. (24) is satisfied.

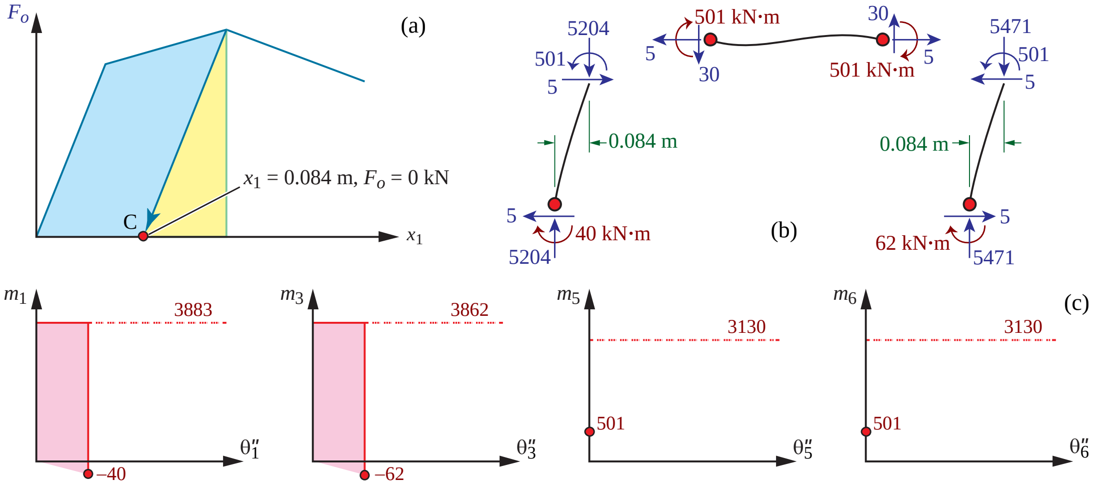

Fig. 4 – State of structure at Point C

5.4 Reloading Up to Point D

Now let the applied force resumes and continues beyond Point B until reaching Point D shown in Fig.1b. At this point, a yield mechanism has formed, which means any additional load can cause instability of the frame. For this reason, displacement control is used. Let the displacement of the frame be $x_1 = 0.457$ m, and the corresponding applied force is calculated to be $F_o = 1995$ kN as shown in Fig.5a. The resultant forces of each member are shown in Fig.5b, and Fig.5c shows that PHLs #1, #3, #5, and #6 are beyond yield with plastic rotations of $\theta_1'' = \theta_3'' = 0.0556$ rad and $\theta_5'' = \theta_6'' = 0.0309$ rad. Corresponding to these plastic rotations, the inelastic moments are shown in Fig.5c. The energy quantities are then calculated as:

$$PE_1 = 96 + (3883 + 40 + 3883 - 515)(0.0556 - 0.0245)/2 = 209 \text{ kJ} \tag{28a}$$

$$PE_3 = 95 + (3862 + 62 + 3862 - 493)(0.0556 - 0.0245)/2 = 208 \text{ kJ} \tag{28b}$$

$$PE_5 = PE_6 = (3130 - 501 + 3130 - 873)(0.0309)/2 = 75.5 \text{ kJ} \tag{28c}$$

$$PE = PE_1 + PE_3 + PE_5 + PE_6 = 568 \text{ kJ} \tag{28d}$$

$$SE = \frac{1}{2}\frac{(1995)^2}{9996} = 199 \text{ kJ} \quad , \quad IE = 462 + \frac{1}{2}(1995 + 2326)(0.457 - 0.316) = 767 \text{ kJ} \tag{28e}$$

Therefore, from Eqs. (28d) and (28e), $SE + PE = IE$, and Eq. (24) is satisfied.

5.5 Unloading to Point E

Finally, let the applied force be completely removed to reach Point E shown in Fig.1b. At this point, the applied force is $F_o = 0$ kN, and the resulting displacement is $x_1 = x_1'' = 0.258$ m as shown in Fig.5a. The resultant forces of each member are shown in Fig.5b, and Fig.5c shows the moment-rotation plot of each plastic hinge. Since the strain energy at zero force is $SE = 0$ kJ, and the plastic energy remains the same during unloading, i.e., $PE_1 = 209$ kJ, $PE_3 = 208$ kJ, and $PE_5 = PE_6 = 75.5$ kJ, the energy quantities are calculated as:

$$SE = 0 \text{ kJ} \quad , \quad PE = PE_1 + PE_3 + PE_5 + PE_6 = 568 \text{ kJ} \quad , \quad IE = 767 - \frac{1}{2}\frac{(1995)^2}{9996} = 568 \text{ kJ} \tag{29}$$

Therefore, from Eq. (29), $SE + PE = IE$, and Eq. (24) is satisfied.

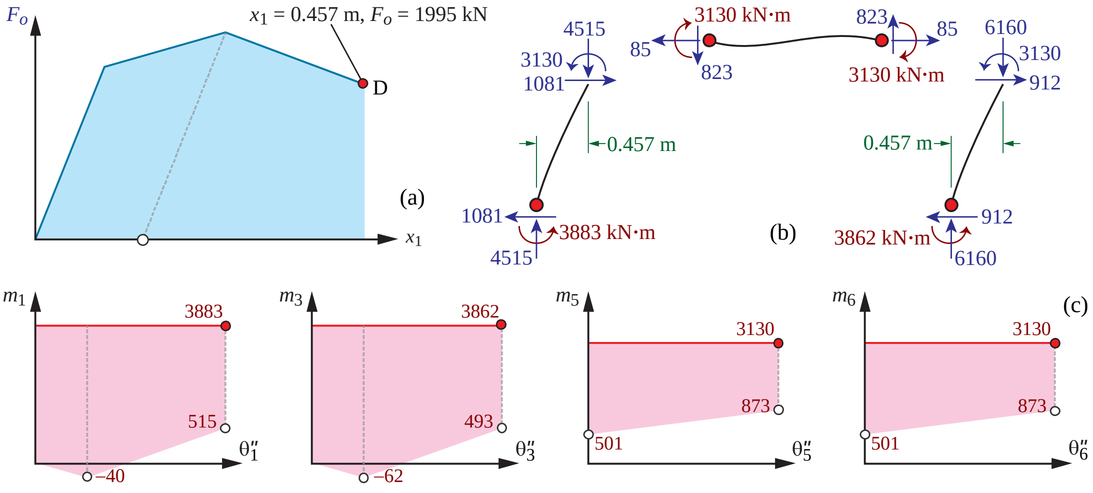

Fig. 5 – State of structure at Point D

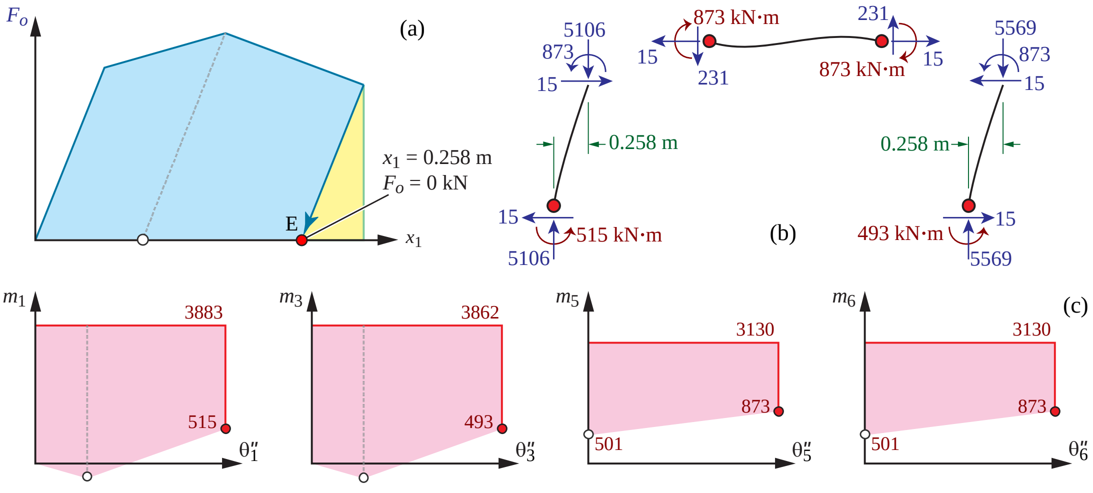

Fig. 6 – State of structure at Point E

6. Numerical Simulation of a 4-story Moment-Resisting Frame

To demonstrate the balance of energy in dynamic analysis, consider the four-story moment-resisting frame as shown in Fig.7a designed according to code [8]. This frame contains 36 DOFs (i.e., $n = 36$), of which 4 are horizontal translations, 16 are vertical translations, and 16 are joint rotations. Also, this frame has a total of 56 PHLs (i.e., $m = 56$). Assume each floor has a mass of 95 000 kg, and gravity load of 431 kN is applied on each exterior column member and 632 kN is applied on each interior column member as shown in Fig.7b. Based on these gravity load on the frame, the stiffness matrices $\mathbf{K}$, $\mathbf{K}'$, and $\mathbf{K}''$ in Eq. (4) are constructed such that geometric nonlinearity is included in the formulation. In addition, a leaning column is used to account for all the gravity loads from other parts of the structure. Let the gravity loads on the leaning column be 3026 kN per floor. Finally, a 2 % damping is assumed in all four modes of vibration.

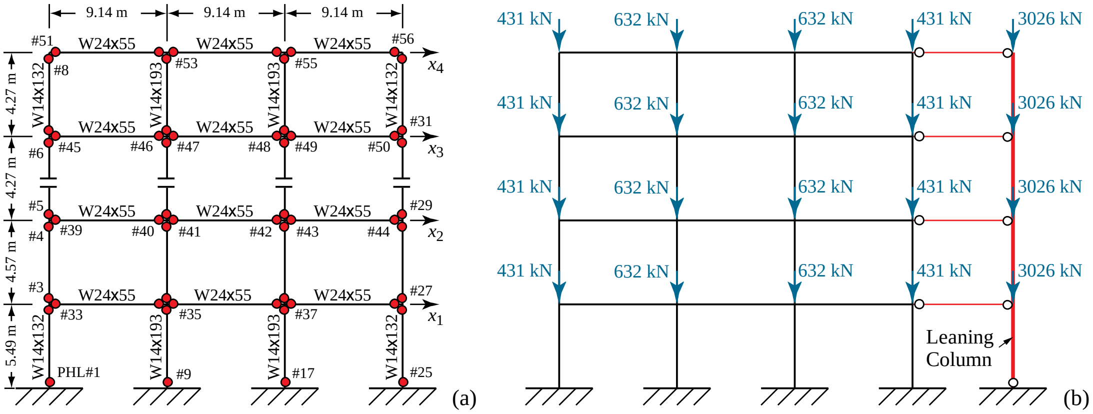

Fig. 7 – Four-story moment-resisting steel frame and corresponding gravity loads

Assume the yield stress of the member is 345 MPa and all 56 plastic hinges exhibit elastic-perfectly-plastic behavior. By subjecting the frame to the 1995 Kobe earthquake ground acceleration shown in Fig.8, the energy response histories are summarized in Fig.9. The results confirm that *KE* and *SE* are always positive (see Fig.9a), *DE* and *PE* are cumulative (see Fig.9b), and *HE* is always negative (see Fig.9d). Of particular interest is Fig.9c, which shows the plot of *IE* and *PE*. This figure shows that significant portion of input energy is dissipated through plastic energy, indicating that significant damage occurs in the structure.

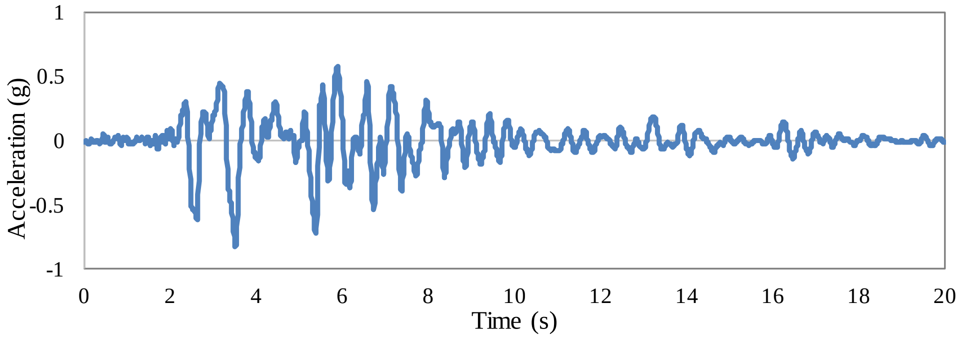

Fig. 8 – Recorded 1995 Kobe earthquake ground motion at Kajima station Component 000

In terms of plastic energy dissipation at individual plastic hinges, Fig.10a shows the maximum plastic energy at each plastic hinge, i.e., PE_i . Since plastic energy accumulates over time, the maximum plastic energy always occurs at the end of the earthquake duration. In addition, summing the plastic energy at all the plastic hinges in Fig.10a gives 950 kJ, which is equal to the total plastic energy dissipation *PE* at the end of the earthquake shown in Fig.9c.

Now consider the same 4-story frame as shown in Fig.7 but is subjected to the Kobe earthquake shown in Fig.8 with a scale factor of 1.4. The energy response histories are shown in Fig.11, where Fig.11a shows the storing energy quantities including *KE*, *SE*, and *HE*, while Fig.11b shows the cumulative energy quantities including *DE*, *PE*, and *IE*. Comparison of results in Fig.11 with those in Fig.9 shows that both *PE* and *IE* increase due to a larger earthquake while other energy quantities remain practically the same. This is consistent with intuition that larger input energy due to larger earthquake must be dissipated through plastic energy, resulting in more structural damage. The plastic energy dissipated in each plastic hinge, i.e., PE_i , is shown in Fig.10b. Summing these individual plastic energy values in Fig.10b gives 1484 kJ, which is equal to the total plastic energy dissipation *PE* at the end of the earthquake shown in Fig.11b.

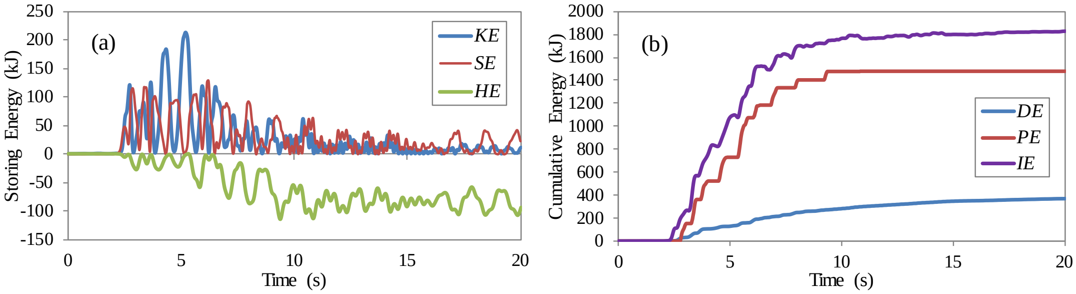

Fig. 11 – Energy responses of the 4-story framed structure due to 1.4 × Kobe earthquake

7. Conclusion

The analytical theory of seismic energy balance and the associated computational method for evaluating the seismic energy in structures are presented with the inclusion of geometric nonlinearity and material nonlinearity. This method successfully separates the coupling effect of material nonlinearity and geometric nonlinearity by using inelastic displacement. By expressing the input energy as the sum of kinetic energy, damping energy, strain energy, higher-order energy, and plastic energy, the energy representation of the structural response due to earthquake ground motion is complete. In particular, the two nonlinear energies are: (1) Higher-order energy (HE), which represents the negative energy stored in the structure that can be detrimental to structural stability; and (2) Plastic energy (PE), which represents the dissipation of energy and reduction of structural response due to material nonlinearity.

Due to static loading, the summation of these energy forms is exactly equal to the input energy. This is verified step by step in the present paper. The key is that plastic energy requires to use of elastic moment in the calculation, which is contrary to many past research [9-13] that uses total moment to calculate the area underneath the moment-rotation plots. The study is then extended to dynamic analysis, where plastic energy dissipation among individual plastic hinges is calculated. By using the elastic moment in the calculation of plastic energy, it is shown that energy is balanced in a dynamic system. This balance of energy is important because it gives a higher level of confidence in quantifying the energy demand in each component (i.e., PE_i), which in turn can be compared with the energy capacity of each component in energy-based design.

Abstract

In 2019, the U.S. National Institute of Standards and Technology (NIST) conducted a leaderboard style speaker recognition challenge using conversational telephone speech (CTS) data extracted from the unexposed portion of the Call My Net 2 (CMN2) corpus previously used in the 2018 Speaker Recognition Evaluation (SRE). The SRE19 CTS Challenge was organized in a similar manner to SRE18, except it offered only the *open* training condition. In addition, similar to the NIST i-vector challenge, the evaluation set consisted of two subsets: a *progress* subset, and a *test* subset. Trials for the *progress* subset comprised 30% of the target speakers from the unexposed portion of the CMN2 corpus and was used to monitor progress on the leaderboard, while trials from the remaining 70% of the speakers were allocated for the *test* subset, which was used to generate the official final results determined at the end of the challenge. Which subset (i.e., *progress* or *test*) a trial belonged to was unknown to challenge participants, and each system submission had to contain outputs for all of the trials. The SRE19 CTS Challenge also served as a prerequisite for entrance to the main SRE19 whose primary task was audio-visual person recognition. A total of 67 organizations (forming 51 teams) from academia and industry participated in the CTS Challenge and submitted 1347 valid system outputs. This paper presents an overview of the evaluation and several analyses of system performance for all primary conditions in the CTS Challenge. Compared to the CTS track of SRE18, the SRE19 CTS Challenge results indicate remarkable improvements in performance which are mainly attributed to 1) the availability of large amounts of in-domain development data (publicly available and/or proprietary) from a large number of labeled speakers, 2) speaker representations (aka embeddings) extracted using extended and more complex end-to-end neural network frameworks, and 3) effective use of the provided large development set.

1. Introduction

The United States National Institute of Standards and Technology (NIST) organized the 2019 Speaker Recognition Evaluation (SRE19) in the summer–fall of 2019. It was the latest in the ongoing series of speaker recognition technology evaluations conducted by NIST since 1996 [1, 2]. The objectives of the evaluation series are 1) for NIST to effectively measure system-calibrated performance of the current state of technology, 2) to provide a common test bed that enables the research to explore promising new ideas in speaker recognition, and 3) to support the community in their development of advanced technology incorporating these ideas. The basic task in the NIST SREs is speaker detection, that is, determining whether a specified target speaker is talking in a given test speech recording.

SRE19 consisted of two separate activities: 1) a leaderboard-style challenge using conversational telephone speech (CTS) extracted from the unexposed portions of the Call My Net 2 (CMN2) corpus collected by the Linguistic Data Consortium (LDC), which was also previously used to extract the SRE18 CTS development and test sets, and 2) a regular evaluation using audio-visual material extracted from the unexposed portions of the Video Annotation for Speech Technology (VAST) corpus [3], also collected by the LDC. This paper describes the task, the performance metric, data, and the evaluation protocol as well as results and performance analyses of submissions for the SRE19 CTS Challenge. The Audio-Visual SRE19 overview and results is described in another paper [4]. It is worth noting here that the CTS challenge also served as a prerequisite for the audio-visual evaluation, meaning that in order to participate in the regular evaluation, one must have first completed the challenge (i.e., submitted to NIST valid system outputs along with sufficiently detailed system description reports). SRE19 was coordinated entirely online using a freshly designed web platform[1] deployed on Amazon Web Services (AWS)[2] that supported a variety of evaluation-related services such as registration, data license agreement management, data distribution, system output submission and validation/scoring, and system description/presentation uploads.

The SRE19 CTS Challenge was organized in a similar manner to the CTS track of SRE18 [5], except it only offered the *open* training condition in which participants were allowed to use any publicly available and/or proprietary data for system training and development purposes. In addition, a much larger development set was released for the SRE19 CTS Challenge which contained the entire SRE18 development and test sets including segments from 213 labeled speakers as well as segments from more than 1000 unlabeled speakers. Furthermore, similar to the NIST i-vector speaker recognition challenge [6], the evaluation set consisted of two subsets: a *progress* subset, and a *test* subset. Trials for the *progress* subset comprised 30% of the target speakers from the unexposed portion of the CMN2 corpus

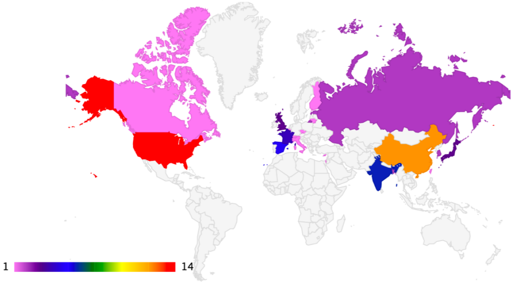

Figure 1: *Heat map of the world countries showing the number of SRE19 CTS Challenge participating sites per country.*

and was used to monitor progress on the leaderboard, while trials from the remaining 70% of the speakers were allocated for the *test* subset, which was used to generate the official final results determined at the end of the challenge. Which subset (i.e., *progress* or *test*) a trial belonged to was unknown to challenge participants, and each system submission had to contain outputs for all of the trials. The participants could make multiple submissions (up to 3 per day), and the leaderboard displayed the best submission performance results thus far received and processed. Over the course of the challenge, which ran from July 15 through October 7, 2019, a total of 51 teams, 23 of which were led by industrial institutions, from 67 sites made 1347 valid submissions (note that the participants processed the data locally and submitted only the output of their systems to NIST for scoring and analysis purposes). Figure 1 displays a heatmap representing the number of participating sites per country. It should be noted that all participant information, including country, was self-reported. The number of submissions per team in the SRE19 CTS Challenge is shown in Figure 2.

Finally, as in SRE18, and in an effort to provide a reproducible state-of-the-art baseline for the SRE19 CTS Challenge, NIST released well in advance of the evaluation period a report [7] containing the baseline speaker recognition system description and results obtained using a state-of-the-art (as of SRE18) deep neural network (DNN) embedding based system (see Section 5 for more details).

2. Task Description

The task for the SRE19 CTS Challenge was *speaker detection*, meaning given a segment of speech and the target speaker enrollment data, automatically determine whether the target speaker is speaking in the segment. A segment of speech (test segment) along with the enrollment speech segment(s) from a designated target speaker constitute a *trial*. The system is required to process each trial independently and to output a log-likelihood ratio (LLR), using natural (base e) logarithm, for that trial. The LLR for a given trial including a test segment s is defined as follows

$$LLR(s) = \log\left(\frac{P\left(s|H_0\right)}{P\left(s|H_1\right)}\right), \tag{1}$$

where $P\left(\cdot\right)$ denotes the probability distribution function (pdf), and H_0 and H_1 represent the null (i.e., s is spoken by the enrollment speaker) and alternative (i.e., s is not spoken by the enrollment speaker) hypotheses, respectively.

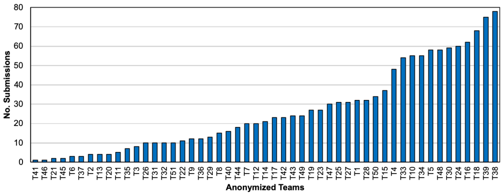

Figure 2: *Submission statistics for the SRE19 CTS Challenge.*

3. Data

In this section we provide a brief description of the data released in the SRE19 CTS Challenge for system training, development, and test.

3.1. Training set

As noted previously, unlike in SRE18 which offered *fixed* and *open* training conditions, the SRE19 CTS Challenge only offered the *open* training condition that allowed the use of any publicly available and/or proprietary data for system training and development purposes. The motivation behind this decision was twofold. First, results from the most recent NIST SREs (i.e., SRE16 [8] and SRE18) indicated limited performance improvements, if any, from unconstrained training compared to *fixed* training, although participants had cited lack of time and/or resources during the evaluation period for not demonstrating significant improvement with *open* versus *fixed* training. Second, the number of publicly available large-scale data resources for speaker recognition has dramatically increased over the past few years (e.g., see VoxCeleb[3]). Therefore, removing the *fixed* training condition would allow more in-depth exploration into the gains that could be achieved with the availability of unconstrained resources given the success of data-hungry Neural Network based approaches in the most recent evaluation (i.e. SRE18 [5]). Nevertheless, it is worth noting here that during the discussion sessions at the post-evaluation workshop, which was held in December 2019 in Singapore, several participating teams requested the re-introduction of the *fixed* training condition to facilitate meaningful and fair cross-system comparisons in terms of core speaker recognition algorithms/approaches (as opposed to particular data) used to develop the systems.

Although SRE19 allowed unconstrained system training and development, participating teams were required to provide a sufficient description of speech and non-speech (e.g., noise samples, room impulse responses, and filters) data resources as well as pre-trained models used during the training and development of their systems.

3.2. Development and evaluation sets

For the sake of convenience, in particular for new SRE participants, NIST provided an *in-domain* development set that could be used for both system training and development purposes. This Development set simply combined the SRE18 CTS development and test sets into one package (i.e. LDC2019E59). Participants could obtain this dataset through the evaluation web platform (`https://sre.nist.gov`) after signing the LDC data license agreement. The first three rows in Table 1 summarize the statistics for this development set.

	3	9515	401,507
Phone# match	Y	24,456	0
	N	23,062	2,000,000
CTS type	PSTN	36,308	1,536,768
	VoIP	11,210	465,400

The speech segments in the SRE19 CTS Challenge development (*DEV*) and evaluation (*EVAL*) sets were extracted from the CMN2 corpus collected by the LDC to support speech technology evaluations. The CMN2 corpus consists of CTS recordings spoken in Tunisian Arabic, which were collected over the traditional Public Switched Telephone Network (PSTN) and the more recent Voice over IP (VOIP) platforms outside North America. For CMN2 data collection, the LDC recruited a few hundred speakers called *claques* who made multiple calls to people in their social network (e.g., family, friends). Claques were encouraged to use different telephone instruments (e.g., cell phone, landline) in a variety of settings (e.g., noisy cafe, quiet office) for their initiated calls and were instructed to talk for at least 8–10 minutes on a topic of their choice. All CMN2 recordings are encoded as a-law sampled at 8 kHz in SPHERE [9] formatted files.

Similar to the most recent SREs (i.e., SRE16 and SRE18), there were two enrollment scenarios for the SRE19 CTS Challenge, namely 1-segment and 3-segment conditions. As the names imply, in the 1-segment condition only one approximately 60 s speech segment was given for enrollment, while in the 3-segment condition three approximately 60 s speech segments (from the same phone number) were provided to build the model of the target speaker. It is worth noting that the 3-segment condition only involved the PSTN data, because the number of VoIP calls per *claque* was limited. As part of the *dev* set for the SRE19 CTS Challenge, an *unlabeled* set of 2332 segments (with speech duration uniformly distributed in 10 s to 60 s range) was also made available by NIST. The *unlabeled* segments were extracted from the non-*claque* side of the PSTN/VoIP calls.

For the SRE19 CTS Challenge, the evaluation trials were divided into two subsets: a *progress* subset, and a *test* subset. Trials for the *progress* subset comprised 30% of the target speakers from the unexposed portion of the CMN2 corpus and was used to monitor progress on the leaderboard, while trials from the remaining 70% of the speakers were allocated for the *test* subset which was used to generate the official final results determined at the end of the challenge. The challenge test conditions were as follows:

- The speech durations of the test segments were uniformly sampled ranging approximately from 10 seconds to 60 seconds.
- Trials were conducted with test segments from both same and different phone numbers as the enrollment segment(s).
- There were no cross-gender trials.

The last two rows of Table 1 show the statistics for the SRE19 CTS Challenge *progress* and *test* subsets.

4. Performance Measurement

Similar to the past SREs, the primary performance measure for the SRE19 CTS Challenge was a detection cost defined as a weighted sum of false-reject (miss) and false-accept (false-alarm) error probabilities. Equation (2) specifies the CTS Challenge primary normalized cost function for some decision threshold θ,

$$C_{norm}\left(\theta\right) = P_{miss}\left(\theta\right) + \beta \times P_{fa}\left(\theta\right), \qquad (2)$$

where β is defined as

$$\beta = \frac{C_{fa}}{C_{miss}} \times \frac{1 - P_{target}}{P_{target}}. \qquad (3)$$

The parameters C_{miss} and C_{fa} are the cost of a missed detection and cost of a false-alarm, respectively, and P_{target} is the *a priori* probability that the test segment speaker is the specified target speaker. The primary cost metric, $C_{primary}$ for the CTS Challenge was the average of normalized costs calculated at two points along the detection error trade-off (DET) curve [10], with $C_{miss} = C_{fa} = 1$, $P_{target} = 0.01$ and $P_{target} = 0.005$. Here, $\log(\beta)$ was applied as the detection

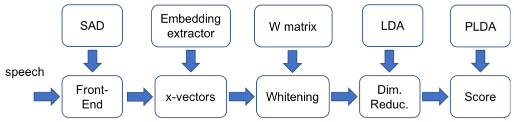

Figure 3: *A simplified block diagram of the baseline speaker recognition system for the SRE19 CTS Challenge.*

threshold θ for computing the actual detection costs. Additional details can be found in the SRE19 CTS Challenge evaluation plan [11].

Similar to the recent SREs (i.e., SRE16 and SRE18), the test data was divided into 16 partitions. Each partition is defined as a combination of: speaker gender (male vs female), number of enrollment segments (1 vs 3), enrollment-test phone number match (Yes vs No), and CTS source type (PSTN vs VoIP). However, because no actual "phone number" metadata was available for either enrollment or test segments extracted from the VoIP calls, the phone number match field only contained "N" for those calls, thereby reducing the effective number of partitions to 12. Also, all non-target trials are from the different (as opposed to the same) phone number partition, assuming each phone number would be only used by one individual. More information about the various partitions in the SRE19 CTS Challenge *progress* and *test* subsets can be found in Tables 2 and 3. $C_{primary}$ was calculated for each partition, and the final result was the average of all the partitions' $C_{primary}$'s.

Also, a minimum detection cost was computed by using the detection thresholds that minimized the detection cost. Note that for minimum cost calculations, the counts for each condition set was equalized before pooling and cost calculation, that is, the minimum cost was computed using a single threshold not one per condition set.

5. Baseline system

In this section, we describe the x-vector baseline system setup including speech and non-speech data used for training the system components as well as the hyper-parameter configurations used in our evaluations. Figure 3 shows a block diagram of the x-vector baseline system. The x-vector system is built using Kaldi [12] (for x-vector extractor training) and the NIST SLRE toolkit for back-end scoring.

5.1. Data

The x-vector baseline system was developed using the data recipes available at `https://github.com/kaldi-asr/kaldi/tree/master/egs/sre16/v2` as well as `https://github.com/kaldi-asr/kaldi/tree/master/egs/voxceleb/v2`. The x-vector extractor for the *progress* set was trained entirely using speech data extracted from combined VoxCeleb 1 and 2 corpora, while the x-vector extractor for the *test* set used the prior SRE data (i.e., SRE04-10 as in the Kaldi `sre16` recipe) in addition to the combined VoxCeleb. This was done to ensure the baseline results would serve as a fair comparison point for the first time participants who might only have access to the VoxCeleb data, but not to the prior SRE data. In order to increase the diversity of the acoustic conditions in the training set, a 5-fold augmentation strategy was used that added four corrupted copies of the original recordings to the training list. The recordings were corrupted by either digitally adding noise (i.e., babble, general noise, music) or convolving with simulated and measured room impulse responses (RIR). The noise and RIR samples are freely available from `http://www.openslr.org` (see [13] for more details).

All recordings are downsampled to 8 kHz using `sox`.

5.2. Configuration

For speech parameterization, we extracted 23-dimensional MFCCs (including c0) from 25 ms frames every 10 ms using a 23-channel mel-scale filterbank spanning the frequency range 20 Hz–3700 Hz. Before dropping the non-speech frames using an energy based SAD, a short-time cepstral mean subtraction was applied over a 3-second sliding window.

For x-vector extraction, an extended TDNN with 12 hidden layers and rectified linear unit (RELU) non-linearities was trained to discriminate among the speakers in the training set. After training, embeddings were extracted from the 512-dimensional affine component of the 11th layer (i.e., the first segment-level layer). More details regarding the DNN architecture (e.g., the number of hidden units per layer) and the training process can be found in [14].

Prior to dimensionality reduction through LDA (to 250), 512-dimensional x-vectors were centered, whitened, and unit-length normalized. The centering and whitening statistics were computed using the in-domain development data (i.e., LDC2019E59). For backend scoring, a Gaussian PLDA model with a full-rank Eigenvoice subspace was trained using the x-vectors extracted from either 170 k concatenated speech segments from the combined VoxCeleb sets (for the *progress* set), or 50 k speech segments from prior SRE data (for the *test* set), as well as one corrupted version randomly selected from {babble, noise, music, reverb}. The PLDA parameters were then adapted on the in-domain development data (i.e., LDC2019E59) using Bayesian maximum *a posteriori* (MAP) estimation.

Finally, the PLDA verification scores were post-processed using an adaptive score normalization (AS-Norm) scheme proposed in [15]. We used LDC2019E59 as the cohort set, and selected the top 10% of sorted cohort scores for calculating the normalization statistics.

It is worth emphasizing that the configuration parameters employed to build the baseline system are commonly used by the speaker recognition community, and no attempt was made to tune the hyperparameters or data lists utilized to train the models.

6. Results and Discussion

In this section we present some key results and analyses for SRE19 CTS Challenge submissions, in terms of minimum and actual costs as well as DET performance curves.

Figure 4 shows performance of the best submissions per team per subset as well as performance of the baseline systems [7] in terms of the actual and minimum costs, for the SRE19 CTS Challenge *progress* and *test* subsets, respectively. Baseline 1 and 2 denote the baseline speaker recognition systems trained without and with prior SRE data, respectively (see Section 5 for more details). Here, the y-axis limit is set to 0.5 to facilitate cross-system comparisons in the lower cost region. Several observations can be made from the two plots. First, performance trends on the two subsets are generally similar, although slightly better results are observed on the *progress* subset compared to the *test* subset, a phenomenon which is speculated to primarily result from overtuning/overfitting of the submission systems on the *progress* set. Second, nearly half of

Sadjadi, Omid; Greenberg, Craig; Singer, Elliot; Reynolds, Douglas; Mason, Lisa; Hernandez-Cordero, Jaime. "The 2019 NIST Speaker Recognition Evaluation CTS Challenge." Paper presented at The Speaker and Language Recognition Workshop: Odyssey 2020, Tokyo, JP. November 01, 2020 - November 05, 2020.

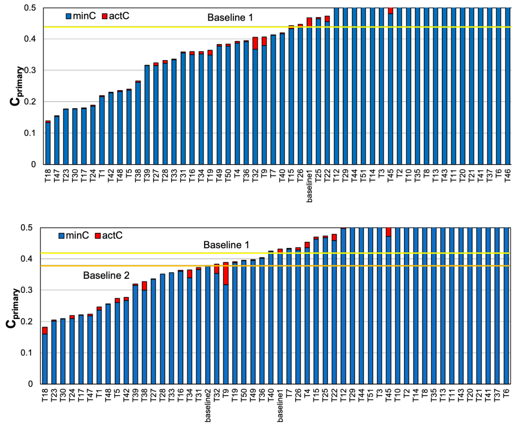

Figure 4: *Performance of the SRE19 CTS Challenge submissions in terms of actual (red) and minimum (blue) costs for the progress (top) and test (bottom) subsets.*

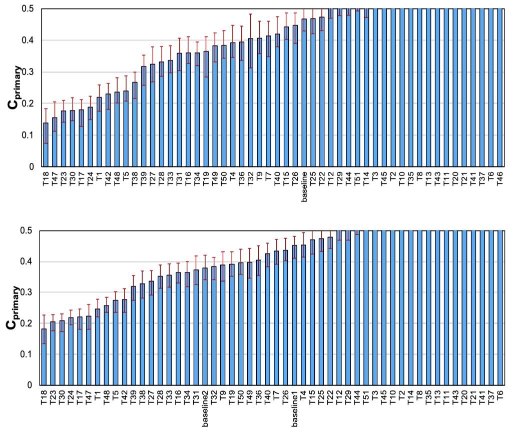

Figure 6: *Performance confidence intervals (95%) of the SRE19 CTS Challenge submissions for the progress (top) and test (bottom) subsets.*

the submissions outperform the baseline system trained on VoxCeleb (i.e., baseline 1), while the number is smaller when compared to the baseline that utilizes the prior SRE data. Third, a majority of the systems achieve relatively small calibration errors, in particular on the *progress* subset. This is in line with the calibration performance of the submitted systems observed for the SRE18 CTS domain. Finally, it can be seen from the figures that, except for the top performing team, the performance gap among the next top-5 teams is not remarkable. A statistical analysis of performance (e.g., confidence intervals for the cost estimates) that sheds more light on actual performance differences among the top performing systems follows later in this section.

Compared to the most recent SRE (i.e., SRE18), there is a notable improvement in speaker recognition performance. Figure 5 presents a performance comparison of SRE18 versus SRE19 CTS submissions for several top performing systems, in terms of actual and minimum detection costs. Performance improvements as large as 70% are achieved by some leading systems, while for others more moderate, but consistent, improvements are observed. These performance improvements are largely attributed to 1) the availability of large amounts of in-domain development data from a large number of labeled speakers (e.g., the entire SRE18 CTS development and test data, or other proprietary in-domain data), and 2) the use of extended and more complex end-to-end neural network frameworks for speaker embedding extraction that can effectively exploit vast amounts of training data made available through data augmentation and/or large-scale datasets such as VoxCeleb[3].

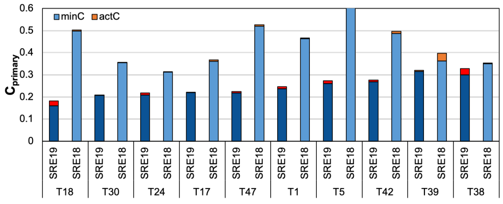

Figure 5: *Performance comparison of SRE18 vs SRE19 CTS submissions for several top performing systems.*

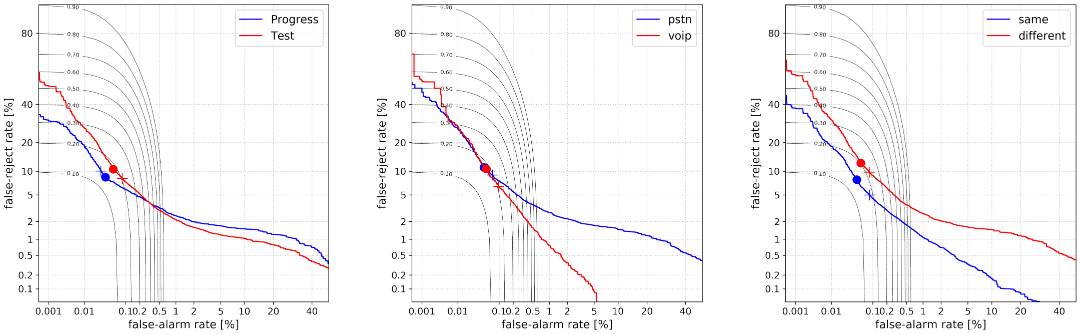
It is common practice in the machine learning community to perform statistical significance tests to facilitate a more meaningful cross-system performance comparison. Accordingly, to encourage the speaker recognition community to consider significance testing while comparing systems or performing model selection, we computed bootstrapping-based 95% confidence intervals using the approach described in [16]. To achieve this, we sampled, with repetition, the unique speaker model space along with the associated test segments 1000 times, which resulted in 1000 actual detection costs, based on which we calculated the quantiles corresponding to the 95% confidence margin. Figure 6 shows the performance confidence intervals (around the actual detection costs) for each submission for both the *progress* (top) and *test* (bottom) subsets. It can be seen that, in general, the *progress* subset exhibits a wider confidence margin than the *test* subset, which is expected because it has a relatively smaller number of trials. Also, notice that a majority of the top systems may perform comparably under different samplings of the trial space. Another interesting observation that can be made from the figure is that systems with larger error bars may be less robust than systems with roughly comparable performance but smaller error bars. For instance, although T_{18} achieves the lowest detection cost, it exhibits a much wider confidence margin compared to the second top system. These observations further highlight the importance of statistical significance tests while reporting performance results or in the model selection stage during system development, in particular when the number of trials is relatively small.

Figures 7a, 7b, and 7c show speaker recognition performance for the top performing submission in terms of DET curves as a function of: evaluation subset (i.e., *progress* vs *test*), CTS type (i.e., PSTN vs VoIP), and enrollment-test phone number match for PSTN calls (same vs different), respectively. The solid black curves in Figures 7a, 7b, and 7c represent equi-cost contours, meaning that all points on a given contour correspond to the same detection cost value. Firstly, consistent with our observations from Figure 4, the detection errors (i.e., false-alarm and false-reject errors) across the operating points of interest (i.e., the low false-alarm region) for the *test* subset are



(a) (b) (c)

Figure 7: *DET performance curves for the leading system by (a) data source (**progress** vs **test**), (b) CTS type (PSTN vs VoIP), and (c) enrollment-test phone number match (**same** vs **different**). Filled circles and crosses represent minimum and actual costs, respectively.*

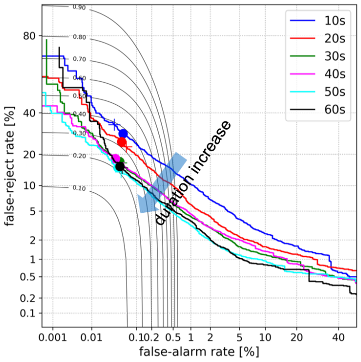


Figure 8: *DET curve performances of a top performing system for the various segment speech durations (10 s–60 s) in the test set.*

greater than those for the *progress* subset. In addition, the calibration error for the *test* subset is relatively larger. As noted previously, we speculate that these primarily result from overtuning/overfitting of the submission systems on the *progress* set. Secondly, contrary to the results observed on the SRE18 CTS domain where performance on the PSTN data was better than that on the VOIP data across all operating points, it seems from Figure 7b that for the operating points of interest (i.e., the low false-alarm region) the performance on the PSTN data is comparable to that on the VoIP data. We speculate this is due to the large amounts of VOIP data available for system development in SRE19 compared to SRE18 where only a small amount of VOIP development data was supplied. Finally, as expected, better performance is observed when speech segments from the same phone number are used in trials. Nevertheless, the error rates still remain relatively high even for the same phone number condition. This indicates that there are factors other than the channel (phone microphone) that may adversely impact speaker recognition performance. These include both intrinsic (variations in speaker's voice) and extrinsic (variations in background acoustic environment) variabilities.

Figure 8 shows DET curves for the various test segment speech durations (10 s–60 s) in the SRE19 CTS Challenge. Results are shown for a top performing submission. Limited performance difference is observed for durations longer than 40 s. However, there is a rapid drop in performance when the speech duration decreases from 30 s to 20 s, and similarly from 20 s to 10 s. This indicates that additional speech in the test recording helps improve the performance when the test segment speech duration is relatively short (below 30 seconds), but does not make a noticeable difference when there is at least 30 seconds of speech in the test segment. It is also worth noting that the calibration error (i.e., the gap between filled circles and crosses) increases as the test segment duration decreases.

7. Conclusion

In 2019, NIST organized the first leaderboard style SRE activity where raw CTS data (as opposed to embeddings) were provided as input to the systems. In this paper, we presented a summary of the SRE19 CTS Challenge (including the task, data, performance metric, the baseline system, as well as results and performance analyses) whose primary objectives were to systematically measure the recent progress in speaker recognition technology, in particular in the CTS domain, and to stimulate new ideas and collaborations. In addition, the CTS Challenge served as a prerequisite for the Audio-Visual SRE19. Results and analyses presented in this paper indicate great progress in speaker recognition technology compared to SRE18, with relative performance improvements as large as 70% for the leading system. Nevertheless, the performance gap on certain data partitions (e.g., PSTN vs VOIP or same vs different phone number) remains relatively large, at least for certain operating regions. This motivates further research towards developing a more robust technology that can maintain performance across a wide range of operating points and conditions (e.g., new data sources, languages, and channels).

8. Disclaimer

The results presented in this paper are not to be construed or represented as endorsements of any participant's system, methods, or commercial product, or as official findings on the part of NIST or the U.S. Government.

Certain commercial equipment, instruments, software, or materials are identified in this paper in order to specify the experimental procedure adequately. Such identification is not intended to imply recommendation or endorsement by NIST, nor is it intended to imply that the equipment, instruments, software or materials are necessarily the best available for the purpose.

HALO – High Amplification Laser-pressure Optic

Alexandra Artusio-Glimpse, Kyle Rogers, Paul Williams, and John Lehman

National Institute of Standards and Technology, Boulder CO, USA
Corresponding e-mail address: alexandra.artusio-glimpse@nist.gov

Efforts are underway at the National Institute of Standards and Technology to drastically reduce the uncertainty of laser power measurements using radiation pressure. The High Amplification Laser-pressure Optic (HALO) system is a cornerstone of this effort as it enables amplification of the laser pressure on a high-quality mirror attached to a precision force sensor. We discuss the HALO architecture here.

MOTIVATION

Laser power measurements based on radiation pressure (RP) use the force of light as it reflects from a mirror to characterize the optical power. Here, we work to reduce measurement uncertainty by amplifying the force of the laser light. If the same light reflects multiple times from the sensing mirror of an RP detector, a passive gain can be realized [1,2]. For decades, the cryogenic radiometer standard has yielded relative measurement uncertainties of 10^{-4} at the milliwatt level. Meanwhile, power measurements above 100 W have relative uncertainties near 10^{-2} for both calorimetric-based and RP-based measurements. By amplifying the force of RP with a multi-reflection optical system, we expect laser power measurement uncertainties to approach 10^{-4} for kilowatt level incident powers.

For a RP measurement where the light reflects N times off the sensing mirror having reflectance R given a round-trip scattering and absorption loss L the signal to noise ratio (SNR) goes as

$$SNR \propto \sum_{j=1}^{N}\big((1-L)R\big)^{j-1}, \qquad (1)$$

which approaches N as $(1-L)R \rightarrow 1$. Absorption in the sensing mirror can heat the force sensor and produce a measurement error $N\eta_T\Delta T_1$ where η_T is the temperature-dependent error coefficient and ΔT_1 is the change in temperature of the force sensor for a single reflection. Thus, for low-loss, high-reflectivity optics, we approximate the fractional measurement error as

$$\varepsilon \approx (\eta_1/N + \eta_T\Delta T_1)/F_1, \qquad (2)$$

where η_1 represents the averaged noise and F_1 the measured force, both for a single reflection. We see that amplifying the force of a single reflection with N reflections, we effectively reduce the fractional contribution of the fixed noise by N, but have no effect on the thermal contribution.

Here we describe a system designed for $N \leq 15$ bounces and accommodating the 40 mm diameter beam from a 10 kW infrared laser. Current efforts emphasize the design and system tolerances, while forthcoming efforts will develop an alignment procedure and mirror reflectance and scatter measurements to meet preliminary tolerances. These are steps toward our goal of achieving relative measurement uncertainties approaching those currently found only in cryogenic radiometers. Moreover, our multi-reflection system can be used to amplify lower power lasers, enabling us to reduce the measurement uncertainty of any RP measurements.

HALO DESIGN

The NIST High Amplification Laser-pressure Optic (HALO) system is depicted in Fig. 1 with a green HeNe laser (5 mW) illuminating the beam path, reflecting off the sensing mirror 14 times, and leaving the system to the upper right.

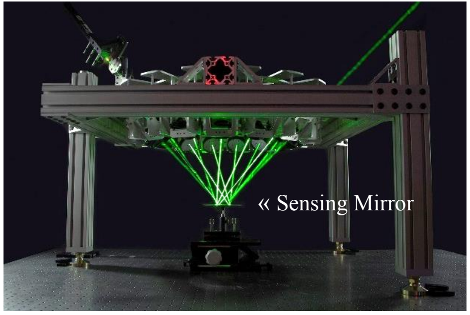

Figure 1. HALO system photograph. A green HeNe illuminates the laser path through 14-bounces and out the system to a beam dump (not shown) at the upper right.

HALO is a pentadecagonal structure with an entrance port and up to 14 upper mirror modules ("ring mirrors", see Fig. 2) that direct the input laser beam to a lower sensing mirror. Importantly, the laser incidence angle on the sensing mirror is always 45°. This both protects the mirror from thermal flexing as the reflectance need only be optimized for a single

Artusio-Glimpse, Aly; Rogers, Kyle; Williams, Paul A.; Lehman, John H. "HALO - High Amplification Laser-pressure Optic." Paper presented at NEWRAD 2020, 14th International Conference on New Developments and Applications in Optical Radiometry, Boulder, CO, US. June 23, 2020 - June 26, 2020.

angle and simplifies propagation of uncertainties. The total structure fills a volume of about 1 m^3. Like toroidal multipass cells used for laser spectroscopy [3], the laser beam traces out a star polygon (Fig. 2). However, here the ring mirrors are pitched downward to the sensing mirror placed at the center of the star pattern. When all 14 ring mirrors are in place, the total beam path in the system is 10.124 m.

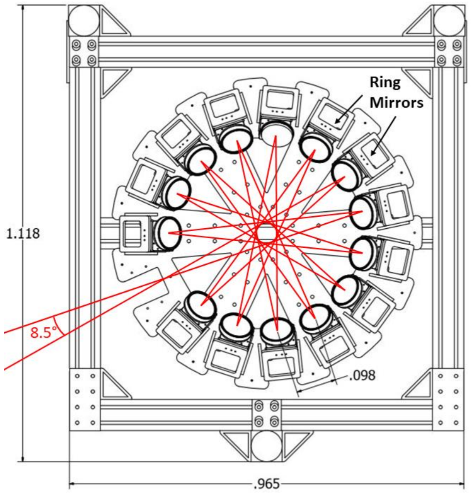

Figure 2. Upper ring mirror modules and star polygon laser path when all 14 mirrors (76.2 mm diameter) are in place. Laser enters through the empty port and exits through the same port, rotated by 8.5°. Alternatively, the laser may exit through any other port when the respective mirror module is removed. (labels in meters)

The spot pattern of the laser on the 150 mm diameter sensing mirror forms two open crescent shapes as the laser beam rotates and expands through the system (Fig. 3). Given the short (90 µm) coherence length of our laser and the large incidence angles and long path length differences between adjacent spots in this system, interference is not a concern.

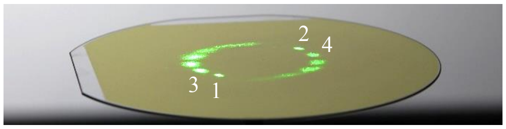

Figure 3. Green HeNe laser spot pattern is visible on the surface of a gold coated fused silica 150 mm diameter wafer. First four bounces of 14 total are labeled.

TIGHT TOLERANCES AND OUTLOOK

In order to reach 10^{-4} uncertainty, near perfect laser alignment and highly-accurate optical characterization of each mirror (reflectance, scatter, absorptance) will be required. As such, our first goal is to reach a relative measurement uncertainty of 10^{-3} at 10 kW.

We simulated laser propagation through the HALO system and modulated geometric and optical parameters to obtain system tolerances. The results of the ray-tracer and Monte Carlo algorithm are listed in Table 1 (totals exclude the force sensor [4]).

Table 1. Alignment and optical measurement tolerances needed to reach two relative uncertainty goals.

Rel. Unc. Goal	10^{-3}	10^{-4}
Sensing Mirror Angle	60 µrad	30 µrad
Ring Mirror Angle	300 µrad	30 µrad
All Mirrors 3D Position	2 mm	2 mm
Reflectance/Scatter	20x10^{-6}	1x10^{-6}
Total Optical Rel. Unc	0.7x10^{-3}	0.75x10^{-4}

In addition to tight system tolerances, if the sensing mirror is bowed, the laser will accumulate astigmatism, as is the case in Fig. 3 where the spots grow in ellipticity as the number of bounces increases. The HALO structure must also be rigid and isolated from vibrations to maintain these tolerances. To reach the 10^{-4} uncertainty goal, simply knowing total scattered power is not enough. The full bidirectional scatter distribution function must be accounted for in the momentum calculations else the calculated laser power from the measured force will be in error by an order of 10^{-4}.

The NIST HALO system has been built and its alignment demonstrated with a low-power, small diameter laser. We now set our attention to alignment with high reflectivity IR mirrors and measurement of a 500 W laser. This incremental advancement is necessary as we progress toward a RP laser power measurement system that will yield measurement uncertainties of 10^{-4} at 10 kW.

Ion-beam radiation damage to DNA by investigation of free radical formation and base damage

Melis Kant[a], Pawel Jaruga[a], Erdem Coskun[a], Samuel Ward[b], Alexander D. Stark[b], David Becker[b], Amitav Adhikary[b], Michael D. Sevilla[b] and Miral Dizdaroglu[a]
[a] Biomolecular Measurement Division, National Institute of Standards and Technology, Gaithersburg, MD, 20899, USA
[b] Department of Chemistry, Oakland University, Rochester, MI 48309, USA

This work investigated the physicochemical processes and DNA base products involved in Ne-22 ion-beam (*ca*. 1.4 GeV) radiation damage to hydrated (12 waters/nucleotide) highly polymerized salmon sperm DNA. For this purpose, approximately 12 small (*ca.* 10 mm x 4 mm x 1 mm) samples were stacked in a sample packet and then ion-beam irradiated at 77 K. Free radicals trapped in ion-beam irradiated DNA at 77 K were elucidated using ESR spectroscopy. After warming the samples to room temperature, the measurement of DNA base damage by GC-MS/MS and LC-MS/MS with isotope dilution revealed the formation of a plethora of products from all four DNA bases, and also the formation of 8,5′-cyclopurine-2′-deoxynucleosides, namely 5′*R*-cyclo-dAdo, 5′*S*-cyclo-dAdo, 5′*R*-cyclo-dGuo and 5′*S*-cyclo-dGuo. This work is the first to use the combination of ESR and mass spectrometry, enabling a better understanding of the mechanisms of radiation damage to DNA along the ion-beam track in terms of the formation of DNA free radicals and products. ESR measurements showed that, as the linear energy transfer (LET) profile of ion-beam radiation increases, the production of cation, anion and neutral radicals of DNA increases along the ion-beam track. The yields of DNA damage products along the ion-beam track were in excellent agreement with the radical production. Because the probability of recombination of DNA radicals in the core increases due to the rise in concentration of proximate ion radicals, the location of the highest energy deposition, the Bragg peak, may show different damage and may not be the location of the maximum damage.

Measurement of PARP1 in human tissues by liquid chromatography tandem mass spectrometry

Erdem Coskun [a,b], Gamze Tuna [a,c], Pawel Jaruga [a], Alessandro Tona [a], Onur Erdem [a,d], Miral Dizdaroglu [a]

Poly(ADP ribose) polymerase 1 (PARP1) is a multifunctional DNA repair protein of the base excision repair pathway and plays a major role in the repair of DNA strand breaks and in replication and transcriptional regulation among other functions. Mounting evidence points to the predictive and prognostic value of PARP1 expression in human cancers. Thus, PARP1 has become an important target in cancer therapy, leading to the development of inhibitors as anticancer drugs. In the past, PARP1 expression levels in tissue samples have generally been estimated by indirect and semi-quantitative immunohistochemical methods. Accurate measurement of PARP1 in normal tissues and malignant tumors of patients will be essential
for evaluating PARP1 as a predictive and prognostic biomarker in cancer and other diseases, and for the development and use of its inhibitors in cancer therapy. In this work, we present an approach involving liquid chromatography–isotope-dilution tandem mass spectrometry to positively identify and accurately quantify PARP1 in human tissues and cultured cells. We identified and quantified PARP1 in human normal ovarian tissues and malignant ovarian tumors, and in three pairs of human cell lines, each pair consisting of a normal cell line and its cancerous counterpart. Significantly greater expression of PARP1 was observed in malignant ovarian tissues than in normal ovarian tissues. In the case of one pair of cell lines, the cancerous cell line also exhibited greater expression of PARP1 than in normal cell line. We also show the simultaneous measurement of PARP1 and apurinic/apyrimidinic endonuclease 1 (APE1) in a given protein extract. The approach presented in this work is expected to contribute to the accurate quantitative assessment of PARP1 levels in basic research and clinical studies.

Measurement of mass loss, absorbed energy, and time-resolved reflected power for laser powder bed fusion

David C. Deisenroth[a], Sergey Mekhontsev, Brandon Lane
National Institute of Standards and Technology[b], 100 Bureau Drive, Gaithersburg, MD 20899

ABSTRACT

Laser powder bed fusion processes are driven by scanned, focused laser beams. Along with selectively melting the metal powder, laser energy may be converted and transferred through physical mechanisms such as reflection from the metal surface, heat absorption into the substrate, vaporization, spatter, ejection of heated particles, and heating of the metal vapor/condensate plume that is generated by the laser-metal interaction. Reliable data on energy transfer can provide input for process modeling, as well as help to validate computational models. Additionally, some related process signatures can serve better process monitoring and optimization. Previous studies have shown that the proportion of the transfer mechanisms depend on laser power, spot size, and scan speed. In the current investigation, the energy conservation principle was used to validate our measurement of reflected energy, absorbed energy, and energy transfer by vaporization on bare plates of Nickel Alloy 625 (IN625). Reflected energy was measured using an optical integrating hemisphere, and heat absorbed into the substrate was measured by calorimetry. Transfer from vaporized mass loss was measured with a precision balance and used to establish an upper bound on energy transfer by mass transfer. In addition to measurement of total reflected energy, the reflected laser power was time-resolved at 50 kHz in the integrating hemisphere, which provided insight into the process dynamics of conduction, transition, and keyhole modes.

Keywords: Laser powder bed fusion, laser coupling, energy transfer in laser melting

1. INTRODUCTION

Metal laser powder bed fusion (LPBF) uses selective laser melting of metal powder to additively manufacture a part layer by layer. Complex physical phenomena occur at the laser-metal interaction area due to phase transitions, vapor pressure, surface tension gradients, wetting effects, melt dynamics, and more[1–3]. The energy density applied to the material has a strong effect on the physics that occur in the meltpool, and ultimately on the outcome of the laser melting process.

There are varying definitions of energy density reported in terms of energy divided by length, energy divided by volume, etc., but for the purposes of the current discussion, a strict definition of energy density is not necessary[4,5]. Regardless of definition, it is qualitatively known that the energy density is proportional to applied power and inversely proportional to scan velocity and beam spot size. Therefore, for a given spot size and scan velocity, decreased laser power decreases meltpool width and depth[6].

The energy density applied to the material is also related to the rate of metal vapor generation from the process. At process conditions producing little to no vapor jet, "conduction mode" occurs. Conduction mode is associated with meltpool aspect ratio (depth divided by ½ the width) of less than unity[7]. Among other defects, insufficient energy density is associated with lack of fusion and balling defects in LPBF[8]. At higher energy densities that result in a high rate of vapor generation, the process transitions into "keyhole mode," in which the meltpool depth increases substantially and the aspect ratio can become much greater than unity. A steep increase in laser power/energy absorption is associated with the transition from conduction mode to keyhole mode due to multiple reflections in the deep cavity formed in the meltpool by the vapor recoil pressure[9–11]. Among other defects, excessive or unstable keyholing is associated with residual porosity and loss of volatile alloy components[12,13].

The ability to measure the power and energy transfer that occur in this complex physical process enhances understanding of the process, aids in validation of computational models, and will ultimately help to improve the quality of parts built

Deisenroth, David; Mekhontsev, Sergey; Lane, Brandon. "Measurement of mass loss, absorbed energy, and time-resolved reflected power for laser powder bed fusion." Paper presented at SPIE Photonics West, San Francisco, CA, US. February 01, 2020 - February 06, 2020.

with LPBF. This preliminary investigation sought to measure the energy transfer of the laser melting process via absorption, reflection, and vaporization. Heat energy absorbed by the substrate was measured via calorimetry and evaporated energy was estimated by mass transfer. Reflected laser energy was measured as time-resolved reflected power at 50 kHz, which provided an additional wealth of information about the dynamics of the process in conduction, transition, and keyhole mode.

Measurement of light reflected from laser melting of metal is a very challenging application of reflectometry. The laser-metal interaction area is a highly dynamic reflective surface, which may potentially cause loss of reflected light from the reflectometer when reflected light propagates in the direction with a reduced throughput; the throughput is the ratio of the flux reaching the detector to the input flux from the source. The incident and reflected light can also be scattered and absorbed by the hot metal plume. At the current state of development, these two potentially important losses could not be quantified, although possible avenues for minimizing and/or measuring those effects are in progress. Nevertheless, the sum of the absorbed, reflected, and evaporated energy compared with the input laser energy places bounds on the combined effects of reflected light or energy absorption by the plume.

Laser power reflectometry can complement thermographic measurements and provide additional insight into the complex processes involved in building thin walls and overhangs. Full hemispherical capture of reflected light imposes significant limitations on the process laser incident angles and can find only a limited use in multilayer builds, which will be discussed in the following sections. As an additional benefit, reflected laser power also appears to be a highly useful process monitoring signature for defect detection[14].

2. EXPERIMENTAL METHODS

The experiments reported here were performed in the National Institute of Standards and Technology (NIST) Additive Manufacturing Metrology Testbed (AMMT)[15,16]. The AMMT is a custom LPBF research platform that was designed to be highly configurable for measurement of all aspects of the LPBF process. The AMMT includes a removable carriage that contains the build-well and a large metrology-well, both of which may be moved laterally within the large build chamber. The laser is an Yb-doped fiber laser with emission wavelength of 1070 nm. Laser power delivery can be adjusted from 20 W to more than 400 W, with a 4-sigma diameter (D4σ, representing diameter within which about 95 % of the Gaussian laser power profile is contained) spot size that is adjustable from 45 µm to more than 200 µm. The laser spot can be scanned with full control of the laser scan path/strategy at 100 kHz and laser power control at 50 kHz, with scan velocity from 0 mm/s to more than 4000 mm/s.

In the current investigation, all scans were performed with a velocity of 500 mm/s, a D4σ spot size of 65 µm, and laser power ranging from 50 W to 300W. The working material was rolled and annealed bare plates of Nickel Alloy 625 (IN625)[c] to avoid the measurement complications imposed by powder in this validation experiment. The manufacturer-reported composition of the Alloy 625 material used in this investigation are shown in Table 1.

Table 1. Constituents by mass % of IN625 used in this investigation

Element	Ni	Cr	Mo	Fe	Nb	Mn	Al	Ti
Mass %	60.6	21.98	8.4	4.38	3.44	0.35	0.21	0.21
Element	Si	Cu	C	Co	Ta	P	S	
Mass %	0.19	0.08	0	0.04	0.01	0.01	0.0001	

The surfaces of the plates were ground with 400 grit silicon carbide paper. The samples were assured to be within ±20 µm flatness and levelness of the build plane, resulting in an additional spot size uncertainty of ±1.3 µm due to the known caustic (solid angle of convergence). The following three experimental subsections will describe the approaches used for the three primary measurands: mass loss, laser energy absorption, and reflected laser power. It should be noted that the

[c] Certain commercial entities, equipment, or materials may be identified in this document to describe an experimental procedure or concept adequately. Such identification is not intended to imply recommendation or endorsement by the National Institute of Standards and Technology, nor is it intended to imply that the entities, materials, or equipment are necessarily the best available for the purpose.

reflected power and absorbed energy experiments were done simultaneously, and the mass loss experiments were performed separately on a larger workpiece.

2.1 Mass loss

For measurement of mass loss caused by liquid metal spatter and/or vaporization, IN625 samples with ground surfaces were carefully cleaned with acetone and ethanol to remove debris. The samples were then stored in dry air for 24 hours to remove adsorbed water. The samples were transported in air-tight containers and then weighed on a precision balance. The laser melting process was performed with directional shield gas flow horizontal across the process at about 8 m/s, which was assumed to transport all of the spattered or evaporated material off of the 25 mm × 25 mm × 3 mm sample. After melting, the samples were carefully cleaned and dried again, then weighed.

The primary measurand was mass transfer, but an estimate of how much energy was transferred from the process due to mass loss can also be obtained. The upper bound of energy transfer due to the mass loss is found by assuming that all of the mass was evaporated. Any material that is evaporated absorbs heat energy through five modes in the transition from room temperature solid to superheated vapor, as shown in Equation (1).

$$E_{evap} \approx \Delta m[c_{p,sol}(T_m - T_r) + h_{fus} + c_{p,liq}(T_b - T_m) + h_{vap} + c_{p,vap}(T_{max} - T_b)] \quad (1)$$

Heat is first absorbed by the solid. The solid absorbs energy proportionally to the specific heat ($c_{p,sol}$) and the temperature rises from room temperature (T_r) to the to the melting temperature (T_m). Heat is then absorbed as the latent heat of fusion (h_{fus}) in the phase change from solid to liquid. The material is next heated as a liquid ($c_{p,liq}$) from the melting temperature to the boiling temperature (T_b). The largest energy transition is in the phase change from liquid to vapor (h_{vap}). Finally, the vapor is heated from the boiling temperature (T_b) to the maximum temperature the material reaches (T_{max}).

All values for the material heat capacity and latent heat were taken as the conservatively high values found in available literature. The solid specific heat is temperature dependent and was taken as the average value of about 0.6 J/g·K in the temperature range between room temperature and the melting temperature[17] of about 1300 °C. The latent heat of fusion is highest at the slowest cooling rates and was taken as the conservatively high value[18] of 290 J/g. Information on the heat capacities of IN625 is sparse above the melting point, but using the properties of the majority constituent (Ni) is a reasonable approximation[19]. The liquid latent heat[19] was taken to be 0.73 J/g·K up to Ni boiling point[20] of 2913 °C. Information on the specific heat of metal vapors is very sparse, so it was conservatively assumed that the vaporous specific heat was equivalent to that of the liquid. Precise temperatures of superheated vapor are also unknown, so it was conservatively assumed that the vapor temperatures reach up to 4500 °C. As stated previously, the phase transition from liquid to vapor is the largest energy conversion in the heating process; indeed, this single energy conversion amounts to about double the energy conversion of the solid-liquid phase change and other heating, combined.

Vaporization rates of liquid mixtures are dependent on the concentration of the constituents and the temperature difference between the vaporization temperature of each constituent and the hottest local material. Therefore, additional information is required to precisely calculate how much energy is converted by vaporization of IN625. Nevertheless, it is known that the latent heat of vaporization of the constituents, comprising about 85 % of IN625[21], is within ±5 % of 6.5 kJ/g. The remaining constituents are refractory and trace elements, and so it is a reasonable assumption that the mass loss can be converted to energy within a reasonable margin of uncertainty with this simplified approach. Uncertainty will be discussed in the next subsection.

2.2 Mass loss uncertainty

The balance used to measure the mass loss has a resolution of 0.01 mg and reproducibility of 0.015 mg for a combined mass uncertainty for a given measurement of 0.018 mg, and a mass change uncertainty of 0.025 mg. Estimating the uncertainty of the energy transfer due to the mass loss is far less straightforward, and given the assumptions, an conservative uncertainty of ±30 % was applied. It will be shown in the results section that the energy transferred to mass loss—with conservative assumptions and generous uncertainty assignment—was small compared to the uncertainty of the absorbed energy and reflected energy, precluding the need for further refinement of this energy transfer calculation. The next section will discuss the experimental methods used to measure energy absorbed into the workpiece.

2.3 Absorbed thermal energy

A small sample of about 3 mm × 3 mm × 8 mm was used for the simple calorimetry approach employed here. After surface preparation and attaching a calibrated thermistor, the sample was mounted on low thermal conductivity polymer pedestals. For low laser powers, longer and/or more scan lines were applied to the workpiece and in all cases a temperature rise of between 2.5 °C and 7.5 °C occurred in the workpiece. All scan tracks that were applied in immediate succession were spaced at least 300 µm apart to assure minimal thermal or metallurgical interaction between adjacent scans. The maximum scan time of 110 ms occurred at 50 W laser power. Three-dimensional finite element transient conduction simulations were performed to determine the time required for the workpiece to reach a temperature uniformity within that of the thermistor measurement uncertainty, which was a maximum of 10 s. The data after 10 s were then curve-fitted with Equation (2).

$$T(t) = T_0 + (T_e - T_0)e^{-t/\tau} \tag{2}$$

In Equation (2), $T(t)$ is the fitted temperature function of the thermistor temperature, T_0 is the initial temperature, T_e is the equivalent uniform initial temperature of the workpiece, t is time, and τ is the fitted curve time constant. All curve fits of the experimental data exhibited $R^2 > 0.9999$. Three-dimensional transient conduction simulations were also performed to assure that there was not an inordinate difference in average workpiece temperature decay between the highly non-uniform experimental surface temperature distribution in the initial 10 s and the ideal uniform workpiece surface temperature. The difference was found to be negligible compared to the measurement uncertainty. The equivalent uniform workpiece temperature (T_e) at 0 s was then used to find the absorbed laser energy (E_{abs}) with Equation (3), in which m is the workpiece mass and c_p is the workpiece specific heat.

$$E_{abs} = mc_p(T_e - T_0) \tag{3}$$

2.4 Absorbed thermal energy uncertainty

The uncertainty caused by the heat generation of the thermistor and the uncertainty of the mass of the sample were found to be negligible components of the uncertainty of the absorbed energy. The error in scan time is also believed to be negligible in the current investigation, leaving the remaining components to be those due to the uncertainty in specific heat and temperature rise of the workpiece. The temperature-dependent specific heat of IN625 was reported with standard uncertainty (1σ) of ±1.5 % by Pawel and Williams[22]. The uncertainty of the thermistor was 0.1 °C, resulting in a temperature difference uncertainty of 0.14 °C. These values were then incorporated into the standard propagation of uncertainty for each experiment. The next section will discuss the most challenging measurement of the current investigation, which was measurement of time-resolved reflected power.

2.5 Time-resolved reflected power

An ideal integrating sphere would capture all the light emanating from a source within the sphere, regardless of the direction, collimation, or transient nature of the light. Although an ideal integrating sphere is not possible in practice, appropriate provisions allow for highly efficient capture and measurement of the intensity of integrated light, regardless of how it is emanated. In the current application, the laser power reflected from the laser-melting process was measured.

The design of the integrating apparatus was constrained by the size of the build chamber, the necessary gas flow provisions for laser-metal interaction, and fabrication limitations. Use of a hemisphere instead of a full sphere allowed for a small laser-entrance port size and sample port size, relative to the total integration area, while fitting within the height of the build chamber of the AMMT. The integrating hemisphere was designed using as many best-practices as possible for isotropic throughput[23,24]. A cross-section view of a computer aided design model of the integrating hemisphere is shown in Figure 1, below. As shown, integration is facilitated by a diffuse, barium sulfate coating and with a specular, polished aluminum base. The focused laser light is directed through an elongated port on the top of the hemisphere, about 8° from vertical. The design allows scans to be done in an area of about 3 mm × 20 mm.

Another design constraint is the inert gas atmosphere required for laser melting to reduce detrimental oxidation[25]. Previous studies have shown that directional and inert shield gas flow is essential to facilitate continuous, consistent beam delivery by removing process biproducts that can distort, scatter, and obstruct beam delivery[26–28]. The base of the hemisphere was designed to be 6.7 mm thick due to an incorporated directional shield gas flow and oxygen sampling provision, shown in

Deisenroth, David; Mekhontsev, Sergey; Lane, Brandon. "Measurement of mass loss, absorbed energy, and time-resolved reflected power for laser powder bed fusion." Paper presented at SPIE Photonics West, San Francisco, CA, US. February 01, 2020 - February 06, 2020.

Figure 1. In the current investigation, laser scanning occurred in the direction perpendicular to the image plane of Figure 1, perpendicular to the directional shield gas flow.

Upon reaching the sample, some of the laser light is absorbed, causing melting, and some is reflected. The thickness of the base of the dome acts as a baffle and results in a reflected light capture angle of about 135°, as shown in Figure 1. The photodetectors (PD's) were located as close as possible to the equator of the hemisphere. At this location, the base thickness has a beneficial baffle-effect, and prevents deleterious direct viewing of reflected light by the PD's, which would circumvent integration. The base thickness, though, causes a loss of light in the remaining 45° of the hemisphere, which is not integrated. In practice, reflections from the laser-metal interaction at an angle less than 22° from the horizontal are unlikely, but possible, and the associated measurement uncertainty will be discussed in the uncertainty section. The fabricated base, hemisphere interior, and assembled integrating hemisphere are shown in Figure 2.

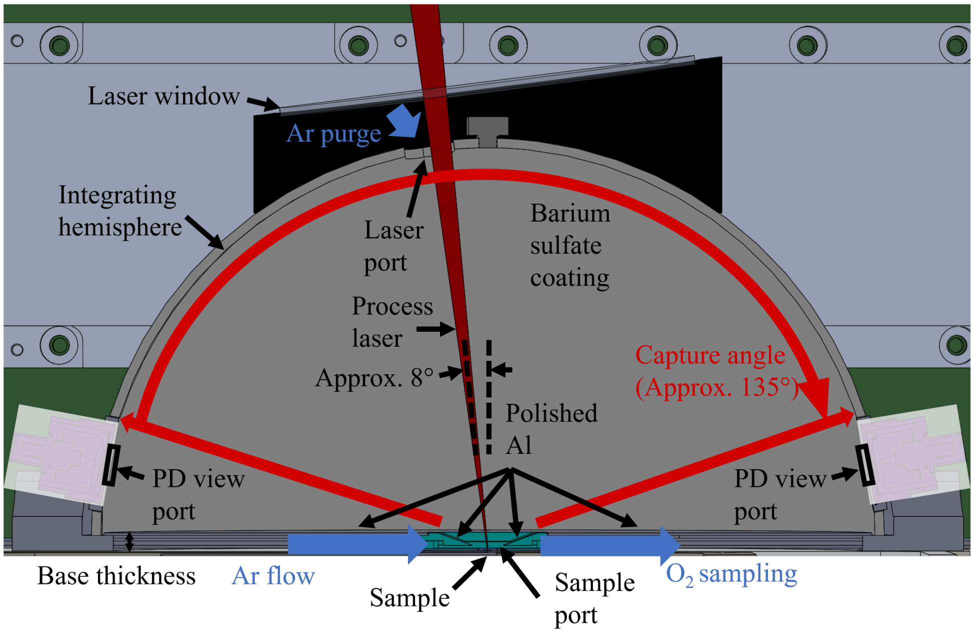

Figure 1. Cross-section view of a computer aided design model of the integrating hemisphere

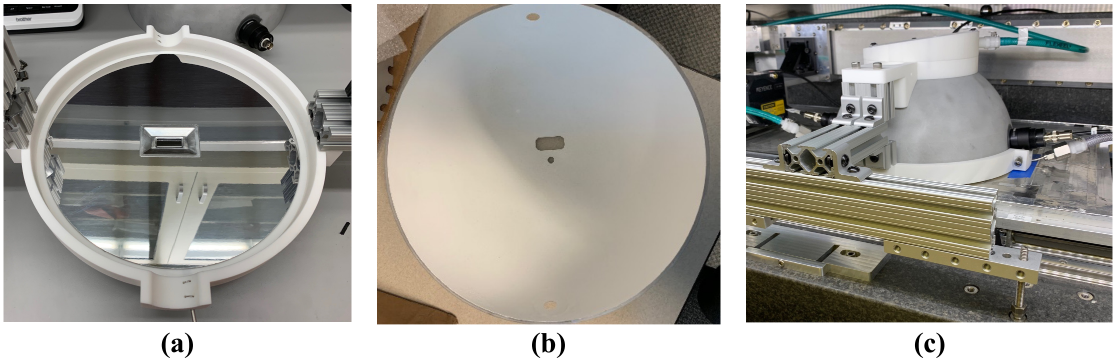

Figure 2. Images of the fabricated integrating hemisphere (a) specular base, (b) barium sulfate coated hemisphere interior, (c) assembled apparatus in build chamber.

The reflected power captured by the integrating hemisphere reflectometer was measured at a rate of 50 kHz. The PD signal was calibrated with a reflectance standard with reflectance of 0.98 at 1070 nm. The heating laser was defocused and directed onto the specular standard in order to correlate the PD signal with applied power. To convert the transient power measurements into total reflected energy from the process, the power was simply integrated in time, as shown in Equation (4).

$$E_{ref} = \int P_{ref}(t)\, dt \qquad (4)$$

2.6 Time-resolved reflected power uncertainty

The light loss due to the laser port and base thickness on the first reflection from the sample were measured by comparing the measured signal with a specular silver standard and a diffuse gold standard. On the first reflection, a specular sample does not result in any port loss or high angle loss. In contrast, a perfectly diffuse sample results in both high angle and port losses. After accounting for the reflectivity of the samples, it was found that the discrepancy was 2.5 % in intensity. Combined with the applied power (calibration) uncertainty of 2.5 %, the resulting reflected power uncertainty is 3.5 %. This value is taken as the estimated (Type B) standard uncertainty for the reflected power[29].

Throughput mapping of the inside of the hemisphere was performed to assure that, aside from the known losses, the relative location-dependent throughput of the integrating surface was uniform. The throughput is the ratio of the flux reaching the detector to the input flux from the source. Throughput mapping was performed with illumination around the equator of the hemisphere via 36 LED's at 850 nm wavelength. The reflectance of barium sulfate is expected to be similar in value at the LED and laser wavelengths. A photodetector was then placed at the entrance port and a gimbal-mounted mirror was mounted at the sample port. The mirror was aimed at a representative number of locations across the inside of the hemisphere. Although the mapping is not a perfect representation of the actual application, it is a good representation because of the similarity of reflectance at the LED and laser wavelengths and the known reciprocity of directional-hemispherical and hemispherical-directional measurements. Therefore, the measurements assure that there are no significant, unforeseen non-uniformities on the integrating surface.

As shown in Figure 3, the throughput uniformity of the surface is within ±1 % across the majority of the surface. It should be kept in mind that due to the Mercator projection; the corresponding true surface area is reduced by the cosine of the vertical angle. Thus, the entrance port area appears significantly greater than its true relative surface area. As was anticipated, significant losses and errors occur at a vertical angle of less than 22°.

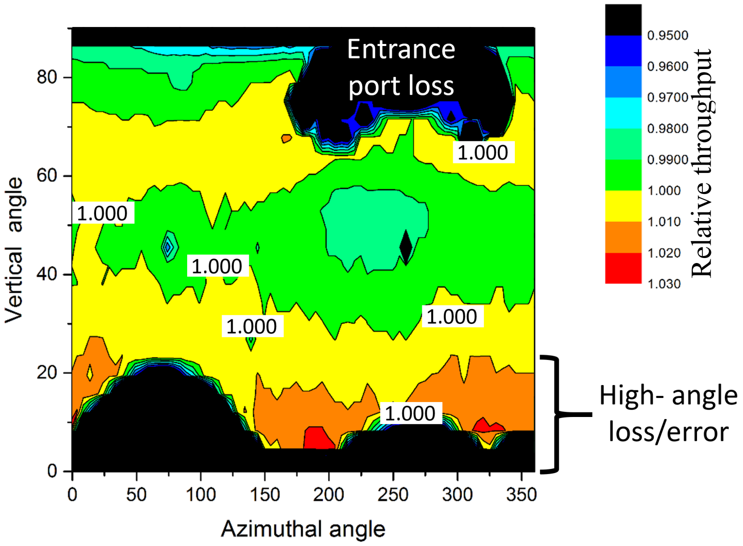

Figure 3. Relative throughput of the hemispherical integrating surface, shown in a Mercator projection.

At the current state of development, there are some significant unknowns about the character of the reflection from the laser-metal interaction. Depending on the applied energy density, the laser incident surface may be steeply inclined, and can reflect light forward along the scan direction, upward, or opposite to the scan direction[30,31]. The laser melting process is also highly dynamic, causing the reflective surface to rapidly change in time.

Further complicating matters, suspended vapor/condensate plume directly above the workpiece surface may also scatter and absorb both the incident and reflected laser light[32]. Incident laser light absorbed by the plume does not reach the workpiece and would not be measured by either calorimetry or reflectometry, which means that the fidelity of neither calorimetry nor reflectometry is compromised by incident laser light absorbed by the plume. Fidelity is retained because the energy reaching the workpiece is reduced and that would be accurately measured. However, plume absorption may affect the laser energy density applied to the surface, and thereby affect the melt pool formation and characteristics.

Incident laser light scattered by the plume may potentially be integrated and registered as light reflected from the workpiece, causing an erroneously high reflected light measurement. Laser light reflected from the workpiece that is then absorbed by the plume may cause an erroneously low measurement of the reflected power. Finally, laser light reflected from the workpiece that is then scattered by the plume would aid in integration, and therefore, not affect reflected power measurement. In summary, incident laser light scattering and reflected light absorption have counteracting erroneous effects on reflectometry, which are not yet well understood.

Therefore, with reflectometry alone, a significant portion of the reflected laser light could be lost or detected as erroneous reflection. Hence, the current investigation has sought to measure the sum of the measured reflected laser energy, the heat absorbed by the substrate, and the energy transfer to vaporization as a preliminary investigation into the magnitude of the combined measurement error and process energy loss to the plume.

The results of mass and energy transfer by vaporization or spatter, time-resolved reflected laser power, calorimetry, and combined energy balance will be presented in the following sections. It should be noted that the results shown in the "time-resolved reflected power" section were obtained with a more rudimentary experimental reflectometer setup than was described in this section, so the absolute values of normalized reflected power have greater uncertainty and port loss than the rest of the results. Nevertheless, the results are used to demonstrate the wealth of data that can be obtained with time-resolved non-contact reflectometry at 50 kHz.

3. RESULTS AND DISCUSSION

Examples of the melt tracks generated from the combined absorption and reflected power experiments are shown first, followed by the results of the mass and energy transfer due to vaporization. Then, time-resolved reflected power measurements with 20 mm long tracks with examples in conduction, transition, and keyhole mode are shown. And finally, the primary result of this effort, the combined energy balance obtained with the three forms of measurement, are discussed.

3.1 Melt tracks from reflectometer and calorimetry experiments

Examples of the melt tracks generated from the combined absorption and reflected power experiments are shown in Figure 4. The laser power at which the tracks were scanned are labeled. The tracks at each power were scanned from left to right and the track succession is from top to bottom. The lines at each laser power were scanned in immediate succession while the temperature of the workpiece was measured. In other words, each set of tracks labeled by applied laser power in Figure 4 represents an energy input that caused a temperature rise in the workpiece that was recorded until the workpiece cooled back to room temperature. It may be observed that the tracks of, for example, 50 W and 100 W are "interleaved," which was simply for convenience. Approximately equivalent energy (about 2 J) was input at each laser power, hence three tracks at 100 W were applied for equivalent energy input to a single 300 W track, and the three 50 W tracks are twice as long as the 100 W tracks. The track length ranged from 3 mm to 7 mm and the spacing between immediately successive tracks was at least 300 µm.

Cross-sections of the tracks formed for this study were not made, but the modes of laser-metal interaction are known from cross-sections performed by previous researchers under comparable conditions, as well as the characteristic changes in absorption[10]. The 60 W laser power resulted in conduction mode. At this power, the melt tracks were narrow and the solidified end of track shapes were short. In transition mode, at 100 W, the melt tracks are significantly wider and the solidified track ends were an elongated teardrop shape. At 300 W in keyhole mode, the melt track is the widest and the solidified track end was a highly elongated teardrop. In all cases, the melt tracks were visibly uniform and repeatable.

Deisenroth, David; Mekhontsev, Sergey; Lane, Brandon. "Measurement of mass loss, absorbed energy, and time-resolved reflected power for laser powder bed fusion." Paper presented at SPIE Photonics West, San Francisco, CA, US. February 01, 2020 - February 06, 2020.

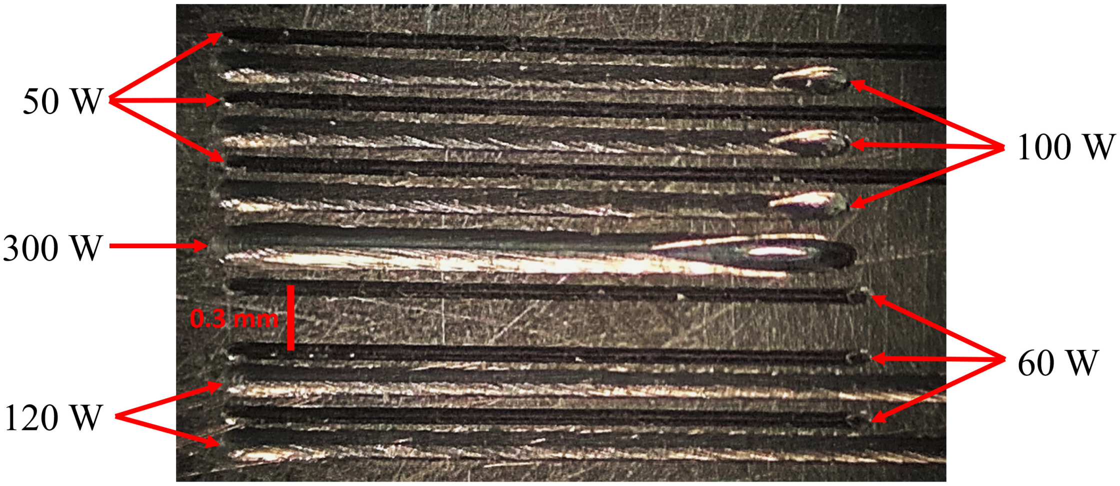

Figure 4. Melt tracks generated in the combined absorption and reflected power experiments with applied laser power pointing to tracks scanned in immediate succession

3.2 Mass and energy transfer due to vaporization

The measured mass transfer divided by distance for three laser powers and the estimated upper bound of normalized energy transfer from that mass are shown in Figure 5. Starting with 50 W, it can be observed that any mass loss was below the measurable limit, and therefore, energy transfer was also below the measurable limit. The mass loss divided by distance increased approximately linearly from no measured amount at 50 W, up to a value of 0.67 mg/m at 300 W.

The mass loss is about three times greater at 300 W compared to 100 W, causing the normalized estimated energy loss in transition mode and keyhole mode to be in close proximity. With the conservative estimate that all of the mass was transferred by vaporization and with an estimated uncertainty of 30 %, the total energy portion converted by mass loss was still less than 0.015 of the input energy. Therefore, because this transfer of energy was on the same order as the measurement uncertainty of both absorbed and reflected energy, energy loss due to mass transfer was taken as an additional 1.5 % uncertainty in the total energy balance for this preliminary investigation.

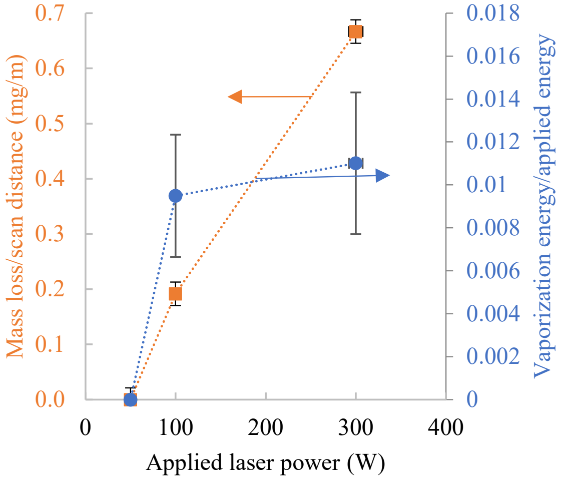

Figure 5. Mass transfer at varying laser power and estimated normalized energy transfer due to mass transfer

3.3 Time-resolved reflected power

The reflected power results were obtained with 20 mm long tracks under the same process parameters (spot size, scan speed, surface finish, etc.) as the rest of the results in this investigation, but with slightly greater uncertainty than the remainder of the results. Nevertheless, the results demonstrate the wealth of data that can be obtained with time-resolved non-contact reflectometry at 50 kHz, as shown in shown in Figure 6. In these results, three tracks were scanned in immediate succession and spaced 0.5 mm apart to avoid thermal and metallurgical interaction.

The reflected power from applied laser powers of 50 W, 100 W, and 200 W are shown in Figure 6 a, b, and c, respectively. Starting with Figure 6 a, about 0.50 of the laser power was reflected during each of the three scans. At the initiation of each 50 W track there is a slight overshoot with higher reflected laser power portion, up to 0.53 after the initial rise time. Overall, the conduction mode tracks exhibited very low variability along the length of the track.

In Figure 6 b, the 100 W tracks are in transition mode and show very high variability in reflected power along the length of the tracks. This high variability of reflected light in transition mode was observed in all experiments in this investigation and appears to be related to establishment of the vapor depression. The tracks exhibit nearly a 60 % difference in the reflected light portion at initiation of the track compared with the constant value of about 0.27 reached after the first 8 mm

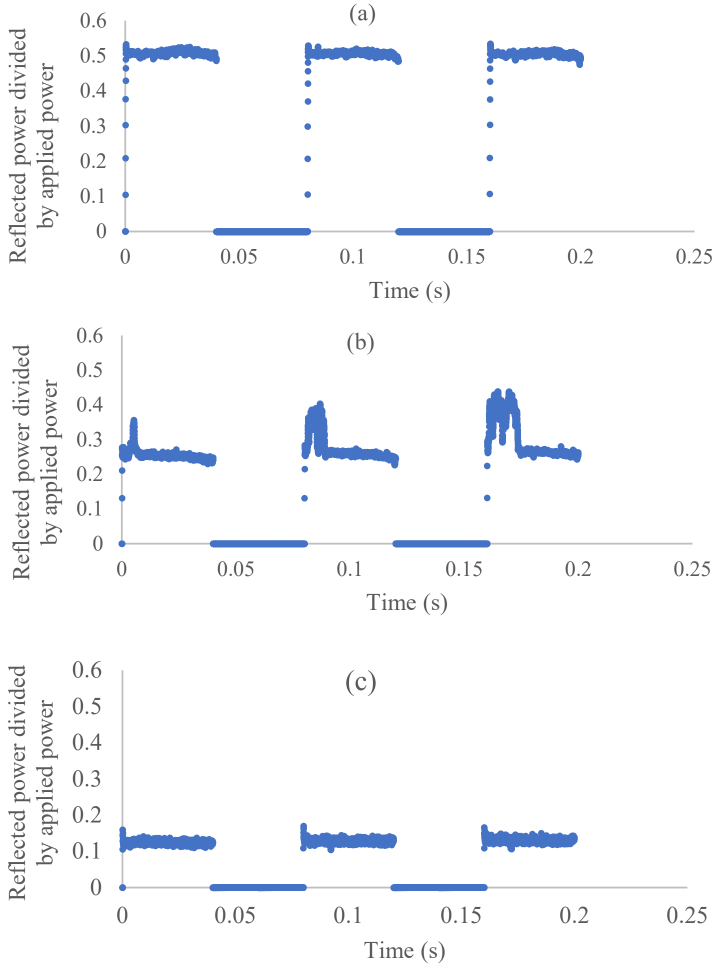

Figure 6. Time-resolved reflected power normalized by applied power. Each scan consists of three 20 mm long tracks scanned at (a) 50 W, (b) 100 W, and (c) 200 W

Deisenroth, David; Mekhontsev, Sergey; Lane, Brandon. "Measurement of mass loss, absorbed energy, and time-resolved reflected power for laser powder bed fusion." Paper presented at SPIE Photonics West, San Francisco, CA, US. February 01, 2020 - February 06, 2020.

of the track. It is currently unknown whether the apparent increase in track establishment length with each track is systematic or stochastic and will be investigated in the future.

Finally, in Figure 6 c, the 200 W tracks are in keyhole mode. At initiation of the track, the reflected light portion overshoots to 0.18 after the short initial rise time, then reaches an average value of about 0.125. In keyhole mode, the reflected light portion showed what appears to be a periodic fluctuation between 0.11 and 0.14 along the length of each scan. The frequency of such periodic fluctuations may be reported in the future.

3.4 Energy sum

The normalized reflected laser energy, absorbed heat energy, and their sum are shown as a function of applied laser power in Figure 7, with vaporization energy based on mass loss measurements added as a 1.5 % uncertainty component of the energy sum uncertainty. The energy values normalized by the applied laser energy indicate the relative proportion of reflected and absorbed energy, which would ideally sum to unity if all of the input energy were measured. It should be noted that the dotted lines in Figure 7 are not curve fits, but simply reference lines to guide the eye.

The trend and values of normalized absorbed energy are consistent with previous results under comparable conditions[9,10]. At 50 W laser power the absorbed energy portion is about 0.34, increasing to only 0.40 at 80 W. Then, the absorbed energy portion jumps to about 0.60 at 100 W and increases steadily to about 0.90 at 300 W. This jump in absorption at 100 W is associated with transition mode, while the low absorption is associated with conduction mode and the high absorption is associated with keyhole mode. The largest discrepancy between tests performed with the same laser power occurred in transition mode at 100 W, which appears to be related to the highly dynamic nature of absorption on the bare plates in transition mode, as was shown in Figure 6. Conversely to the portion of absorbed energy, the normalized reflected energy portion starts at 0.60 at 50 W, drops to about 0.30 at 100 W, and then the reflected energy portion falls to 0.07 at 300 W.

Turning now to the non-melting tests performed with an approximately 300 µm defocused laser spot under the same conditions, it can be seen from Figure 7 that a portion of 0.97 of the ideal energy sum was measured with 4.5 % uncertainty. The uncertainty is reported with 1σ confidence, indicating 68 % certainty that the measured value lies within the error

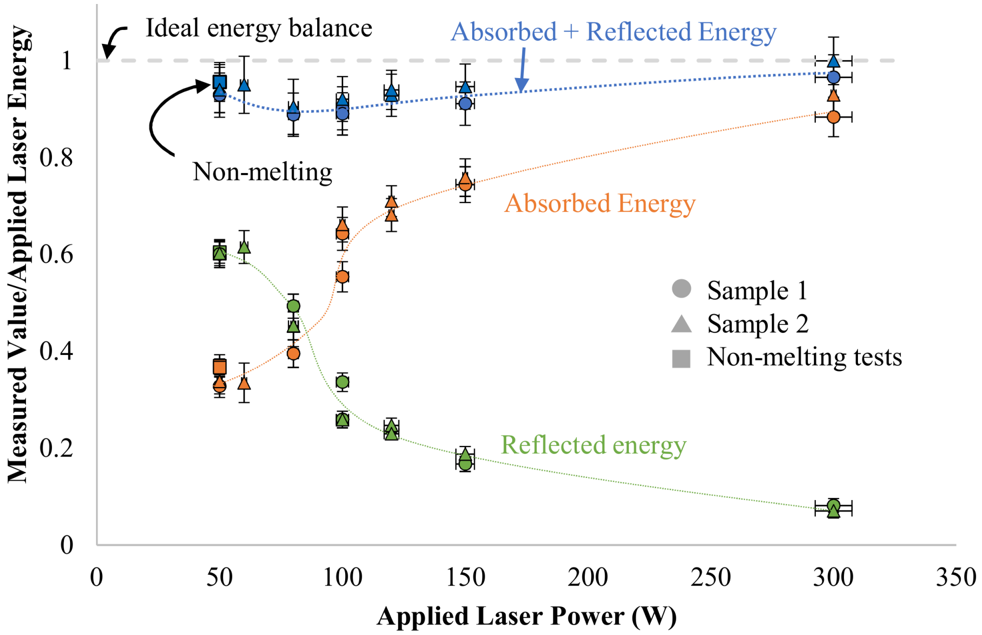

Figure 7. Reflected energy, absorbed energy, and the measured energy sum as a function of applied laser power. The dotted lines are to guide the eye along each data locus. Vertical and horizontal error bars indicate the combined standard uncertainty representing approximately 68 % confidence

bars. Therefore, the ideal energy balance was measured within the uncertainty under non-melting conditions, that likely generate a specular reflection.

In tests that caused melting, the error bars (which include energy transfer due to mass loss as an uncertainty) are within 1.5 % or less of the ideal energy balance, indicating that essentially all of the energy was measured at 50 W and 300 W. The maximum discrepancy between the ideal energy balance occurred at 80 W, at which between 7 % to 16 % of the applied energy was left unmeasured. In the current state of development, it is unclear whether this unmeasured energy is due to losses from the reflectometer (port losses or high-angle losses), or if a larger portion of the energy is converted to heating the ambient gas above the process in transition mode.

4. CONCLUSIONS

We are reporting the first known to us measurements of time-resolved reflected laser power from laser-matter interaction under conditions of interest for LBPF, which was accompanied by measurements of mass loss and absorbed laser energy. These three measurements performed together are meant to offer the modeling community a comprehensive set of data related to the laser-matter interaction processes. The measurement process can be streamlined so that such data sets can be developed for multiple materials and process parameters of interest.

In this investigation, tracks were laser melted into bare plates of IN625 with process conditions of interest for LPBF. The scan speed was 500 mm/s, the D4σ spot size was 65 µm, and the laser power was varied from 50 W to 300 W. Under the conditions tested, it was found that less than 1.5 % of the input energy was converted to vaporization. With time-resolved (50 kHz) reflected laser power measurements, it was observed that laser coupling is highly dynamic in transition mode, and periodic fluctuations in coupling were observed in keyhole mode.

Conservation of energy was confirmed to be measured in non-melting tests with a defocused beam. In tests with melting, conservation of energy was measured to be within 1.5 % or less of the 1σ error bars at the lowest and highest laser power. The maximum discrepancy between the measured and ideal energy balance occurred in transition mode, at which between 7 % to 16 % of the applied energy was left unmeasured. In the current state of development, it is unclear whether this unmeasured energy is due to port losses or high-angle losses in the integrating hemisphere, or if a larger portion of the energy is converted to heating the ambient gas/vapor/condensate above the process in transition mode.

Further developments depend on the interest of the community and can be directed either toward perfection of the reported measurements (such as reducing the uncertainties), expanding the functionality (e.g. measuring in the multilayer build condition with a powder layer), or connecting these measurands with the process outcomes.

ACKNOWLEDGEMENTS

The authors wish to thank to Mark Stoudt of the NIST Materials Measurement Laboratory for use of the precision balance for measuring mass loss. The authors also wish to thank you to Leonard Hanssen of NIST Physical Measurement Laboratory (PML) for aid in reflectometry uncertainty and analysis. The authors further wish to thank Brian Simonds of NIST PML for technical discussions. Finally, the authors with to thank Vladimir Khromchenko of NIST PML and Daniel Cardenas-Garcia of the National Metrology Center of Mexico for their work in characterizing the reflectometer.

Anomalous accelerated negative-bias- instability (NBI) at low drain bias

K. P. Cheung
National Institute of Standards & Technology, Gaithersburg, MD USA

We observed at very low drain bias an anomalous acceleration of Negative-bias-instability at room temperature, as if the channel temperature has been raised significantly. The channel width and channel length dependent of this acceleration suggest that in addition to the conventional self-heating effect that raises the lattice temperature, there is indication that hot holes thermalized at a temperature (T_e) higher than the lattice temperature (T_L) is the cause of this anomaly. Analysis of the frequency dependent of drain bias modulation, as well as the wave shape dependent of the modulation support this explanation.

Self-heating accelerated channel-hot-carrier-degradation (CHD) and bias-temperature-instability (BTI) is a current concern for advanced technology nodes [1-3]. While there are disagreements on the severity of the problem, consensus is that there is an elevated lattice temperature (T_L) in the channel resulting from inhibition of thermal energy removal in advanced geometries such as FinFet or Gate-all-around (GAA) Fet, leading to accelerated CHD and BTI. The observed acceleration of degradations so far seems to entirely attributable to the increase in T_L, even though theoretical works [4, 5] suggest that non-equilibrium effect such as a carrier temperature T_e higher than T_L exists at the drain end of the channel and can lead to an even more severe degradation. This may be deal to most studies are done at stress conditions that produced strong "conventional" degradation that make it difficult to identify the non-equilibrium effect.

In this work, we choose a stress condition that should have weak expected conventional degradations to search for the non-equilibrium effects. From the thermal argument, a planar MOSFET (power devices excluded), particularly a standalone one in nanoscale, should not have notable self-heating accelerated degradation [1]. We choose normal NBTI gate bias but no elevated temperature to suppress normal NBTI. We choose low to very low drain bias to suppress CHD. Under these conditions, we observed a clearly anomalous acceleration of NBI. We argue that elevated electron temperature (T_e) may be the culprit. If true, this is perhaps the first example of reliability impact of high T_e. Naturally, we expect what we observed applies to advanced geometry as well.

The p-MOSFET used in our experiment are standalone 2μ x 50nm devices with 1.6nm (EOT) nitride gate oxide and polysilicon gate. All stresses are done using -2V gate bias. Stress-measure-stress sequence was done at fixed cycle: 600s stress, 4s wait, 5s measure, 4s wait, 5s measure, 4s wait, 5s measure. So, the total interval is 627 seconds. Checking the three measurements (V_t extraction: V_G sweep from -0.8V to 0V, V_D = -0.6V) found that they agree to within measurement noise (indicated by the error bars in fig. 1a). The average of the three is used as the measured result. All experiments were carried out at room temperature, apart from the standard NBTI reference run.

Fig. 1a shows the threshold voltage (V_t) shift as a function of stress time for various drain bias. The fitted lines have been forced to have zero intercept, meaning that V_t shift after 1 second stress is within the measurement noise. In other words, there is no sudden rise in V_t shift due to filling of existing traps as found in many reports in the literature. Fig. 1b shows the V_t shift as a function of drain bias after 7200 seconds of stress. A monotonic rise starting at zero bias is evident.

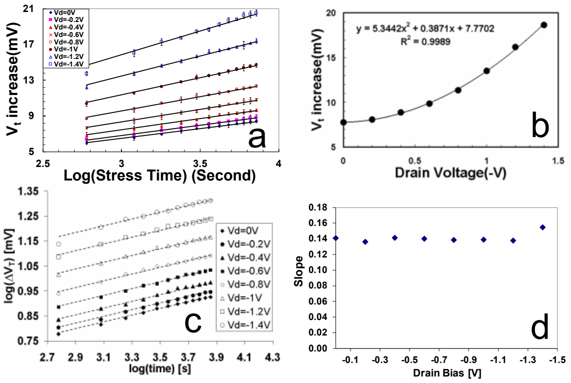

Fig.1 **a**. V_t shift as a function of stress time for various drain bias; **b**, V_t shift after 7200s stress as a function of drain bias; **c**, data in a replotted in log-log scale, **d**, slopes of the plots in c.

NBTI and CHD are intertwined and studies [2, 6, 7] showed that normally the overall degradation decreases with increasing drain bias until a turn-around point at which the increase in CHD overtakes the decrease in NBTI and degradation will increase with drain bias. The reason is at drain bias below -1V the population of energetic hot holes is so low that CHD is negligible. Since drain bias also reduces the oxide field in the channel, a reduction in NBTI as well as the overall degradation results. Contrary to these observations, our data showed only accelerated degradation even at very low drain bias. Note that our devices are from a production technology of a major foundry and very well behave. It is very unlikely that unusually bad devices are the culprit. Indeed, unusually bad devices that degrade easily even at very low drain bias means high density of preexisting defects. The fact that all lines cross zero (the fast, early degradation commonly reported is absent) in figure 1a indicates the quality of the devices studied here were superior to most of the devises reported in the literature. Thus, we call our result anomalous.

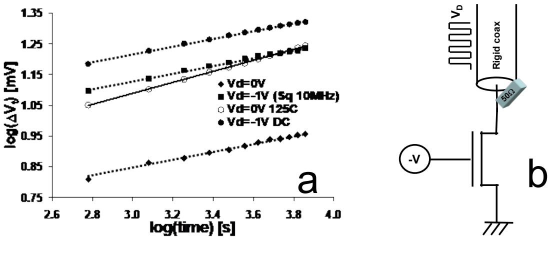

Fig. 2 **a**, V_t shift vs stress time for various conditions; **b**, measurement set up for high-speed drain modulation.

Adding to the anomaly is fig. 1c where the degradations are plotted in the more common log-log fashion and the slope of the fitted lines for all drain bias are 0.14 as shown in fig. 1d, lower than expected for NBTI or CHD [1-3]. To show that this is not an artefact of our experiment, a reference NBTI measurement (V_G = -2V, source/drain grounded, wafer heated to 125ºC using hot chuck) was performed and the slope was found to be 0.18 as

Cheung, Kin (Charles). "Anomalous accelerated negative-bias- instability (NBI) at low drain bias." Paper presented at 2020 International Reliability Physics Symposium, Virtual Dallas, TX, US. April 28, 2020 - May 30, 2020.

shown in fig. 2a. The 0.18 slope is consistent with the theoretical value when a finite delay is used in the measurement [1].

Also plotted in fig. 2a is a modulated rain bias case using a square wave at 10 MHz (0.5 ns rise/fall time). Note that this is not an AC stress with modulated gate bias. Instead, this is a "pulsed" drain bias. To ensure that the drain bias waveform is not distorted, a 50Ω terminated probe as shown in fig. 2b was used. This probe was verified to be good to 25 GHz using time-domain reflectometry measurement. As can be seen, the 10 MHz drain modulated case produced similar level of degradation as the 125°C zero bias case, as if the -1V modulated drain bias is heating the transistor to 125°C. However, the expected temperature rise is less than 10°C [1] for the 0.38 mW/μm power dissipation in this case. If CHD is indeed negligible as expected, then this large degradation is anomalous.

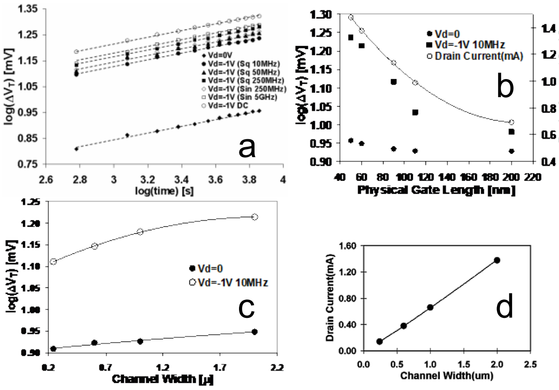

Fig. 3 **a**, V_t shift vs stress time for various drain bias frequency and wave shapes; **b**, V_t shift after 7200s stress and drain current vs channel lengths; **c**, V_t shift vs channel widths; **d**, drain current vs channel widths.

Fig. 3a shows more drain bias modulation cases involving different frequencies and wave shapes. For the square wave modulations, increasing the frequency from 10 MHz to 50 MHz to 250 MHz results in a commensurate increase in degradation, toward the level from DC bias. This again is counter to the expectation from heat removal argument [1] which says lower frequency modulation leads to higher peak temperature and therefore higher degradation. We note that if CHD were responsible for the degradation (instead of being negligible as we argued), the degradation could increase with frequency if gate voltage is modulated. Since gate voltage is steady and at least double the drain voltage at all time, this is not the case.

Sine waves were also used to modulate the drain bias at higher frequencies up to 5GHz (fig. 3a). We note that the degradation due to 250MHz sine wave modulation is very close to the degradation due to 50MHz square wave modulation. From this observation, we reason that the 5 GHz sine wave modulation should be like a 1GHz square wave modulation. The progression from 10MHZ to 1GHz square wave is asymptotically approaching the DC bias level.

Fig. 3b shows that log(degradation) tracks the drain current density (fixed channel width), suggesting that degradation increases exponentially with drain current density. Fig. 3C shows saturation of increases in log(degradation) with channel width. This means degradation increases with power dissipation even though the current density is unchanged (Drain current tracks the channel width as shown in fig. 3d).

Note that even though the degradations measured here are small, ranging from 8mV to 19mV, it is not insignificant given that the stress time is only 7200 seconds and the drain is only at operation voltage. For advanced nodes, 19mV is nearly 10% of V_t.

How to explain this collection of experimental results? We start with the channel width and channel length dependent behavior. The phonon mean-free-path for silicon is ~300nm [8] so the channel widths are all large enough that the thermal diffusion picture is valid (Fourier equation applicable). From narrow width to wide width the heat source changes from short line source to a long line source. For a uniform heat generation rate, the temperature will be higher for longer line. So, the channel width effect may be interpreted as conventional self-heating effect like those reported in the literature [1-3] (Similar to single fin vs multi fins in Finfets). Comparing fig. 3b and c, we see that the degradation change is significantly smaller for the channel width data set than the channel length data set. For the small power dissipation rate of 0.38mW/μm, we may assume that the thermal effect for the narrow width device is negligible and the entire range of degradation in the channel width data set is a measure of the conventional self-heating contribution, which translates to about 6mV out of the 19mV V_t shift.

Since the frequency dependent degradation counters the conventional self-heating picture, it further reinforces the notion that the larger degradation fraction is not due to conventional self-heating (T_L increase). In conventional self-heating heat diffusion is by acoustic phonons and T_e is the same as T_L. In nanoscale hot spot creation, local T_e and "temperature" of optical phonons (T_r) can rise much faster [9] and to a much higher level [4, 5], all riding on top of the slower responding conventional lattice temperature (T_L). How much higher than T_L obviously depends on both the drain current and drain bias. Both T_e and T_r provide a source of hot holes that can accelerate degradation. Also obvious is that at the very low drain bias level, both effects should be very weak. However, even a weak increase in hot holes population would impact the degradation rate.

With higher T_e and T_r the frequency dependent degradation can be explained as follows: As the drain bias is turned on, holes flow from source to drain. As they travel across the channel, they gain energy from the electric field and, at the same time, loss part of what they gain to phonon scattering. Upon arrival at the drain, some of these energetic carries lose their energy by creating optical phonons and the rest will thermalize extremely rapidly [9] to T_e by carrier-carrier scattering. The created optical phonons convert to acoustic phonons rapidly. Nevertheless, a steady state higher optical phonon population ($T_r > T_L$) can be expected.

A well-known argument [1] is that higher phonon scattering will lower the average carrier energy and therefore reduce the phonon generation rate. This argument will be important for the discussion later. For now, we point out that a T_e much higher than T_L will still result at steady state even with this negative feedback mechanism.

Since the optical phonon to acoustic phonon conversion is rapid, T_r follows the drain bias closely, meaning that $T_r \sim T_L$ at the end of the low drain bias cycle. When drain bias rises in the next cycle, T_r rises from a low value. Thus, every time there is a rising edge, there is a transient increase in T_e due to reduced optical phonon scattering as illustrated in fig. 4. Higher frequency means more rising edges, leading to more degradation. Eventually, frequency is high enough that T_r no longer falls with drain bias, one would approach the DC bias condition in agreement with data in fig. 3a.

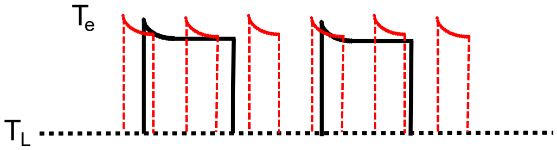

Fig 4. Profile of T_e and T_L in two frequencies (different color) showing the transient higher T_e at the rising edge.

What role does the T_L play in this scenario? T_L is too slow to follow the modulation at 10MHz or higher frequency. It is known that at low frequency, lower frequency leads to higher peak temperature [1]. That argument does not work here because at high frequency T_L does not respond fast enough. Any residual T_L modulation will be too small to show up as frequency dependent effect.

Substrate temperature is known to affect impact ionization rate in silicon and, at low drain bias the effect is positive, meaning that higher temperature leads to higher impact ionization rate [10]. (Note that, at high drain bias the opposite is true.) As impact ionization requires carrier energy higher than the drain voltage at low drain bias, the physics is very similar to what we are dealing with here – high energy carriers are needed to overcome the injection barrier into the SiO_2 layer for degradation to occur. It was suggested [10] that the high energy tail of the carrier distribution (at T_L) entering the channel preserves its shape after acceleration. This means higher T_L leads to higher T_e. Since even after acceleration the mean energy is still not high enough at low drain bias, it is the high energy tail of the T_e distribution that really matters. Consequently, higher T_L leads to higher degradation rate even when the dominant mechanism is T_e.

The reason why sine wave drain bias produces smaller degradation (~5x) than square wave can then be understood by the extremely fast thermalization of hot holes. It literally means that time spent at high voltage is what counts. Sine wave spend much less time at peak voltage.

Finally, what is the explanation for the low exponent of the degradation log-log plots? We do not have one at this point. Perhaps the fact that the channel is not uniformly heated may have something to do with it. However, we do notice that even when drain bias is zero at room temperature, the slope has the same low value.

In summary, we observed at very low drain bias an acceleration of Negative-bias-instability at room temperature, as if the channel temperature has been raised significantly. Many of the observed properties of the degradation is counter to the prevailing understanding of self-heating effects, thus are anomalous. The channel width and channel length dependent of this acceleration suggest that in addition to the conventional self-heating effect that raises the lattice temperature, there is indication that hot holes thermalized at a higher temperature is causing more degradation. Analysis of the dependence of drain bias modulation frequency, as well as the dependence on modulation wave shape further suggest non-equilibrium phonon distribution (optical phonon "temperature" higher than lattice temperature) also plays a role. The use of a regular planar MOSFET at low drain bias facilitated the study of the effect of carrier temperature because conventional self-heating effect is minimized, and CHD is also suppressed. The effect of high carrier temperature, if we are right, should exist in other geometries such as FinFets and GAA Fets.

Abstract

In 2019, the U.S. National Institute of Standards and Technology (NIST) conducted the most recent in an ongoing series of speaker recognition evaluations (SRE). There were two components to SRE19: 1) a leaderboard style Challenge using unexposed conversational telephone speech (CTS) data from the Call My Net 2 (CMN2) corpus, and 2) an Audio-Visual (AV) evaluation using video material extracted from the unexposed portions of the Video Annotation for Speech Technologies (VAST) corpus. This paper presents an overview of the Audio-Visual SRE19 activity including the task, the performance metric, data, and the evaluation protocol, results and system performance analyses. The Audio-Visual SRE19 was organized in a similar manner to the audio from video (AfV) track in SRE18, except it offered only the *open* training condition. In addition, instead of extracting and releasing only the AfV data, unexposed multimedia data from the VAST corpus was used to support the Audio-Visual SRE19. It featured two core evaluation tracks, namely audio only and audio-visual, as well as an optional visual only track. A total of 26 organizations (forming 14 teams) from academia and industry participated in the Audio-Visual SRE19 and submitted 102 valid system outputs. Evaluation results indicate: 1) notable performance improvements for the audio only speaker recognition task on the challenging *amateur* online video domain due to the use of more complex neural network architectures (e.g., ResNet) along with soft margin losses, 2) state-of-the-art speaker and face recognition technologies provide comparable person recognition performance on the *amateur* online video domain, and 3) audio-visual fusion results in remarkable performance gains (greater than 85% relative) over the audio only or visual only systems.

1. Introduction

The United States National Institute of Standards and Technology (NIST) organized the 2019 Speaker Recognition Evaluation (SRE19) in the summer–fall of 2019. It was the latest in the ongoing series of speaker recognition technology evaluations conducted by NIST since 1996 [1, 2]. The objectives of the evaluation series are 1) for NIST to effectively measure system-calibrated performance of the current state of technology, 2) to provide a common test bed that enables the research community to explore promising new ideas in speaker recognition, and 3) to support the community in their development of advanced technology incorporating these ideas.

SRE19 consisted of two separate activities: 1) a leaderboard-style Challenge using conversational telephone speech (CTS) extracted from the unexposed portions of the Call My Net 2 (CMN2) corpus collected by the Linguistic Data Consortium (LDC), which was also previously used to extract the SRE18 CTS development and test sets, and 2) a regular evaluation using audio-visual material extracted from the unexposed portions of the Video Annotation for Speech Technologies (VAST) corpus [3], also collected by the LDC. This paper presents an overview of the Audio-Visual SRE19 including the task, the performance metric, data, and the evaluation protocol as well as results and performance analyses of submissions. The SRE19 CTS Challenge overview and results are described in another paper [4]. It is worth noting here that the CTS challenge also served as a prerequisite for the Audio-Visual SRE19, meaning that in order to participate in the regular evaluation, one must have first completed the challenge (i.e., submitted to NIST valid system outputs along with sufficiently detailed system description reports). SRE19 was coordinated entirely online using a freshly designed web platform[1] deployed on Amazon Web Services (AWS)[2] that supported a variety of evaluation related services such as registration, data license agreement management, data distribution, system output submission and validation/scoring, and system description uploads.

The Audio-Visual SRE19 was organized in a similar manner to the audio from video (AfV) track of SRE18 [5], except it only offered the *open* training condition which allowed participants to use any publicly available and/or proprietary data for system training and development purposes. Moreover, in addition to the regular audio-only track, the Audio-Visual SRE19 also introduced audio-visual and visual-only tracks. Addition of these new tracks change the basic task in the Audio-Visual SRE19 to person detection (as opposed to speaker recognition), that is, determining whether a specified target person is present in a given test video recording. System submission was required for the audio and audio-visual tracks, but optional for the vi-

Table 1: *Audio-Visual SRE19 tracks.*

Track	Input	Required
Audio	Audio from Video	Yes
Audio-Visual	Audio and Frames from Video	Yes
Visual	Frames from Video	No

sual track. Table 1 summarizes the tracks for the Audio-Visual SRE19.

In addition, instead of extracting and releasing only the AfV data, unexposed multimedia data (i.e., videos) from the VAST corpus was used to support the Audio-Visual SRE19. Unlike the AfV track in SRE18 for which NIST released a very small in-domain development set containing data from only 10 speakers, SRE19 provided a much larger in-domain development set containing videos from 52 individuals from the VAST portion of SRE18 (i.e., only the videos in which the target individuals' faces were visible). In addition to the VAST development data, LDC also released selected data resources from the IARPA JANUS Benchmark-B [6], namely the JANUS Multimedia Dataset [7] which could also be used for system training and development purposes. The participants could register up to three systems for each track (i.e., audio, audio-visual, and visual), one of which under each track should have been designated as the primary system, and the other two as either contrastive or single best systems. Teams could make an unlimited number of submissions for each of the three systems until the evaluation period was over. Over the course of the evaluation, which ran from August 15, 2019 through October 21, 2019, a total of 14 teams, 8 of which were led by industrial institutions, from 26 sites made 102 valid submissions (note that the participants processed the data locally and submitted only the output of their systems to NIST for scoring and analysis purposes). Figure 1 displays a heatmap representing the number of participating sites per country. It should be noted that all participant information, including country, was self-reported. The number of submissions per team per track (i.e., audio, visual, and audio-visual) in the Audio-Visual SRE19 is shown in Figure 2.

Finally, as in SRE18, and in an effort to provide reproducible state-of-the-art baselines for the Audio-Visual SRE19, NIST released well in advance of the evaluation period a report [8] containing descriptions of speaker and face recognition baseline systems and results obtained using these standalone state-of-the-art (as of SRE18) deep neural network (DNN) embedding based systems as well as their fusion (see Section 5 for more details).

2. Task Description

The primary task for the Audio-Visual SRE19 was *person detection*, meaning that given a test video segment and a target individual's enrollment video, automatically determine whether the target person is present in the test segment. The test segment along with the enrollment segment from a designated target individual constitute a *trial*. The system is required to process each trial independently and to output a log-likelihood ratio (LLR), using natural (base e) logarithm, for that trial. The LLR for a given trial including a test segment s is defined as follows

$$LLR(s) = \log\left(\frac{P\left(s|H_0\right)}{P\left(s|H_1\right)}\right). \qquad (1)$$

where $P\left(\cdot\right)$ denotes the probability distribution function (pdf), and H_0 and H_1 represent the null (i.e., the target individual is present in s) and alternative (i.e., the target individual is not present in s) hypotheses, respectively.

3. Data

In this section we provide a brief description of the data released for the Audio-Visual SRE19 for system training, development, and test.

3.1. Training set

As noted previously, unlike in SRE18 which offered both *fixed* and *open* training conditions, the Audio-Visual SRE19 only offered the *open* training condition that allowed the use of any publicly available and/or proprietary data for system training and development purposes. The motivation behind this decision was twofold. First, results from the most recent NIST SREs (i.e., SRE16 [9] and SRE18) indicated limited performance improvements, if any, from unconstrained training compared to *fixed* training, although, participants had cited lack of time and/or resources during the evaluation period for not demonstrating significant improvement with *open* versus *fixed* training. Second, the number of publicly available large-scale data resources for speaker and face recognition has dramatically increased over the past few years (e.g., VoxCeleb[3]). Therefore, removing the *fixed* training condition would allow more in-depth exploration into the gains that could be achieved with the availability of unconstrained resources given the success of data-hungry Neural Network based approaches in the most recent evaluation (i.e. SRE18 [5]). Nevertheless, it is worth noting here that during the discussion sessions at the post-evaluation workshop, which was held in December 2019 in Singapore, several participating teams requested the re-introduction of the *fixed* training condition to facilitate meaningful and fair cross-system comparisons in terms of core speaker recognition algorithms/approaches (as opposed to particular data) used.

Although SRE19 allowed unconstrained system training and development, participating teams were required to provide a sufficient description of speech, non-speech (e.g., noise samples, room impulse responses, and filters), and visual data resources as well as pre-trained models used during the training and development of their systems.

	TEST	47 / 102	149	452	452	66,896

*gender information not available

3.2. Development and test sets

For the sake of convenience, in particular for the audio-visual and visual-only tracks, NIST provided two *in-domain* development (DEV) sets that could be used for both system training and development purposes. The Audio-Visual SRE19 *DEV* sets were as follows:

- JANUS Multimedia Dataset (LDC2019E55)
- 2019 NIST Speaker Recognition Evaluation Audio-Visual Development Set (LDC2019E56)

The JANUS Multimedia Dataset (LDC2019E55) [7], which was extracted from the IARPA JANUS Benchmark-B datatset [6], was available from the LDC, subject to approval of the LDC data license agreement. It consists of two subsets, namely CORE and FULL, each with a *DEV* and *TEST* split. We only consider the CORE subset in this paper, because it better reflects the data conditions in the Audio-Visual SRE19 *DEV* and *TEST* sets where target speakers are assumed visible. The first two rows in Table 2 summarize the statistics for the JANUS Multimedia Dataset CORE subset.

The SRE19 Audio-Visual Development (*DEV*) Set (LDC2019E56), on the other hand, contained the original videos from which the VAST portion of the SRE18 *DEV* and *TEST* sets were compiled. Participants could obtain this dataset through the evaluation web platform (`https://sre.nist.gov`) after signing the LDC data license agreement. Unexposed portions of the VAST corpus were used to compile the Audio-Visual SRE19 *TEST* set. The second two rows in Table 2 summarize the statistics for the Audio-Visual SRE19 *DEV* and *TEST* sets.

The speech segments in the Audio-Visual SRE19 *DEV* and *TEST* sets were extracted from the VAST corpus collected by the LDC to support speech technology evaluations. Unlike existing publicly available datasets derived from online “red carpet” and interview style videos featuring celebrities (e.g., VoxCeleb[3]), the VAST corpus contains *amateur* video recordings such as video blogs (Vlogs) extracted from various online media hosting services. The videos are mostly shot using personal recording devices such as cell phones in extremely diverse acoustic backgrounds, illuminations, facial poses and expressions. The videos vary in duration from a few seconds to several minutes and include speech spoken in English. Each video may contain audio-visual data from potentially multiple individuals who may or may not be visible in the recording, therefore manually produced diarization labels (i.e., speaker time marks) and *keyframe* indices[4] along with bounding boxes that mark an individual’s face in the video were provided for both the *DEV* set and *TEST* set enrollment videos (but not for the test videos in either set). All video data were encoded as MPEG4. Figure 3 shows speech duration histograms for the enrollment and test segments in the Audio-Visual SRE19 *DEV* (left) and *TEST* (right) sets. Note that enrollment segment speech durations are calculated after applying diarization, while no diarization has been applied to test segments. Nevertheless, the enrollment and test histograms both appear to follow log-normal distributions, and overall they are consistent across the *DEV* and *TEST* sets.

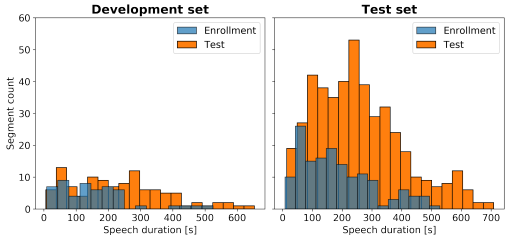

Figure 3: *Distributions of speech duration for the enrollment and test segments in the Audio-Visual SRE19 DEV and TEST sets.*

Similar to the AfV track in SRE18, there was only a 1-segment enrollment condition for the Audio-Visual SRE19 in which the system was given one video segment, that could vary in duration from a few seconds to several minutes, to build the model of the target individual. Note that for the audio track of the Audio-Visual SRE19, speech extracted from the enrollment video served as enrollment data, while for the visual track, face frame(s) (i.e., frames in which the face of the target individual was visible) extracted from the video served that purpose. Since NIST only released video files for the Audio-Visual SRE19, participants were responsible for extracting the relevant data (i.e., speech or face frames) for subsequent processing.

As in the most recent evaluations, gender labels were not provided for the enrollment segments in the *TEST* set. The test conditions for the SRE19 were as follows:

- The test segment video duration could vary from a few seconds to several minutes.
- The test video could contain audio-visual data from potentially multiple individuals.
- There were both same-gender and cross-gender trials.

4. Performance Measurement

Similar to past SREs, the primary performance measure for the Audio-Visual SRE19 was a detection cost defined as a weighted sum of false-reject (miss) and false-accept (false-alarm) error probabilities. Equation (2) specifies the Audio-Visual SRE19 primary normalized cost function for some decision threshold θ,

$$C_{norm}\left(\theta\right) = P_{miss}\left(\theta\right) + \beta \times P_{fa}\left(\theta\right), \qquad (2)$$

[4] Note that only a few (out of potentially many) target face frames per enrollment video were manually annotated.

where β is defined as

$$\beta = \frac{C_{fa}}{C_{miss}} \times \frac{1 - P_{target}}{P_{target}}. \quad (3)$$

The parameters C_{miss} and C_{fa} are the cost of a missed detection and cost of a false-alarm, respectively, and P_{target} is the *a priori* probability that the test segment speaker is the specified target speaker. The primary cost metric, $C_{primary}$ for the Audio-Visual evaluation was the normalized cost calculated at one operating point along the detection error trade-off (DET) curve [10], with $C_{miss} = C_{fa} = 1$, $P_{target} = 0.05$. Here, $\log(\beta)$ was applied as the detection threshold θ where log denotes the natural logarithm. Additional details can be found in the Audio-Visual SRE19 evaluation plan [11].

In addition to $C_{Primary}$, a minimum detection cost was also computed by using the detection threshold that minimized the detection cost.

5. Baseline systems

5.1. Speaker Recognition

In this section we describe the x-vector baseline speaker recognition system setup including speech and non-speech data used for training the system components as well as the hyper-parameter configurations used in our evaluations. Figure 4 shows a block diagram of the x-vector baseline system. The x-vector system is built using Kaldi [12] (for x-vector extractor training) and the NIST SLRE toolkit for back-end scoring.

5.1.1. Data

The x-vector baseline system was developed using the data recipe available at `https://github.com/kaldi-asr/kaldi/tree/master/egs/voxceleb/v2`. The x-vector extractor was trained entirely using speech data extracted from combined VoxCeleb 1 and 2 corpora. In order to increase the diversity of the acoustic conditions in the training set, a 5-fold augmentation strategy was used that added four corrupted copies of the original recordings to the training list. The recordings were corrupted by either digitally adding noise (i.e., babble, general noise, music) or convolving with simulated and measured room impulse responses (RIR). The noise and RIR samples are freely available from `http://www.openslr.org` (see [13] for more details).

5.1.2. Configuration

For speech parameterization, we extracted 30-dimensional MFCCs (including c0) from 25 ms frames every 10 ms using a 30-channel mel-scale filterbank spanning the frequency range 20 Hz–7600 Hz. Before dropping the non-speech frames using an energy based SAD, a short-time cepstral mean subtraction was applied over a 3-second sliding window.

For x-vector extraction, an extended TDNN with 12 hidden layers and rectified linear unit (RELU) non-linearities was trained to discriminate among the speakers in the training set. After training, embeddings were extracted from the 512-dimensional affine component of the 11th layer (i.e., the first segment-level layer). More details regarding the DNN architecture (e.g., the number of hidden units per layer) and the training process can be found in [14].

Prior to dimensionality reduction through LDA (to 250), 512-dimensional x-vectors were centered, whitened, and unit-length normalized. The centering and whitening statistics were computed using the in-domain development data (i.e., LDC2019E56). For backend scoring, a Gaussian PLDA model with a full-rank Eigenvoice subspace was trained using the x-vectors extracted from 170 k concatenated speech segments from the combined VoxCeleb sets as well as one corrupted version randomly selected from {babble, noise, music, reverb}. The PLDA parameters were then adapted to the in-domain development data (i.e., LDC2019E56) using Bayesian maximum *a posteriori* (MAP) estimation.

Finally, the PLDA verification scores were post-processed using an adaptive score normalization (AS-Norm) scheme proposed in [15]. We used LDC2019E56 as the cohort set, and selected the top 10% of sorted cohort scores for calculating the normalization statistics.

It is worth emphasizing that the configuration parameters employed to build the baseline system are commonly used by the speaker recognition community, and no attempt was made to tune the hyperparameters or data lists utilized to train the models.

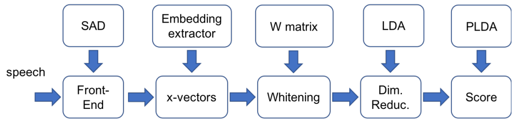

Figure 4: *A simplified block diagram of the baseline speaker recognition system for the Audio-Visual SRE19.*

5.2. Face Recognition

In this section, we describe the baseline face recognition system setup including the visual data used for training the system components as well as the hyper-parameter configurations used in our experiments. Figure 5 shows a block diagram of the baseline face recognition system which was built using open-source TensorFlow based implementations [16, 17] of 1) a face detector termed MultiTask Cascaded Convolutional Networks (MTCNN) [18], and 2) a face recognizer termed FaceNet [19] (for face encoding extraction). We use the NIST SLRE toolkit for back-end scoring.

5.2.1. Data

The baseline face recognition system utilized a pre-trained model available at `https://github.com/davidsandberg/facenet` (model name: 20180402-114759) which was trained on the VGGFace 2 dataset [20] using the Inception ResNet V1 architecture [21].

5.2.2. Configuration

We began processing by extracting one frame per second from the videos using `ffmpeg`. Then, we applied the MTCNN based face detector on the extracted frames to 1) filter out frames with no faces, and 2) compute the bounding box for the face

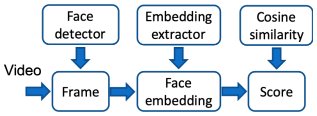

Figure 5: *A simplified block diagram of the baseline face recognition system for the Audio-Visual SRE19.*

that is closest to the center of the frame (as in [17]). Next, the face images were cropped using the bounding box coordinates, whitened (mean and variance normalized), and resized to 160 × 160 pixels. Finally, FaceNet was used to extract face encodings from the cropped, whitened and resized images.

For enrollment, we used the average of face encodings extracted from the enrollment video for each target individual to build a model for that individual. We only retained the face encodings that scored the highest (greater than 0.5 using cosine similarity) against the average of face encodings obtained using the manually produced bounding box coordinates for the enrollment videos. For test, we kept all face encodings extracted for each test video. In order to compute a single score for each trial involving an enrollment video and a test video, we computed the maximum of the cosine similarity scores obtained by comparing the enrollment encoding and test encodings. Finally, the scores were post-processed using the AS-Norm. We used the *DEV* set as the cohort set, and selected the top 10% of sorted cohort scores for calculating the normalization statistics.

6. Results and Discussion

In this section we present some key results and analyses for the Audio-Visual SRE19 submissions, in terms of the minimum and actual costs as well as DET performance curves.

Figure 6 shows the performance of the primary submissions per team per track, as well as performance of the baseline systems (see Section 5), in terms of the actual and minimum costs for the Audio-Visual SRE19 *TEST* set. Here, the y-axis limit is set to 0.5 to facilitate cross-system comparisons in the lower cost region. Several observations can be made from this figure. First, compared to the most recent SRE (i.e., SRE18), there seem to be notable improvements in audio only speaker recognition performance (see Figure 2b in [5]), which are largely attributed to the use of extended and more complex end-to-end neural network architectures (e.g., ResNet) along with soft margin loss functions (e.g., angular softmax) for speaker embedding extraction that can effectively exploit vast amounts of training data made available through data augmentation and/or large-scale datasets such as VoxCeleb[3]. Second, performance trends of the top 4 teams are generally similar, where the actual detection costs for the audio only submissions are larger than those for the visual only submissions, and the audio-visual fusion (i.e., the combination of speaker and face recognition system outputs) results in substantial gains in person recognition performance (i.e., greater than 85% relative in terms of the minimum detection cost for the leading system compared to their speaker- or face-recognition system alone). Third, more than half of the submissions outperform the baseline audio-visual system, with the leading system achieving larger than 90% improvement over the baseline. Fourth, in terms of calibration performance, mixed results are observed; for some teams (e.g., the top 2 teams) the calibration errors (i.e., the absolute different between the maximum and minimum costs) for speaker recognition systems are larger than those for face recognition systems, while for some others the opposite is true. Finally, in terms of the minimum detection cost, the two top performing speaker and face recognition systems achieve comparable results, which is a very promising outcome of this evaluation for the speaker recognition community, given the results reported in prior studies (e.g., see [7] where face recognition is shown to outperform speaker recognition by a large margin). It is worth emphasizing here that the top performing speaker and face recognition systems (i.e., team T_4) are both single systems (i.e., no fusion).

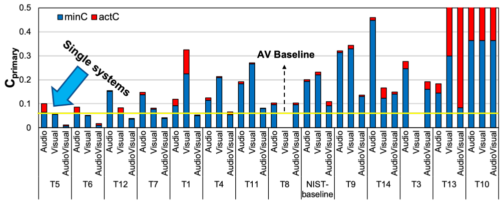

Figure 6: *Performance of the primary submissions for all three tracks (i.e., audio, visual, and audio-visual tracks) of the Audio-Visual SRE19 in terms of the minimum (in blue) and actual (in red) detection costs. The top performing audio and visual systems are both single systems (i.e., no fusion).*

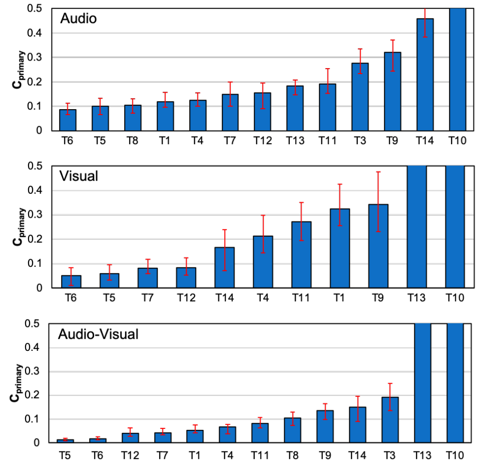

Figure 7: *Performance confidence intervals (95%) of the Audio-Visual SRE19 submissions for the audio (top), visual (middle), and audio-visual (bottom) tracks.*

It is common practice in the machine learning community to perform statistical significance tests to facilitate a more meaningful cross-system performance comparison. Accordingly, to encourage the speaker recognition community to consider significance testing while comparing systems or performing model selection, we computed bootstrapping-based 95% confidence intervals using the approach described in [22]. To achieve this, we sampled, with repetition, the unique speaker model space along with the associated test segments 1,000 times, which resulted in 1,000 actual detection costs, based on which we calculated the quantiles corresponding to the 95% confidence margin. Figure 7 shows the performance confidence intervals (around the actual detection costs) for each team for the audio (top), visual (middle), and audio-visual (bottom) tracks. It can be seen that, in general, the audio systems exhibit narrower confidence margins than their visual counterparts. This could be partly due to the fact that the majority of the participants, who are from the speaker recognition community, used off-the-shelf face recognition systems along with pretrained models not necessarily optimized for the task at hand in SRE19. Also, notice that several leading systems may perform comparably under different samplings of the trial space. An-

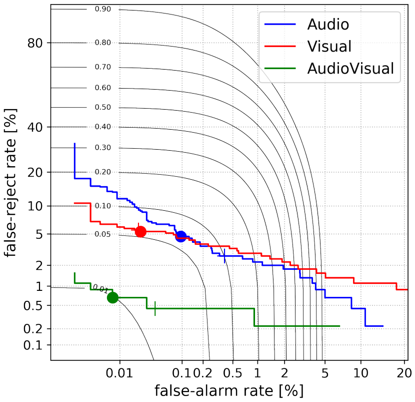

Figure 8: *DET curve performance of the top performing system for the* ***audio****,* ***visual****, and* ***audio-visual*** *tracks. Filled circles and crosses represent minimum and actual costs, respectively.*

other interesting observation that can be made from the figure is that audio-visual fusion seems to boost the decision making confidence of the systems by a significant margin, to the point where the two leading systems statistically significantly outperform the other systems. These observations further highlight the importance of statistical significance tests while reporting performance results or in the model selection stage during system development, in particular when the number of trials is relatively small.

Figure 8 shows DET performance curves from the leading system for the audio, visual, and audio-visual tracks. The solid black curves in the figure represent equi-cost contours, meaning that all points on a given contour correspond to the same detection cost value. Firstly, consistent with our observations from Figure 6 1) the audio-visual fusion provides remarkable improvements in performance across all operating points on the DET curve, which is expected given the complementarity of the two modalities (i.e., audio and visual), and 2) for a wide range of operating points, the speaker and face recognition systems provide comparable performance. Hence, the DET curves in Figure 8 confirm that the operating point dependent results in Figure 6 are consistent across a wider range of operating points, if not all of them.

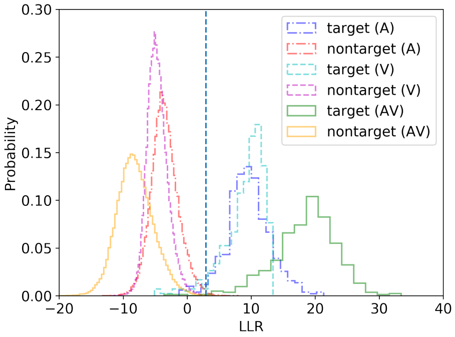

Figure 9: *Normalized target and non-target score distributions from the leading system for the* ***audio (A)****,* ***visual (V)****, and* ***audio-visual (AV)*** *tracks. The vertical dashed line represents the detection threshold.*

Motivated by the relatively low person recognition error rates achieved by the leading audio-visual system, i.e., 0.44% equal error rate (EER), we also conducted an error analysis of low scoring target and high scoring non-target trials, to gain insights regarding the nature of the issues associated with the remaining system errors on the Audio-Visual SRE19 *TEST* set. We found that, out of a total of 452 and 66,896 target and non-target trials, respectively, the system only made 2 false-reject (miss), and 27 false-accept (false-alarm) errors. A manual inspection of the trials (i.e., both enrollment and test videos) associated with these errors suggests that the majority of these trials indeed present challenging conditions for even humans (non-expert) due to the diversity of the acoustic backgrounds, illuminations, poses, facial expressions, and appearances (e.g., facial hair, glasses, caps/hats).

Figure 9 shows normalized target and non-target score distributions from the leading system for all tracks. The vertical dashed line represents the detection threshold. It can be seen that the score distributions from the audio only and face only systems roughly align, with the target and non-target distributions exhibiting some overlap at the threshold point. However, after the audio-visual fusion, the target and non-target classes are well separated with minimal overlap at the threshold, thereby significantly reducing the detection errors, in particular the false-rejects (misses).

7. Conclusion

Given the observed performance challenges presented by the AfV data in SRE18 and the growing interest of the speaker recognition research community in applying speaker recognition to more realistic multimedia applications, in 2019, NIST organized the first audio-visual SRE to 1) facilitate further exploration of speaker recognition technology in the AfV data domain, and 2) provide participants the opportunity to explore the possibility of fusing face and speaker recognition technologies. In this paper, we presented an overview of the Audio-Visual SRE19 activty including the task, data, the performance metric, the baseline system, as well as results and performance analyses. Compared to SRE18, the evaluation results indicate great progress in audio-only speaker recognition on the challenging AfV domain which is mainly attributed to the use of more complex neural network architectures (e.g., ResNet) along with soft margin losses. In addition, the audio-visual fusion was found to result in remarkable performance gains (greater than 85% relative) over the audio only or face only systems. Finally, state-of-the-art speaker and face recognition technologies were found to provide comparable person recognition performance on the challenging *amateur* online video domain.

8. Disclaimer

These results presented in this paper are not to be construed or represented as endorsements of any participant's system, methods, or commercial product, or as official findings on the part of NIST or the U.S. Government.

Certain commercial equipment, instruments, software, or materials are identified in this paper in order to specify the experimental procedure adequately. Such identification is not intended to imply recommendation or endorsement by NIST, nor is it intended to imply that the equipment, instruments, software or materials are necessarily the best available for the purpose.

***Abstract*— Many machine learning algorithms examine large amounts of data to discover insights from hidden patterns. Testing these algorithms can be expensive and time-consuming. There is a need to speed up the testing process, especially in an agile development process, where testing is frequently performed. One approach is to replace big datasets with smaller datasets produced by random sampling. In this paper, we report a set of experiments that are designed to evaluate the effectiveness of using reduced datasets produced by random sampling for testing machine learning algorithms. In our experiments, we use as subject programs four supervised learning algorithms from the Waikato Environment for Knowledge Analysis (WEKA). We identify five datasets from Kaggle.com to run with the four learning algorithms. For each dataset, we generate reduced datasets of different sizes using two random sampling strategies, i.e., pure random and stratified random sampling. We execute our subject programs with the original and the reduced datasets, and measure test effectiveness using branch and mutation coverage. Our results indicate that in most cases, reduced datasets of even very small sizes can achieve the same or similar coverage achieved by the original dataset. Furthermore, our results indicate that reduced datasets produced by the two sample strategies do not differ significantly, and branch coverage correlates with mutation coverage.**

***Keywords*— Testing classifiers, Random sampling, Reduced datasets, Testing machine learning, Branch coverage, Software testing.**

I. Introduction

Many machine learning algorithms examine large amounts of data to discover insights from hidden patterns. Testing machine learning algorithms can be expensive and time-consuming. There is a need to speed up the testing process, especially in an agile development process, where testing is frequently performed. One approach is to replace big datasets with smaller datasets produced by random sampling. One natural question to ask about this approach is the following: How does a reduced dataset compare to the original dataset in terms of effectiveness from a testing perspective?

In this paper, we report a set of experiments that are designed to evaluate the effectiveness of using reduced datasets for testing machine learning algorithms. We measure test effectiveness using both branch coverage and mutation coverage. In our experiments, we use as our subject programs four supervised learning algorithms from the Waikato Environment for Knowledge Analysis (WEKA), which is a widely used machine learning workbench written in Java [1]. We identify five datasets, each of which represents a different application domain, from Kaggle.com to run with these algorithms. Kaggle.com is an online data science community that maintains a repository of public datasets.

After we identify subject programs and datasets, we first execute each subject program with each of the five datasets and measure test effectiveness in terms of branch coverage and mutation coverage. Second, we create two groups of reduced datasets. The first group is generated using pure random sampling, i.e., in a purely random manner. The second group is generated using stratified random sampling, i.e., in a random manner that maintains the class distribution. In another word, a reduced dataset produced by stratified random sampling has the same class distribution as the original dataset. In the rest of the paper, we will refer to pure random sampling as random sampling and stratified random sampling as stratified sampling. Third, we execute the reduced datasets with subject programs and measure branch and mutation coverage. Finally, we compare the coverage results achieved by the reduced datasets to the coverage results achieved by the original datasets.

The major findings from our experiments are summarized as follows:

- In most cases, reduced datasets of even very small sizes achieve coverage identical or similar to the original datasets. In our experiments, the original datasets have the number of instances ranging from 142,193 to 999,999. The reduced datasets are of four sizes, i.e., 100, 200, 400, and 800, which are a fraction of the original dataset size. However, 522 out of 800 reduced datasets achieved the same coverage as the original datasets. Also, 112 out of 800 reduced datasets achieved more than 90% of the coverage achieved by the original datasets.
- One might expect that stratified sampling can be more effective than random sampling. However, in our experiments, the coverage results of the reduced datasets produced by the two sampling strategies are very similar. In particular, 628 out of 800 reduced datasets produced by the two sampling strategies achieved the same coverage. It is interesting to note that in several cases, random sampling achieved higher coverage than stratified sampling. The reason is that when the sample size is small, and when the dataset is skewed in terms of class distribution, stratified sampling may produce no instances for a particular class, which could significantly reduce coverage.

Kacker, Raghu N.; Kuhn, D. Richard. "Effectiveness of dataset reduction in testing machine learning algorithms." Paper presented at IEEE International Conference on Artificial Intelligence Testing, Oxford, UK. April 13, 2020 - April 16, 2020.

- In most cases, branch coverage correlates with mutation coverage. Since mutation testing is quite expensive to perform, this suggests that branch coverage could be used as a practical alternative in place of mutation coverage for testing machine learning algorithms.

The rest of the paper is organized as follows. In Section II we present the design of our experiments, including the research questions, subject programs, datasets and metrics used in our experiments, and discussion about the generation of reduced datasets. Section III presents the results of our experiments, including branch and mutation coverage results for original and reduced datasets as well as implications of these results. Section IV discusses potential threats to validity, including both internal and external threats. Section V reviews existing work that is related to ours. Section VI provides conclusion remarks and a few directions for the future work

II. Experimental Design

In this section, we present how we design our experiment, including the research questions, the selection of subject programs and datasets, the sampling approaches used to generate reduced datasets, and the metrics used to measure the effectiveness of the dataset executions.

A. Research Questions

Our main objective is to investigate the effectiveness of using a reduced dataset (in terms of volume, i.e., number of instances in a dataset) to test machine learning algorithms. We formulate the following research questions:

- How effective is it to test machine learning algorithms using reduced datasets, in comparison with the original datasets?
- How do the two sampling strategies, i.e., random sampling and stratified sampling, compare to each other?
- In testing machine learning algorithms, can branch coverage be used as a substitute for mutation coverage?

B. Subject Programs

Waikato Environment for Knowledge Analysis (WEKA) is a machine learning workbench developed by University of Waikato. WEKA has a collection of supervised and unsupervised algorithms implemented in Java. Using WEKA, a user can perform tasks such as classification, regression, clustering and association rule mining. Four supervised algorithms from WEKA are used as our subject programs.

In WEKA, classification algorithms are categorized into seven different groups. We select one algorithm from each of the following four groups, *bayes*, *meta*, *rules* and *trees.* When we choose one algorithm from a group, we only consider algorithms that satisfy two conditions: (1) they support datasets with nominal class labels and (2) they generate a *model* at the end of its training phase. When there are multiple algorithms that satisfy the two conditions, we randomly choose one from these algorithms. The reason for condition (1) is that we use WEKA`s built-in filter to generate smaller datasets for stratified sampling. This filter is applicable only to datasets with nominal class labels. The reason for condition (2) is that during mutation testing, we need expected output to determine if a mutant is killed by comparing against the actual output. If an algorithm generates a model, then the model can be used as expected output during mutation testing.

For example, WEKA lists eight algorithms under the *trees* category. However, one of the eight algorithms, M5p, does not work on a nominal class label. Hence we exclude M5P. Similarly, of the remaining seven algorithms, *random forest* works on a nominal class label dataset, but at the end of its training phase, the model is not accessible to the user with default configuration options. Hence, we exclude *random forest*. From the remaining six algorithms, we randomly select j48 as one of our subject algorithms.

Among different categories of classifiers listed in WEKA, we selected four algorithms namely NaiveBayes classifier [27], AdaBoost1 classifier [28], OneR classifier [29] and J48 classifier [30]. Table I lists our subject algorithms and some information about these algorithms, including package/class information, and number of branches. Each algorithm is executed with its default configuration values (as provided in WEKA) using command line interface (CLI).

Table I also lists information about an algorithm called DecisionStump. Classification accuracy of simple learning algorithms (weak learners), e.g., decision trees, naïve bayes, can be affected by potential bias in the training dataset. Thus, ensemble classifiers are used to improve their classification accuracy. AdaBoost1 belongs to a class of ensemble classifiers (boosting) that help to improve the classification accuracy of weak learners by training them iteratively, with different sets of weights assigned to class labels in each iteration. WEKA's default configuration of *AdaBoost1* implements a meta classifier that improves the accuracy of the model built using *DecisionStump,* a tree-based classifier (weak learner).

Algorithm	Subject Programs	Number of Branches	Number of Mutants
j48	weka.classifiers.trees.j48*	750	3796
NaiveBayes	weka.classifiers.bayes.NaiveBayes.java	203	1075
AdaBoost1	weka.classifiers.meta.AdaBoost1.java	90	491
DecisionStump	weka.classifiers.trees.DecisionStump.java	128	921
OneR	weka.classifiers.rules.OneR.java	88	510

Table I – Information about subject programs

C. Datasets

We identify suitable datasets from Kaggle.com, which provides access to public databases. By default, dataset search results on Kaggle.com are sorted by hotness, a measure indicative of the amount of interests and recency of datasets on their platform [9]. Other methods of sorting include *New, Recently Active, Most Votes, Updated and Relevance.* As Kaggle.com does not release the hotness calculation formula to the public [10], we are not completely clear of how the hotness of datasets is computed. Hence, we sort the search results by *Most Votes*, which sorts datasets based on the most popular datasets of all time. Then, the results are further filtered with the following two criteria: (a) *size – 10 MB to 1GB* and (b) *File types – CSV.* Next, we inspect each dataset in the order sorted by Kaggle.com and select datasets that require no cleaning and can be executed in WEKA.

We identified five datasets from different application domains, including *AustralianWeather [23], ForestCover [24, 25], Crime [26]*, *SupplyChain* [21] and *VideoGames [22].* The *ForestCover* dataset is a multi-label classification dataset with seven different class labels. The remaining four datasets consist of binary class labels. Table II lists the datasets and their information.

We selected datasets such that data preprocessing is minimal. No modification was required for *AustralianWeather and SupplyChain* as their respective class labels were nominal by default. The class labels of the remaining three datasets, i.e. *ForestCover, Crime and VideoGames* were converted from numeric to nominal using WEKA's built-in filter.

DATASET	# OF CLASS LABELS	# OF INSTANCES	# OF ATTRIBUTES
ForestCover	7	581,012	55
AustralianWeather	2	142,193	23
Crime	2	284,807	31
SupplyChain	2	580,251	5
VideoGames	2	999,999	56

TABLE II – DATASET INFORMATION

D. Generation of Reduced Datasets

For each original dataset in Table II, two groups of smaller datasets are generated. Group 1 consists of reduced datasets generated using pure random sampling, whereas in Group 2, reduced datasets are generated using stratified sampling. Recall that stratified sampling maintains the overall class distribution of the original datasets. For each group, we generate samples of four different sizes, i.e., 100, 200, 400, 800. Also, in order to reduce variations in random sampling, we generate five samples for each sample size by using different random seeds. Thus, each dataset has 20 samples per group and a total of 40 samples in the two groups.

WEKA provides a set of pre-processing filters that allow users to modify datasets. Reduced datasets in Group 1 (random sampling) are generated using WEKA's pre-processing filter *weka.filters.**unsupervised**.instances. Resample*. Reduced datasets in Group 2 (stratified sampling) are generated using pre-processing filter *weka.filters.**supervised**.instances.Resample*. These filters allow the user to select the sample size, usually specified as a percentage of the original dataset. Note that both filters perform a volumetric reduction, i.e. the number of instances in the dataset is reduced whereas the number of attributes will remain unchanged.

For example, consider a dataset of 100,000 data instances with four class labels, A, B, C and D. Assume that their class distribution is as follows: 30% instances belong to Class A, 40% instances belong to Class B, 10% instances belong to Class C and the remaining 20% belongs to Class D. Generating a smaller dataset with 100 instances using stratified sampling (Group II) will consists of 30 instances belonging to Class A, 40 instances belonging to Class B, 10 instances belonging to Class C and 20 instances belonging to Class D. In contrast, samples generated using random sampling (Group I) does not necessarily maintain the class label distribution.

The *Crime dataset* (284,807 instances) has the following class distribution: 99.82% instances belong to Class 0 (284,315 instances), and 0.18% instances belong to Class 1 (492 instances). When generating a reduced dataset with 800 instances using WEKA's pre-processing filter, it is highly likely that random sampling fails to produce a reduced dataset that include instances in both Class 0 and Class 1. Instead, it is likely that all of the 800 instances belong to Class 0. A developer might face the above said scenario when s/he generates a reduced dataset using random sampling from a class-imbalanced (or skewed) dataset. As a workaround, a developer can create a reduced dataset while preserving the original class distribution. This is our motivation to use two different groups of samples and to investigate their impact in testing supervised learning algorithms. The original datasets and their reduced versions are made publicly available at [32].

E. Metrics

We use both branch coverage and mutation coverage to measure test effectiveness. Branch coverage is recorded using JaCoCo [18]. Mutation coverage is obtained using PITest (PIT), which is a widely used mutation testing framework [19]. PIT can automatically seed one fault at a time into SUT and execute the mutated code against the unit test(s) specified. In our experiments, we have thirteen mutation operators including all the default mutators (seven), three experimental mutators and three optional mutators [20, 31].

Given the nature of our subject algorithms, there may be loops that could be executed for a large number of times. In this scenario, it is possible that PITest mistakenly concludes that an algorithm has entered an infinite loop and thus kills the execution, thus resulting in a false positive. To prevent this scenario, we set the timeout constant factor to 100000 milliseconds. The reason for choosing 100000 milliseconds is based on our observation that among 20 baseline executions (5 original datasets x 4 algorithms), 16 executions (80%) completed under 50 seconds. Therefore, we choose the timeout constant to be 2 x 50 = 100 seconds.

The machine we used for our experiments is a workstation with two Xeon E5- 2630V3 8 core CPUs @ 2.40GHz, 64GB DDR4 2133 MT/s memory, and a Samsung 850 EVO 500GB SSD.

III. EXPERIMENTAL RESULTS

In this section, we present our experimental results and discussion about our results. In Section III.A, we present the branch coverage results achieved by the original datasets. These results are considered to be the baseline results. In Section III.B, we present the branch coverage results achieved by the reduced datasets. These results are compared to the baseline results. In Section III.C, we present the mutation coverage results achieved by both of the original and reduced datasets.

A. Branch Coverage of the Original Datasets

Table III presents the branch coverage achieved by algorithms with original datasets. Among the datasets, *SupplyChain* consistently achieve higher coverage for all the algorithms. We observe that across algorithms, a considerable number of methods, and their branches were not executed, and thus the overall branch coverage appears to be considerably lower (<= 50%). This, however, can be explained as follows. Consider the branch coverage results of the OneR algorithm. The *SupplyChain* dataset achieves the highest branch coverage (57%), i.e., 51 out of 88 total branches. Among the missing 37 branches, 18 branches missed due to default configuration options. Seven branches are related to error handling, such as missing attribute values, and the remaining 12 branches cannot be covered as cross-validation is not performed while building models using the command-line interface (CLI).

To our surprise, *AustralianWeather* covers a significantly smaller number of branches (17) compared to the rest. This can be explained as follows: Among the five datasets, all the attributes of *AustralianWeather* belong to the nominal data type. All the attributes of *ForestCover, VideoGames, and Crime* belong to the numeric data type. In the case of *SupplyChain,* 3 out of 4 attributes belong to the numeric data type, and the remaining attribute belongs to the nominal data type. When executing the OneR algorithm with *AustralianWeather,* a method, newNumericRule(), was missed that has 36 branches and handles numeric attributes. Hence, *AustralianWeather* achieves a significantly lower branch coverage, whereas *SupplyChain* achieves the highest branch coverage, as it covers branches related to both numeric and nominal data types.

In our experiments, we executed the algorithms using WEKA's default configuration options only. This could cause branching conditions that are specific for other configuration options to be missed. As shown in [2], executing different configuration options could significantly increase branch coverage. Also, the branches related to error handling and GUI are not covered as we run our tests with clean datasets using the CLI.

We emphasize that, although branch coverage achieved by original datasets is not high, this does not affect the purpose of our experiments, which is to determine whether reduced datasets could achieve the same or similar coverage as the original dataset.

Datasets	Algorithms	# of Branches Covered	Total Number of Branches	Branch Coverage
AustralianWeather	j48	180	750	24%
ForestCover		202		26%
SupplyChain		201		26%
VideoGames		202		26%
Crime		195		26%
AustralianWeather	Naïve Bayes	73	203	35%
ForestCover		77		37%
SupplyChain		99		48%
VideoGames		79		38%
Crime		78		38%
AustralianWeather	AdaBoost1	28	90	31%
ForestCover		17		18%
SupplyChain		28		31%
VideoGames		28		31%
Crime		28		31%
AustralianWeather	DecisionStump	50	128	39%
ForestCover		47		36%
SupplyChain		71		55%
VideoGames		48		37%
Crime		48		37%
AustralianWeather	OneR	17	88	19%
ForestCover		44		50%
SupplyChain		51		57%
VideoGames		45		51%
Crime		45		51%

TABLE III - BRANCH COVERAGE FOR ORIGINAL DATASETS

B. Branch Coverage of Reduced Datasets

In this section, we present the branch coverage results achieved by reduced datasets. For each dataset, we generate reduced datasets using two different approaches: random sampling and stratified sampling; we generate reduced datasets in four different sizes: 100 instances, 200 instances, 400 instances, and 800 instances, as discussed in Section II-D. Due to limited space, we present the median branch coverage achieved by each size relative to their baseline coverage.

Tables IV and V present the branch coverage results of reduced datasets generated using random sampling and stratified sampling, respectively. All the coverage results presented here are relative to their corresponding baseline. i.e., a relative branch coverage of 1.0 suggests that a reduced dataset achieves a branch coverage identical to the original dataset. Note that, in Tables IV and V, 39 out of 50 reduced datasets of size 800 produced by both random and stratified sampling, achieved branch coverages identical to the baseline; for the remainder of the cases, we notice the coverages do not significantly vary among different sample sizes. Therefore, in our experiments we did not consider sample size larger than 800 instances.

The results indicate that, for the j48 algorithm, reduced datasets of size 800 instances produced by both random and stratified sampling of *ForestCover, SupplyChain, and VideoGames* can retain their baseline branch coverage. For the NaiveBayes algorithm, the reduced versions of all five datasets can retain their branch coverage achieved by their respective original datasets and in some cases, reduced datasets achieving even higher branch coverage. Similarly, for the remaining three algorithms namely AdaBoost1, DecisionStump, and OneR, the reduced versions of all datasets except *Crime*, in most cases either retain their respective baseline branch coverage (1.0) or in some cases achieve a branch coverage closer to its baseline (0.9<=branch coverage<1.0).

For the reduced datasets of *Crime,* we observe that three out of five algorithms (j48, AdaBoost1, One-R) suffer from a loss in branch coverage. In particular, consider the case of j48 (Row 5 in Tables IV and V), which suffers from a significant loss in branch coverage. This is attributed to the class imbalance problem. The *Crime* dataset consists of 284,807 instances with two class labels: (0, 1); 99.82% instances belonging to Class 0 and remaining 0.18% belonging to Class 1. Due to class imbalance, chances of drawing all hundred samples (at random) that belong to Class 0 is higher.

In our experiments, for the reduced datasets of size 100 produced by random sampling, four out of five samples have all their instances belonging to Class 0, and they achieve a relative median branch coverage of 0.12. On the contrary, three out of five reduced datasets of size 200 produced by random sampling have representation from both of the class labels, and they achieve a higher branch coverage comparatively (0.35). We notice that, in the case of j48, if a reduced dataset consists of a single label, there is a significant loss in branch coverage.

Next, we compare the coverage results of random sampling and stratified sampling. Our results indicate that, in most cases, the datasets reduced using both random and stratified sampling can achieve the same branch coverage.

Datasets	Algorithms	Size of the reduced dataset			
		100	200	400	800
AustralianWeather	j48	0.75	0.75	0.71	0.71

Crime		0.76	0.76	0.76	0.92

Table V – Relative Branch Coverage of Reduced Datasets (Stratified Sampling)

In the cases of *AustralianWeather*, *SupplyChain* and *VideoGames*, the datasets reduced using both random and stratified sampling achieves identical branch coverage. This can be explained by the fact that all reduced datasets have a good class label representation. For example, all five sample datasets of *AustralianWeather* of size 100 that are reduced using stratified sampling have the following class label distribution: 78 instances belong to *No*, and 22 instances belong to *Yes.* In the case of random sampling, amongst five samples, sample 5 consists of 86 instances belong to *No* and 14 instances belongs to *Yes* whereas, Sample 3 consists of 74 instances belong to *No* and 26 instances belongs to *Yes.*

Our results indicate that the reduced datasets of *ForestCover* generated using both random and stratified sampling achieve the same branch coverage as the original datasets across all algorithms. In comparison, the reduced datasets generated from *AustralianWeather*, *SupplyChain*, *VideoGames*, and *Crime* suffer from a minimal to moderate coverage loss in at least one of the five algorithms. This may be attributed to the fact, *ForestCover* is a multilabel dataset (7 class labels), whereas the rest of the four datasets are binary label dataset. More experimental data is required to obtain a better understanding. Also, our results indicate that in the case of the AdaBoost1 algorithm, the reduced datasets achieve a better branch coverage compared to the baseline, i.e., the original datasets. To some extent, this result is surprising, given the significant increase in branch coverage. This is possible because the reduced datasets may trigger execution scenarios that are different than the original datasets.

In the case of the *Crime* dataset, three algorithms suffer from a coverage loss. In particular, consider the coverage achieved by the reduced datasets of *Crime* produced by both random and stratified sampling. Row 5 in Tables IV and V indicates that the reduced dataset of size 200 produced by random sampling achieves a higher branch coverage (0.35) compared to the reduced dataset produced by stratified sampling of the same size (0.12). This can be attributed to the representativeness of the class label. On examination of reduced datasets, we observe that three out of five samples generated using random sampling have instances belonging to two class labels (Class 0 and Class 1). However, in the case of datasets reduced using stratified sampling, all instances belong to a single class (Class 0). Hence, subject programs achieve lower coverage while executing with stratified samples as they fail to trigger the execution of certain branches. The branch coverage results of the OneR algorithm suggest a similar pattern, i.e., the reduced dataset of size 200 produced by random sampling achieves a higher coverage (0.92) compared dataset reduced using stratified sampling of the same size (0.76).

This behavior of stratified sampling, i.e., all the instances of a reduced dataset belonging to a single class, is expected as it draws samples in a way that maintains the class distribution of the original dataset. Recall that the *Crime* dataset consists of 284,807 instances with two class labels: (0, 1); 99.82% instances belonging to Class 0 and remaining 0.18% belonging to Class 1. To generate a reduced dataset of size 200 instances using stratified sampling, instances are drawn in the following way (99.82% * 200) > 199 (instances) belonging to Class 0 and (0.18% * 200) < 1 (instances) belonging to Class 1. Hence, all the instances belong to Class 0 and thus, the reduced dataset suffers from lack of class representativeness.

For the *Crime* dataset, a minimum of 556 instances is required to guarantee that a reduced dataset (stratified sampling) consists of instances belonging to both classes (0 and 1). Among four different sizes (100, 200, 400, and 800) of reduced datasets generated using stratified sampling, in three groups (100,200 and 400), all instances belong to class 0 and thus achieve a low branch coverage (0.12). In the case of reduced datasets of 800 instances, all five samples consist of instances of both classes and thus achieve a relatively higher branch coverage (0.35).

Our results indicate that approximately 80% of the reduced datasets achieve coverage identical or similar to the original datasets. In another word, the volume of a dataset does not directly attribute to branch coverage. Instead, factors such as lack of representativeness of class labels in a reduced dataset could impact branch coverage. The results suggest that in most cases, reduced datasets do not suffer from branch coverage loss. In this respect, they can be used in place of the original datasets to speed up the testing process.

Among the two sampling approaches, the results indicate that in most cases (around 75%) reduced datasets generated using both random and stratified sampling exhibit identical behavior. However, when a tester decides to use stratified sampling, he/she should choose the size of the reduced dataset (minimum number of samples) based on the original class distribution such that each class label is represented in the reduced dataset.

C. *Mutation Coverage of Reduced Datasets*

In this section, we present the mutation coverage results achieved by algorithms while executing with reduced datasets.

Given the size of the datasets and the number of mutants generated for SUT, the overall execution time can be between a few hours to several days. Due to time constraints, our experiments have an execution time limit of 48 hours (chosen arbitrarily). If a dataset takes more than 48 hours to complete, then we kill the test execution and use a relatively smaller dataset (10000 instances) as our baseline. Out of 20 baseline test executions, one baseline execution, j48 algorithm with the *VideoGames* dataset executed for more than 2 days. Hence, we generated five smaller samples of *VideoGames* dataset with 10000 instances each and used their median coverage as a baseline.

DATASETS	ALGORITHMS	SIZE OF THE REDUCED DATASET			
		100	200	400	800
AustralianWeather	j48	0.50	0.50	0.44	0.50

TABLE VII-RELATIVE MUTATION COVERAGE OF REDUCED DATASETS (STRATIFIED SAMPLING)

Tables VI and VII present the mutation coverage results of the reduced datasets. All the coverage results presented here are relative to their corresponding baseline. The results from Tables VI and VII suggest that the j48 algorithm performs poorly with the reduced datasets of *AustralianWeather* and *SupplyChain.* Similarly, the reduced datasets of *Crime* result in a mutation coverage decrease for all the algorithms except Naive Bayes. The rest of the reduced datasets generated using both random and stratified sampling can retain their baseline mutation coverage.

We report that the majority of the mutation coverage results (except reduced datasets of *SupplyChain* on j48) mirrors with their respective branch coverage results (Table IV & V; Table VI & VII).

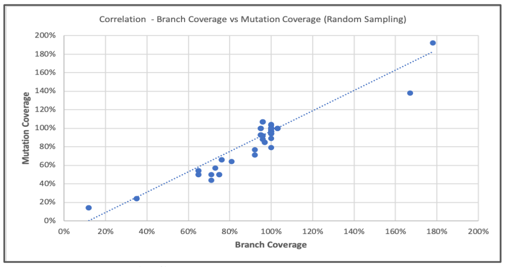

FIGURE 1 – CORRELATION GRAPH – RANDOM SAMPLING

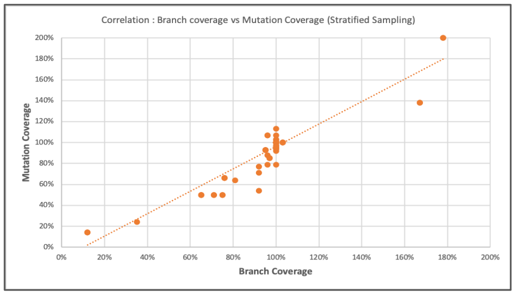

FIGURE 2 – CORRELATION GRAPH – STRATIFIED SAMPLING

Figures 1 and 2 present a correlation graph of branch coverage vs. mutation coverage for random sampling and stratified sampling, respectively. In Figures 1 and 2, x-axis indicates branch coverage, and the y-axis indicates mutation coverage. For the datasets reduced via random sampling, branch vs. mutation coverage has a Pearson correlation coefficient of 0.944148, whereas the datasets reduced via stratified sampling has a fractionally lower Pearson correlation coefficient of 0.939506. The result suggests that in most cases, mutation coverage has a strong positive correlation with the branch coverage. To our surprise, the mutation results of j48 using the *SupplyChain* dataset reduced using stratified sampling does not appear to correlate well with branch coverage, and we plan to investigate this further as part of our future work.

IV. THREATS TO VALIDITY

Threats to internal validity are factors that may be responsible for experimental results, without our knowledge. To reduce human errors in the experimental procedure, we tried to automate our experiments as much as possible. In particular, we wrote scripts to automatically execute tests, measure code and mutation coverage, and generate coverage reports. Further, the results generated from samples of each dataset were verified manually, whenever possible.

Threats to external validity occur when the experimental results could not be generalized to other subjects. Using a single dataset for our experiments might impact the validity of our results due to lack of representativeness. To mitigate this threat, we used four supervised learning algorithms from WEKA that belong to different groups and five datasets from different application domains. More experiments using other learning algorithms, including both supervised and unsupervised algorithms, and other datasets, can further reduce the threats to external validity.

V. RELATED WORK

First, we review existing work reported on testing machine learning algorithms. One challenge in testing machine learning algorithms is how to deal with the test oracle problem. Murphy et al. [4,5] proposed a metamorphic testing technique to test machine learning algorithms. They developed metamorphic properties for three machine learning algorithms, including MartiRank, SVMLight, and PAYL. Similarly, Nakajima et al. [7] proposed a systematic approach to derive metamorphic properties and translation functions for testing a special class of classifiers known as Support Vector Machines (SVM). Xie et al. [11] proposed a metamorphic testing approach to test supervised learning algorithms, namely Naïve Bayes classifier and k-nearest neighbor classifier. Our work differs from these works in that we focus on evaluating the effectiveness of using smaller datasets in testing supervised learning algorithms.

Second, we review existing work on dataset reduction for testing big data applications. Such work is relevant because many machine learning algorithms are big data applications in that they are designed to learn from large amounts of data. Ur Rehman et al. [13] reviewed existing data reduction techniques such as compression-based data reduction method, dimension reduction techniques for big data applications. Czarnowski et al. [14] proposed an agent-based population learning algorithm for data reduction. Their algorithm aims at finding a subset of the original dataset that can be used to build a classifier that is similar to the classifier built using the original dataset. This is different from our work, which tries to find a subset of the original dataset that preserves test effectiveness.

We mention that a significant amount of work is reported on data reduction techniques in terms of dimensionality reduction and feature space [3, 6, 8, 16, 17]. In contrast, our work focuses on volume reduction, i.e., reducing the number of instances in a big dataset. To the best of our knowledge, our work is the first to investigate the effectiveness of volume reduction in testing machine learning algorithms.

VI. CONCLUSION AND FUTURE WORK

In this paper, we report a study that investigates the use of reduced datasets in testing machine learning algorithms. We used four supervised learning algorithms from WEKA as our subject programs. Five publicly available datasets from Kaggle.com were chosen as subject datasets. For each dataset, we generated reduced datasets in four different sizes using random and stratified sampling. Then, we executed the algorithms with the original and the reduced datasets and measured test effectiveness in terms of branch and mutation coverage. Our results indicate, in most cases, reduced datasets of very small sizes (e.g. 800 instances) can retain branch and mutation coverage of the original, big datasets (e.g., >100,000 instances). This suggests that reduced datasets can be used to effectively test machine learning algorithms. Our results also indicate a high correlation between branch coverage and mutation coverage. Thus, branch coverage can be used when mutation testing is prohibitively expensive.

This is the first step in our larger effort to speed up testing machine learning algorithms. We plan to continue our work in the following directions. First, we plan to investigate the reduction of even bigger multi-label datasets (> 1 GB) and its effect on testing machine learning algorithms. Second, we plan to expand our study to include unsupervised learning algorithms. Compared to supervised learning algorithms, unsupervised learning algorithms learn from unlabeled datasets and thus could be harder to validate its output. Third, our experiments show that there exists a high correlation between branch and mutation coverage. However, some recent work reports that traditional code coverage measures such as branch coverage may not be adequate for testing deep learning algorithms. We believe that this has to do with the nature of the algorithms and also the types of fault that may exist in the algorithms. We plan to study this further by conducting experiments on deep learning algorithms. Finally, we plan to develop new methods, i.e., methods other than random sampling, for dataset reduction. For example, we are investigation how to perform equivalence partitioning among instances in a big dataset, and then choose one or more representatives from each equivalence group.

Abstract — **Quantized Hall array resistance standards (QHARS) span values from 100 Ω to 1 MΩ and demonstrate precision approaching that of single devices. This paper focuses on QHARS having values near 1 kΩ for increased sensitivity using room-temperature direct current comparator (DCC) bridges and digital impedance bridges. We introduce a dc QHARS design that uses the Wheatstone bridge principle as a precise test of the QHARS self-consistency for dc measurements. Branched contacts and superconducting interconnections help to reduce ac and dc loading and leakage errors with near-zero resistance at magnetic flux densities of 9 T.**

Index Terms **— electrical measurement standards, quantized Hall resistance, epitaxial graphene, Wheatstone bridge.**

I. Introduction

Equivalent-circuit models of multi-terminal devices [1] have been employed to explore loading and contact resistance effects in measurements of R_H, the quantized Hall resistance (QHR). The main observation is that current drawn from the Hall voltage terminals can cause significant loading error due to the effective series source resistance $r_s = R_H/2$ between the contact (reservoir) and the edge state of the QHR device [2] in a strong magnetic field. In 1993, the metrological application of these principles was established by designs of circuits with multiple links between two or more devices [3]. The first link carries the majority of the current and sets up the equipotential edges on each device, so that Hall voltage interconnections have much smaller loading currents. Thus, loading and dc contact resistance effects can be reduced to negligible levels in QHARS networks. Likewise, multiple connections minimize the effects of parasitic loading in impedance measurements of single devices, and the development of QHR standards in the audio-frequency range has been based on this advance.

II. Ac measurement standards

Prior work in the metrology community with ac QHR standards [4], [5] has not incorporated QHARS devices, since complex circuit interconnections increase the parasitic capacitance. Positive contributions to the frequency-dependent impedance [4] may occur when capacitive current flows between the edge states and conductors that shield the device. Loss occurs only at the edges because the Corbino effect prevents dissipation from the interior, incompressible state of the two-dimensional electron gas. Similarly, ac current across the capacitive junction between the two equipotential edges creates a negative impedance contribution. We have recently reported on epitaxial graphene QHE devices with single-layer NbTiN superconducting interconnections [6], [7] and propose to use this technique for developing ac QHARS having 13 devices in parallel, yielding a resistance near 992.8 Ω. Confocal optical microscope images of sections of prototype arrays are shown in Fig. 1. Superconducting connections include branching contacts to the source and drain [7] and do not require isolated crossovers of the current and potential leads.

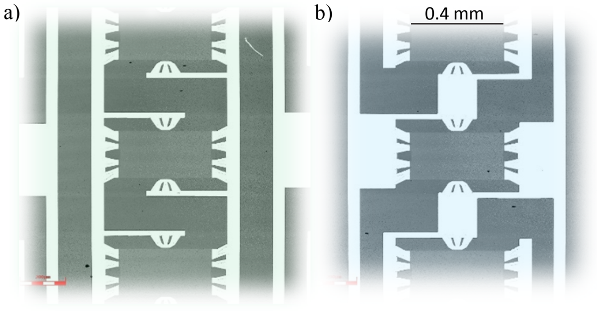

Fig. 1. QHARS device arrays. (a) Current flows in the same direction for all devices. (b) Current flows in alternating directions for adjacent devices to reduce capacitive losses between devices.

III. Dc measurement standards

In comparison with cryogenic current comparator (CCC) systems, room-temperature DCC bridges are less expensive and can be controlled through intuitive automated interfaces. Resistance standards at 1000 Ω are essential for DCC metrology based on the $\nu = 2$ plateau ($R_H \approx 12.9064$ kΩ) and for DCC scaling measurements between 100 Ω and 10 kΩ.

Elmquist, Randolph; Kruskopf, Mattias; Patel, Dinesh; Hu, I Fan; Liu, Chieh-I; Rigosi, Albert; Panna, Alireza; Payagala, Shamith; Jarrett, Dean G. "AC and DC Quantized Hall Array Resistance Standards." Paper presented at 2020 Conference on Precision Electromagnetic Measurements(CPEM 2020), Denver, CO, US. August 24, 2020 - August 28, 2020.

We previously reported on scaling results for DCC measurements based on a single device [7], finding Type A uncertainty about five times smaller for ratios of 1 kΩ/100 Ω than for 12.9 kΩ/1 kΩ with the same current of 1 mA applied to the 1 kΩ standard. Lower uncertainty results for a 1 kΩ/100 Ω ratio because the 1 kΩ measurement current flows in the more sensitive primary winding. Laboratories using DCC bridges could thus improve SI traceability by using QHARS devices at 1 kΩ as the realization of the unit.

Designs of some QHARS incorporate hundreds of devices at present [8] – [11], and superconducting connection designs may allow even higher density integration [6]. The concern that we address for wider adoption of QHARS technology at dc is the reliability of quantum SI traceability. Recommended longitudinal resistance and contact resistance measurements, used for single QHR devices, are impractical at large scales.

Figure 2 shows a dc QHARS circuit with superconducting interconnections. Two identical series-parallel (S/P) arms formed by sets of 11 and 15 QHR devices create a balanced Wheatstone bridge at two null points with voltage V_{SD} applied at the source and drain. A resistance of ≈1016.868 Ω is realized by the series-parallel arms. Three sets of 14 devices in series (S) between the source and drain trim the resistance correction to ≈ -14.696 μΩ/Ω from the nominal 1 kΩ value, and also have intermediate terminals. The design of the array allows an estimation of QHARS resistance error from the consistency of null-voltage measurements at the intermediate terminals with voltages of $V_{\mathrm{S/P}} \approx 0.577\ V_{\mathrm{SD}}$ and $V_{\mathrm{S}} = 0.5\ V_{\mathrm{SD}}$.

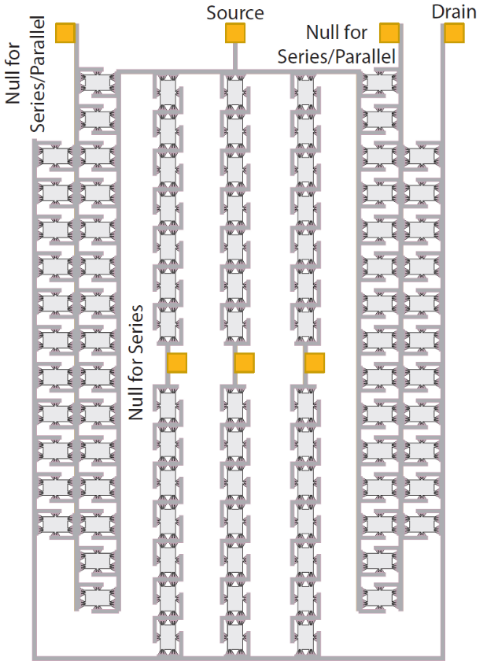

Fig. 2. QHARS array of 94 QHR devices with symmetric Wheatstone bridge elements allows null voltage measurements between intermediate contacts at similar voltage.

IV. Conclusion

Our approach condenses the multi-series interconnection principle by using superconducting NbTiN junctions to create two-terminal series and parallel quantum Hall arrays, thus eliminating possible errors from leakage and reducing internal loading errors in QHARS circuits. The capacitive parasitic loading error is minimized, since loading current is supplied by the source and drain, and this may allow parallel QHARS arrays to provide an alternative to single devices for use in ac bridges. To improve dc reliability, we will apply the Wheatstone bridge principle for *in-situ* characterization of QHARS circuits so that any contact resistance and longitudinal resistance contributions also may be detected for reduced uncertainty.

UNCERTAINTY IN THE SEISMIC RESPONSE OF REINFORCED CONCRETE STRUCTURES DUE TO MATERIAL VARIABILITY

C.L. Segura Jr.(1) and S. Sattar (2)

Abstract

Inherent variability in the mechanical properties of reinforcing steel and concrete introduces uncertainty into the seismic assessment of reinforced concrete structures. Due to the high level of uncertainty associated with earthquake shaking characteristics, uncertainty due to variability in material properties is typically disregarded for seismic assessments. However, the potential impact of incorporating multiple sources of uncertainty in the seismic assessment framework is not well understood. To quantify the impact of material uncertainty, one-hundred iterations of a numerical model of a reinforced concrete structure are evaluated for their seismic performance at several earthquake shaking intensity levels. The one-hundred models differ only by the constitutive parameters used to model the materials, which are selected in accordance with measured statistical distributions of the mechanical properties of reinforcing steel bars and concrete. Material property statistical distributions, and correlations between material properties, are established using test data collected by the authors and test data available in the scientific literature. Preliminary results from analyses at the component level (i.e., individual column) indicate that dispersion in the predicted drift response for a given ground shaking intensity ($S_a[T_1]$) generally increases with shaking intensity, especially in the post-peak response regime for which a coefficient of variation (COV) in excess of 30 % is observed in the analyses presented herein. Of particular interest is the fact that a COV up to 20 % is observed for ground shaking intensities that produce only moderate ductility demands, prior to the onset of strength loss.

Keywords: uncertainty; performance-based earthquake engineering; seismic assessment; reinforced concrete

Segura, Christopher; Sattar, Siamak. "Uncertainty in the Seismic Response of Structural Components due to Material Variability." Paper presented at 17th World Conference on Earthquake Engineering, Sendai, JP. September 13, 2020 - September 18, 2020.

1. Introduction

Variability in the material properties of steel reinforcing bars and concrete affects the strength and deformation capacity of reinforced concrete structural components and, as a result, introduces uncertainty in the seismic assessment of reinforced concrete structures. Variability in material properties can be attributed to several factors including differences in the chemical composition of the steel and concrete materials, the source of the materials, and the material manufacturing processes. It is generally assumed that the contribution of material uncertainty to the overall uncertainty in the seismic assessment of a structure can be disregarded, particularly because of the relatively high level of uncertainty associated with earthquake shaking (record-to-record uncertainty). However, the potential impact of incorporating multiple sources of uncertainty, including that attributed to material variability, in the seismic assessment framework is not well understood. The importance of identifying and quantifying sources of uncertainty other than that associated with record-to-record variability has been highlighted by the results of recent blind prediction competitions in which relatively large dispersions have been reported for seismic response parameters predicted by experts in the field of nonlinear dynamic modeling of reinforced concrete structures [e.g., 1]. What is particularly concerning about the variability in contestant responses for blind prediction competitions is that the input earthquake shaking is known – that is, there is no record-to-record uncertainty.

The Performance-Based Earthquake Engineering (PBEE) framework [2,3] provides a convenient mechanism to account for the various sources of uncertainty that may impact the seismic assessment of structures. This paper describes the methodology used to quantify uncertainty due to variability in material properties. This work is one part of a project aimed at developing a framework to quantify the individual contributions of three main sources of uncertainty on the seismic response of reinforced concrete structures: 1) uncertainty associated with variability in material properties; 2) uncertainty related to the nonlinear modeling formulation used to conduct seismic analyses; and 3) uncertainty in earthquake shaking.

To evaluate the significance of material uncertainty, one-hundred iterations of a nonlinear structural analysis of a reinforced concrete structure are conducted at various earthquake shaking intensity levels. The one-hundred analysis iterations differ only by the constitutive parameters used to model the materials, which are selected in accordance with measured statistical distributions of the material properties of reinforcing steel and concrete, as well as correlations between material properties. To conduct the material uncertainty study, an analytical model representing a circular bridge column tested on the University of California, San Diego (UCSD) shake table in September 2010 [4] is developed. The UCSD bridge column structure is selected for uncertainty quantification because: 1) the bridge column is a simple structure that can be used to evaluate component-level uncertainty; 2) a blind prediction contest was organized and carried out by the UCSD research team [1] in coordination with the shake table test; and 3) comprehensive data are available on the experimental test.

The following sections describe: 1) the formulation of material statistical distributions used to conduct material uncertainty quantification; 2) the range of lateral drift predictions made by contestants of the UCSD blind prediction contest; 3) the development and verification of the analytical model of the bridge column; and 4) preliminary findings for the component-level (column) uncertainty study.

2. Statistical Variability in Material Properties

Variability in the mechanical properties of steel reinforcement and concrete is quantified as a set of statistical distributions and correlations developed using data available in the literature [5,6,7], an extensive database of steel reinforcing bar material tests provided to the authors courtesy of the Concrete Reinforcing Steel Institute (CRSI) [8], and a set of concrete cylinder tests collected by the authors. Material test data used by the authors consists of more than 80,000 tests on Grade 60 (f_y=420 MPa) reinforcing bars satisfying the requirements of ASTM A706 [9], as well as 88 concrete cylinder tests on normal-weight concrete with design compressive strengths between 31 MPa and 35 MPa. ASTM A706 places strict limits on the: 1) minimum and maximum allowable yield strength, to control the forces that can develop in yielding members; 2) minimum allowable tensile strength; 3) minimum allowable tensile-to-yield strength ratio, to ensure adequate spread of plasticity at yielding sections; and 4) minimum allowable tensile rupture strain.

Statistical distributions are developed for material parameters that describe the monotonic stress-strain behavior of Grade 60 ASTM A706 reinforcement and concrete materials, idealized in Fig. 1a and Fig. 1b, respectively. Important material properties include the yield strength (f_y), elastic modulus (E_s), strain hardening modulus (E_{sh}), tensile strength (f_u), and rupture strain (ε_{rup}) of reinforcing steel, as well as the peak compressive stress-strain (ε_{c0}, f_{c0}) and crushing strain (ε_{cu}) of concrete (Fig. 1).

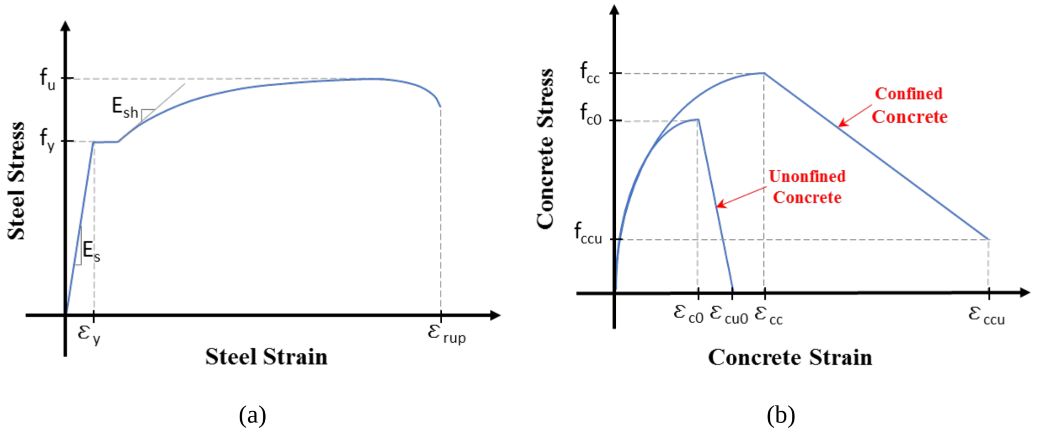

Fig. 1 – Theoretical Stress vs. Strain Behavior – (a) Reinforcing Steel in Tension; and (b) Concrete in Compression (Compressive Stress Shown as Positive)

For uncertainty quantification, material properties are represented as a set of statistical distributions. Fig. 2 provides a representative comparison of the experimental data to normal and lognormal probability distribution function (PDFs) (Fig. 2a) and cumulative distribution functions (CDFs) (Fig. 2b). Correlation coefficients between material properties are determined using a Spearman correlation analysis with a 95 % confidence criterion [10].

Confined concrete properties are not easily derived from test data because several factors contribute to the confined properties. However, confinement models that have been developed using laboratory tests that account for the various factors that affect the confined properties are available in the literature. Uncertainty in confined properties of concrete is quantified using the confinement models developed by Saatcioglu and Razvi [11] and Legeron and Paultre [12]. Specifically, statistical distributions for the peak confined stress-strain (ε_{cc}, f_{cc}) and confined concrete crushing strain (ε_{ccu}) are determined. Two additional confinement models [13,14] were evaluated, but both were deemed to introduce excessive dispersion in confined properties because the model was either developed specifically for rectangular sections, while the analyses reported herein are for a circular column, or because the method used to determine strains on the softening branch of the confined stress-strain curve is inconsistent with the other confinement models [15].

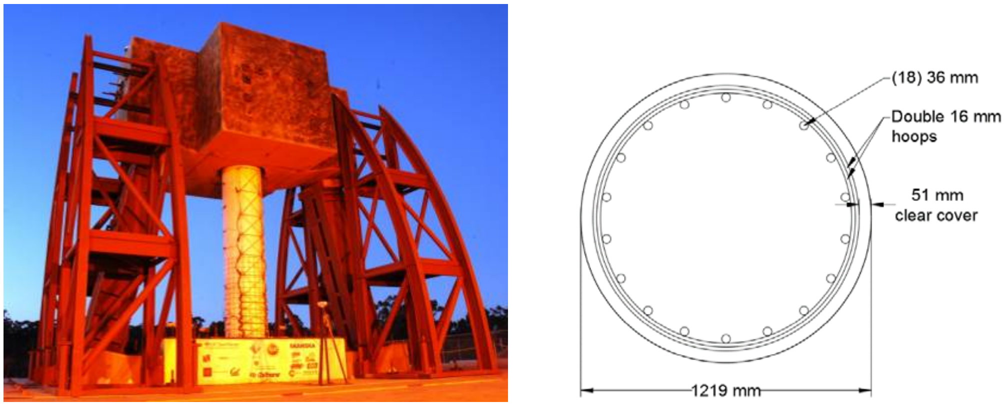
3. Model Development and Verification

3.1 UCSD Shake Table Test and Blind Prediction Contest

The impact of material uncertainty is quantified by evaluating the seismic performance of an analytical model representing a circular bridge column tested on the University of California, San Diego (UCSD) shake table in September 2010 [4]. A photo of the shake table test setup and a cross-sectional drawing of the column are provided in Fig. 3. The column was 1219 mm in diameter and 7315 mm in height. A large concrete mass with

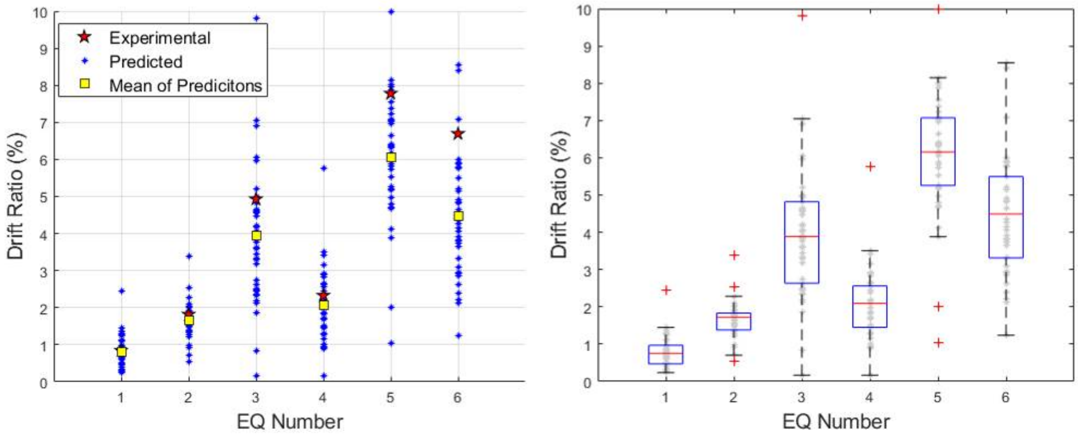


(a) (b)

Fig. 3 – UCSD Bridge Column Shake Table Test – (a) Test Setup; and (b) Column Cross-Section [4]

a total tributary weight of 2.32 MN was attached to the top of the column (Fig. 3). Longitudinal reinforcement consisted of eighteen 36 mm diameter bars spaced evenly about the circumference of the column. Transverse reinforcement consisted of two bundled 16 mm diameter hoops spaced at 152 mm on-center. All reinforcement was specified as Grade 60 (f_y=414 MPa) ASTM A706 and the specified concrete compressive strength (f'_c) was 28 MPa. Measured concrete cylinder compressive strength at the time of testing was 41 MPa. Compressive strains at peak cylinder strength ranged between about 0.0025 and 0.003. The average yield strength and ultimate strength measured for two of the 36 mm diameter reinforcing bar samples were 518 MPa and 706 MPa, respectively, and average rupture strain for the rebar samples was 0.122 [4].

The bridge column was subjected to a series of six earthquake acceleration records, designated as EQ1 through EQ6, that were selected and scaled for target displacement ductility demands of 1.0 (EQ1), 2.0 (EQ2 and EQ4), 4.0 (EQ3 and EQ6), and 8.0 (EQ5). EQ2 and EQ4 used the same scaled record, as did EQ3 and EQ6 [1,4]. Fig. 4a compares maximum drift ratios predicted by the forty-two participants of the blind prediction contest to the experimentally measured responses for the six applied ground motion records. The mean of the predicted responses is also plotted in Fig. 4a. The relative difference in the mean predicted response and the experimentally measured drift ratio (i.e., mean bias) ranges between -6 % (EQ1) and -33 % (EQ6), indicating that the analytical models, on average, tend to underestimate the deformation of the bridge column. Fig. 4b presents boxplots of the contestant predictions for each earthquake record. For each boxplot, the bottom and top edges of the "box" indicate the extents of the data within one standard deviation of the mean of the predicted responses; the top and bottom "whiskers" indicate data within 2.7 standard deviations of the mean; and the "+" markers indicate outliers from a normal distribution. Relatively large dispersion in the predicted response is evident – particularly for EQ3, EQ5 and EQ6 – demonstrating the importance of quantifying potential sources of uncertainty in the seismic assessment framework.



(a) (b)

Fig. 4 – UCSD Blind Prediction Contest Responses – (a) Comparison of Predicted Drift Ratio to Experimental and Mean; and (b) Boxplot of Predicted Responses

3.2 Analytical Model Description

A distributed plasticity model (i.e., fiber model) of the bridge column is developed and nonlinear analyses are conducted in OpenSees [16]. A fiber element formulation is selected because, unlike lumped plasticity models, fiber models enable direct definition of material constitutive properties, thereby making it possible to straightforwardly quantify uncertainty due to variability in material properties. A displacement-based fiber element model (stiffness formulation) is developed and verified against experimental measurements from the UCSD shake table test. The spatial discretization of the fiber model is shown in Fig. 5. The model consists of eight equal length elements, each with three Gauss-Lobatto integration points (Fig. 5a) [17]. An axial load of 2.32 MN is applied at the top node of the column model (Fig. 5a) and held constant throughout the analyses. A lumped mass of 237 000 kg (i.e., 2.32 MN/g_a) is also applied at the top node of the column. Confined concrete is discretized into 8 sections in the radial dimension of the column and 8 sections in the circular direction for a total of 64 confined concrete fibers (Fig. 5b). A total of 32 fibers (4 radial, 8 circular) are used to model unconfined cover concrete. Steel reinforcing bars are discretized into 18 fibers located at the centroid of the bar locations indicated in Fig. 3. Second-order P-Delta effects are accounted for in the nonlinear analyses.

The Concrete02 constitutive model implemented in OpenSees is used to model unconfined concrete. Confined concrete is modeled using the Concrete07 constitutive model and steel reinforcing bar materials are modeled using the SteelMPF model, both of which employ sophisticated constitutive hysteretic rules [18,19,20]. Regularization of the compressive material properties for concrete and steel is conducted in accordance with the technique developed by Coleman and Spacone [21]. The regularization technique adjusts the stress-strain relationships for uniaxial fibers such that analytical results are insensitive to the model spatial discretization. The OpenSees MinMax constitutive model is used to assign tension and compression strain limits for the SteelMPF reinforcing bar constitutive model. The tension strain limit is set as the steel rupture strain capacity while the compression strain limit signals the reinforcing bar material to degrade to zero stress (i.e., rebar buckling) once the confined concrete reaches its crushing strain.

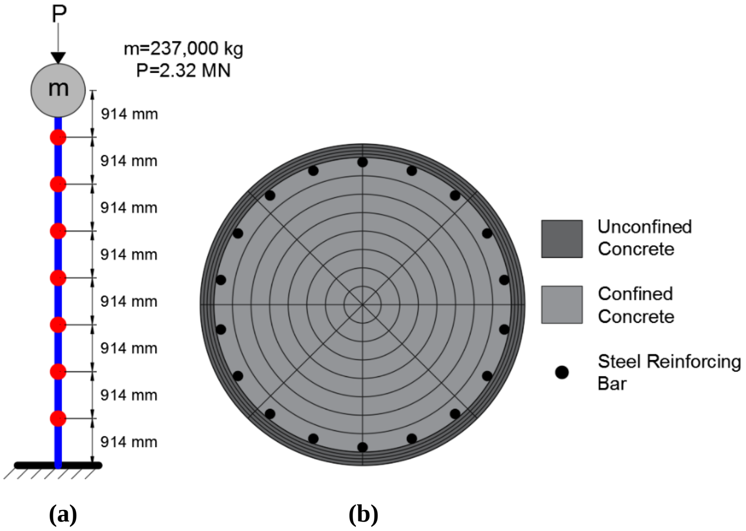


Fig. 5 – Analytical Model Discretization – (a) Elements and Nodes; and (b) Cross-Section

3.3 Model Verification

Model verification is conducted by comparing the response of the analytical model to the response measured experimentally on the shake table at UCSD. To do so, the analytical model is subjected to the acceleration time series applied during the UCSD shake table test, which consisted of six earthquake acceleration records applied separately. A comparison of the analytical and experimentally measured lateral drift ratio, measured at the top of the column, is shown in Fig. 6. Only the experimental deformation attributed to flexure is plotted in Fig. 6 to enable a direct comparison with the results for the fiber element model, which is only capable of capturing the flexural response of the column. It is evident in Fig. 6 that the analytical model is capable of capturing the deformation response of the bridge column, including residual inelastic deformations. For each earthquake record, the maximum analytical and experimental drift ratio are compared in Fig. 6. The difference in the predicted and experimental maximum drift ratio ranges between 3 % (EQ3) and 29 % (EQ5). It is emphasized that model parameters are not "calibrated" to achieve the results presented in Fig. 6; rather, the uniaxial fiber material parameters are taken directly from the measured material properties [4] and confinement models, adjusted for mesh size in accordance with the material regularization technique developed by Coleman and Spacone [21].

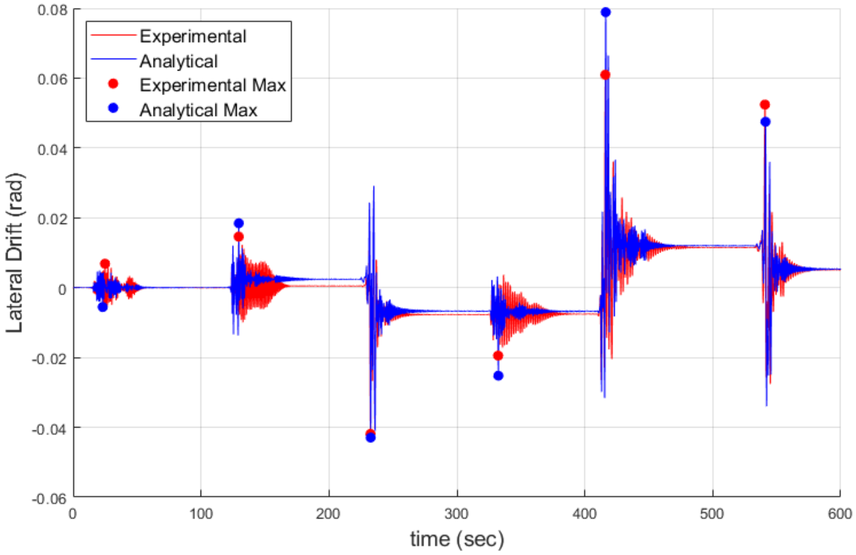

Fig. 6 – Model Verification – Experimental vs. Analytical Lateral Drift Ratio

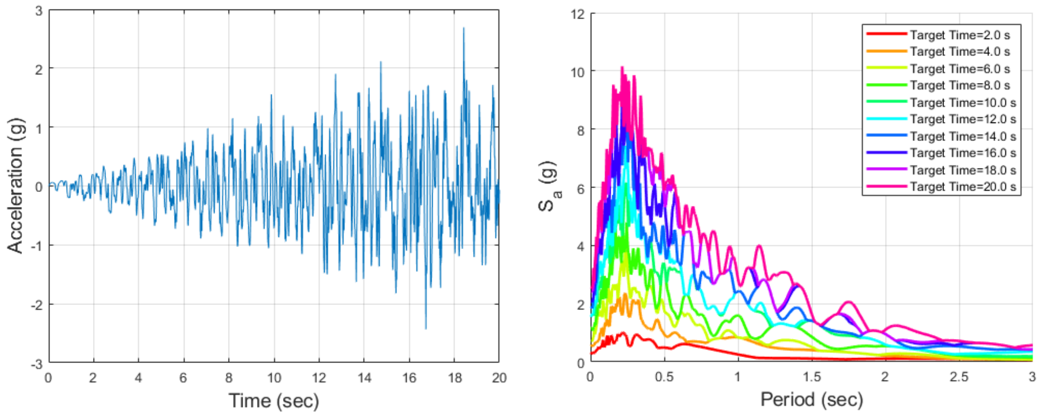
4. Uncertainty Quantification

One-hundred iterations of the analytical model (Fig. 5) are constructed and nonlinear analyses are conducted in OpenSees to quantify the impact of uncertainty in the material properties of reinforcing steel and concrete. The one-hundred iterations of the analytical model are the same in their formulation (Fig. 5), differing only by the material properties used to define the constitutive behavior of the fiber elements. The input constitutive parameters for each model are selected from a set of one-hundred realizations of reinforcing steel, unconfined concrete, and confined concrete material properties. Mean, minimum, and maximum values of the one-hundred material realization set are given in Table 1 for three representative material properties (f_{c0}, f_y, and ε_{rup}). The one-hundred material property realizations are selected to represent the statistical distributions of the material properties, and correlations between properties, described in Section 2 with minimal variation from the desired statistical distributions. The variation in the mean and coefficient of variation for the one-hundred material realization set and the statistical distributions is below 5 % for all material properties.

Table 1: Ranges of Representative Material Properties (See Fig. 1 for Description of Properties)

	Mean	Minimum	Maximum
$\mathbf{f_{c0}}$	33.8 MPa	23.5 MPa	46.4 MPa
$\mathbf{f_y}$	482 MPa	429MPa	529 MPa
$\boldsymbol{\varepsilon_{rup}}$	0.157	0.107	0.211

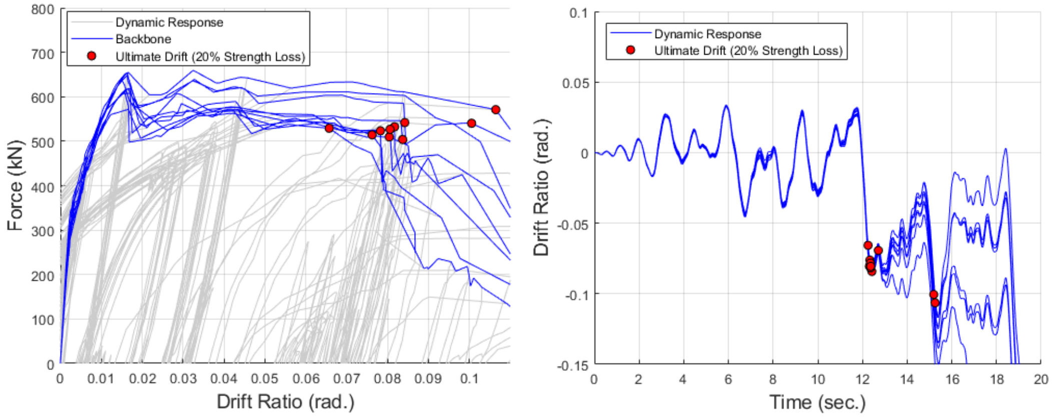
Nonlinear analyses of the analytical models are conducted in OpenSees using an Endurance Time Acceleration Function (ETAF) (e.g., see [22]). ETAF enables the evaluation of the analytical model at progressively increasing ground shaking intensities using a single, unique ground acceleration record. ETAF is, therefore, analogous to a dynamic pushover analysis. A plot of ground acceleration vs. time for the ETAF is provided in Fig. 7a. Fig. 7b presents the 2.5 %-damped pseudo acceleration response spectra (S_a) for ten different target time intervals. A target time interval represents the elapsed time from the beginning of the record. For example, a target time of 10 seconds captures ground shaking for the time between 0 and 10 seconds, whereas a target time of 12 seconds captures ground shaking from time 0 to 12 seconds. As shown in Fig. 7b, the spectral acceleration demands for the ETAF record increase with increasing target time.



(a) (b)

Fig. 7 – (a) Acceleration Record for ETAF; and (b) 2.5 %-Damped Response Spectra (S_a) at Various Target Times

Fig. 8a presents the lateral force vs. drift ratio backbone curves for ten representative analyses of the one-hundred model iterations. The models demonstrate very ductile response, as would be expected for the well-confined section with relatively low axial stress. For each model, the ultimate drift ratio from the analysis is indicated as a red circle on the figure. The ultimate drift ratio is designated as the lateral drift at the last analysis step for which the residual strength exceeds 80 % of the peak capacity (i.e., 20 % strength loss). Variability in the column shear force is evident beyond a drift ratio of about 1 %; however, as shown in Fig. 8b, dispersion in the deformation response of the column is small until the onset of strength loss. Following strength loss, a wide range of deformation responses is evident. The coefficient of variation of the predicted lateral drift ratio ranges between 2.5 % and 8 % for lower earthquake shaking intensities – that is, for target times less than about 8 seconds. For higher earthquake shaking intensities, following strength loss, coefficients of variations reach approximately 16 %.



(a) (b)

Fig. 8 – (a) Lateral Force vs. Drift Ratio; and (b) Drift Ratio Time Series

Overall, dispersion in the predicted deformation response of the column for a particular analysis target time is within what is typically considered an acceptable range for seismic analysis [e.g., see 23,24]. It is important to point out, however, that in the PBEE framework [2,3], the vulnerability of a structure to collapse is often expressed in terms of the probability of reaching a particular engineering demand parameter (EDP) at a given ground shaking intensity. The EDP and the ground shaking intensity measure often used to characterize collapse risk are the maximum lateral drift (Δ_{max}) and the first mode elastic spectral acceleration ($S_a[T_1]$), respectively. Characterization of the dispersion in Δ_{max} for a given $S_a(T_1)$ is, therefore, important to account for uncertainty in the PBEE framework. To illustrate this dispersion, the predicted Δ_{max} values determined for the one-hundred model iterations are presented as lognormal PDFs in Fig. 9 for three earthquake shaking intensity levels: $S_a(T_1)$=0.5g, $S_a(T_1)$=1.5g, and $S_a(T_1)$=3.0g. The best-fit distribution based on the Kolmogorov–Smirnov test at different shaking intensities may differ. A lognormal distribution is used herein because it is commonly used in the field of structural engineering to represent the uncertainty in the lateral drift response of structures. A modal damping coefficient of 2.5 % is assumed for the spectral accelerations in Fig. 9, as is the case for the spectra shown in Fig. 7b. As can be seen in Fig. 9, dispersion generally increases for increasing $S_a(T_1)$. For smaller spectral acceleration demands (i.e., $S_a[T_1]$=0.5g), the dispersion in drift ratio is low. This is expected as the column response is primarily elastic for this level of shaking. As yielding of the column's longitudinal reinforcement occurs (i.e., $S_a[T_1]$=1.5g), dispersion in Δ_{max} increases. Strength loss is observed in most of the one-hundred models for $S_a[T_1]$>2g, after which dispersion in the predicted drift response becomes large in proportion to the variability in $S_a(T_1)$. A similar trend of increasing dispersion in the lateral drift response for higher earthquake shaking intensity levels has been observed for steel columns [25]. It is noted that, due to the use of the ETAF loading protocol (Fig. 7), drift ratio results for larger $S_a(T_1)$ values include previous damage associated with lower $S_a(T_1)$ values.

Table 2 summarizes statistical parameters for the lognormally distributed Δ_{max} at the three ground shaking intensities shown in Fig. 9. The mean $(\bar{\mu}_{\Delta_{max}})$ and median $(\tilde{\mu}_{\Delta_{max}})$ values reported in Table 2 are calculated according to Eqns. 1 and 2, respectively:

$$\bar{\mu}_{\Delta_{max}} = e^{\mu_{\ln(x)}+\frac{1}{2}\sigma_{\ln(x)}{}^2}, \tag{1}$$

$$\tilde{\mu}_{\Delta_{max}} = e^{\mu_{\ln(x)}}, \tag{2}$$

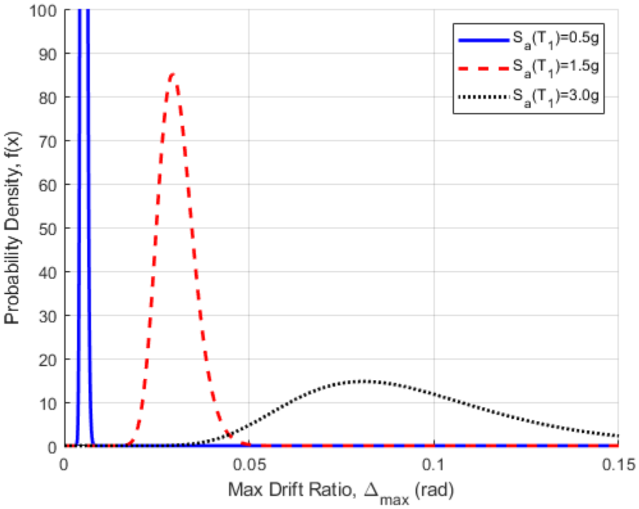


Fig. 9 – PDF of Maximum Drift Ratio for Different $S_a(T_1)$

where $\mu_{\ln(x)}$ and $\sigma_{\ln(x)}$ are the mean and standard deviation of the natural logarithms of drift values. The coefficient of variation reported in Table 2 is calculated according to Eqn. 3:

$$COV_{\Delta_{\max}} = \sqrt{e^{\sigma_{\ln(x)}^{2}} - 1}. \tag{3}$$

For ground shaking intensities that result in elastic response of the column model (e.g., $S_a[T_1]$=0.5g), the coefficient of variation for Δ_{max} is generally around 10 % or less. In the inelastic response regime, prior to the onset of strength loss (e.g., $S_a[T_1]$=1.5g), the dispersion in Δ_{max} becomes larger, reaching a coefficient of variation up to approximately 20 %. The largest dispersion in the predicted drift response (e.g., COV≈30 % for $S_a[T_1]$=3.0g) is associated with a reduction in the lateral load-carrying capacity of the column (softening). The larger dispersion in the softening regime is attributed to the uncertainty in the post-peak behavior of the confined concrete material.

Table 2: Statistical Parameters of Δ_{max} for Different $S_a(T_1)$

$S_a(T_1)$	Mean $(\bar{\mu}_{\Delta_{\max}})$	Median $(\tilde{\mu}_{\Delta_{\max}})$	Coefficient of Variation $(COV_{\Delta_{\max}})$
0.5g	0.53 %	0.52 %	10.8 %
1.5g	3.04 %	3.01 %	15.9 %
3.0g	9.42 %	8.95 %	32.7 %

5. Summary

A methodology to quantify uncertainty in the seismic assessment of structures due to variability in the mechanical properties of concrete and reinforcing steel is presented. This material uncertainty quantification study is one part of an ongoing project aimed at developing a framework to quantify the individual contributions of uncertainty on the seismic response of reinforced concrete structures, at both the component level (individual column) and at the system level (frame) due to: (1) variability in material properties, (2) the choice of nonlinear modeling formulation used to conduct seismic analyses, (3) and earthquake shaking. Uncertainty in the seismic response of a structural component is quantified using one-hundred iterations of an analytical model of a reinforced bridge concrete column. The one-hundred model iterations capture the statistical distributions of concrete and reinforcing steel mechanical properties determined using data collected by the authors and data available in the scientific literature. Analytical seismic responses at various earthquake shaking intensities (i.e., $S_a[T_1]$) are determined for the one-hundred models using an Endurance Time Acceleration Function, which subjects the model to increasing seismic demands using a single ground acceleration record. Results of the component level study demonstrate that dispersion in the predicted drift response due to material variability generally increases with increasing $S_a(T_1)$. In the elastic response regime, dispersion is low (coefficient of variation, COV, around 10 % or less); however, as flexural yielding occurs, dispersion increases (COV up to 20 %) even though a hardening response is still evident in the models. Larger dispersion in the post-peak regime (COV around 30 %) can be attributed to greater uncertainties in the material response of concrete as material softening occurs.

6. Acknowledgements

The authors would like to express their gratitude to the Concrete Reinforcing Steel Institute (CRSI) for providing reinforcing bar mechanical property test results collected from steel reinforcing bar manufacturers in North America. The authors would also like to thank Dr. Vesna Terzic for providing the response data for the UCSD blind prediction contest.

***Abstract* — We have extended the voltage range of the Josephson arbitrary waveform synthesizer from 1 mV down to 1 µV at frequencies from 60 Hz to 1 kHz to calibrate precision lock-in amplifiers. Experimental results show that the system's uncertainty is dominated by the resolution of the lock-in amplifier. We anticipate that the Josephson arbitrary waveform synthesizer-based system will extend the lower voltage and frequency range of ac voltage metrology and improve the uncertainties by one order of magnitude compared to conventional techniques.**

***Index Terms* — Voltage measurement, voltage standards, electric potential, Josephson junction, measurement uncertainty.**

I. Introduction

A Josephson arbitrary waveform synthesizer (JAWS) utilizes the accuracy of the ac Josephson effect to produce voltages calculated from first principles at frequencies up to several megahertz [1]. Behr *et al.* [2] used the JAWS to generate small voltages (from some nV to some mV). We have extended the use of a JAWS to the voltage range from 1 µV to 1 mV, at frequencies from 60 Hz to 1 kHz, to provide traceability to lock-in amplifiers. This offers a convenient and intrinsically accurate alternative to conventional methods for the calibration of lock-in amplifiers, such as those based on the generation of low voltages by means of a calibrated semiconductor source and a calibrated inductive voltage divider (IVD) [3].

II. System Description

Fig. 1 shows the block diagram of the JAWS system. The system is described in [4] and uses Josephson junction arrays (JJAs) and a microwave circuit design developed at the National Institute of Standards and Technology (NIST) [5]. The low voltages required to calibrate lock-in amplifiers are generated directly by the JJAs without any compensation signal. An arbitrary waveform generator (AWG) is used to provide an external reference voltage to phase-lock the lock-in amplifier.

III. Experimental Results

The JAWS produces quantized voltage pulses with a time integral of *h/2e* across each Josephson junction. Given that the JJA produces quantized pulses, for the JAWS to be a fundamental standard its operation must be independent of (a) the JJA used; (b) the biasing electronics (rf amplifiers and dc blocks); (c) the rf power; and, (d) the repetition frequency and the rf pattern of the pulses (i.e., if a particular waveform can be obtained by using more than one repetition frequency and pattern of pulses, the resulting waveforms should be the same). The various parts of the JJA generate sinewaves with slightly different phases due to delays in the arrival of the pulses within various parts of the JJA or the Josephson junctions, resulting in a voltage error. The last condition (d) tests for any errors due to these delays since the number of changes from a "zero" to a "non-zero" value (and vice versa) in the pattern depends on the repetition frequency.

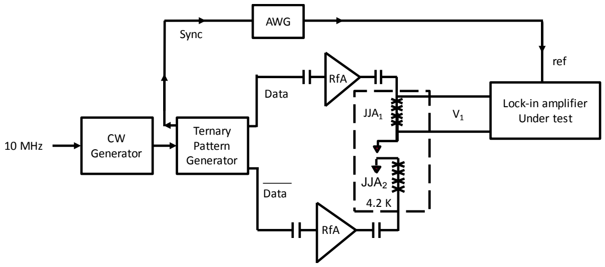

Fig. 1. Block diagram of the JAWS-based system for the calibration of lock-in amplifiers.

We conducted several experiments to provide evidence that these conditions are met. In this summary, we present some of these experiments. We used a commercial lock-in amplifier (SR865A) as a transfer standard.[1] Further experiments will be presented at the conference.

First, we investigated whether the operation of the JAWS-based system was independent of the JJA. We used the same biasing electronics (ternary pattern generator and rf amplifier) to sequentially drive two different JJAs and measured the correction of the lock-in amplifier (1 mV at 1 kHz). The results agreed within 0.08 µV, well below the resolution of the lock-in amplifier (0.1 µV for the 1 mV range).

Next, we investigated whether the JAWS system is independent of the biasing electronics and the repetition

[1] Commercial instruments and design tools are identified in this paper to adequately specify the experimental procedure. Such identification does not imply recommendation or endorsement by NIST and NMIA, nor does it imply that the equipment identified is necessarily the best available for the purpose.

Georgakopoulos, Dimitrios; Budovsky, Ilya; Benz, Samuel P. "Josephson Arbitrary Waveform Synthesizer as a Reference Standard for the Calibration of Lock-in Amplifiers." Paper presented at 2020 Conference on Precision Electromagnetic Measurements (CPEM), Denver, CO, US. August 24, 2020 - August 28, 2020.

frequency of the rf pattern of pulses used to generate the desired signal. We generated four waveforms with the same rms value (1 mV) and frequency (1 kHz), using four different rf repetition frequencies. We then used two different sets of biasing electronics (CH1 and CH2) to bias the same JJA sequentially and measured the correction of the lock-in amplifier (Fig. 2). The results show consistency in the measurements.

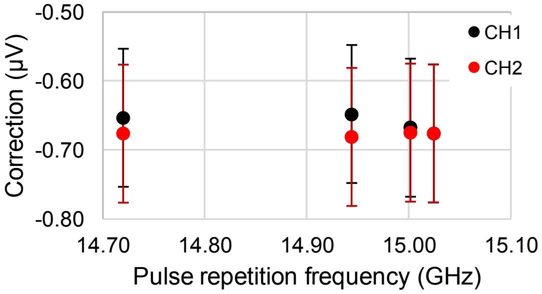

Fig. 2. Correction of the lock-in amplifier at 1 mV and 1 kHz for various pulse repetition frequencies. The error bars show the resolution of the lock-in amplifier

The quantization of the JAWS is usually checked by measuring the spectrum of the generated signal. Fig. 3 shows the spectra of these waveforms, measured with a National Instruments 5922 digitizer at a sampling frequency of 10 MHz, and the spectrum of a signal with the same characteristics produced by dividing a 1 V output voltage of a calibrator (Fluke 5700A) with an IVD (Sullivan F9200) with ratio 1000:1. Fig. 3 also shows the Fourier transform of one of the pattern of pulses downloaded to the pattern generator (for repetition frequency 15.0016 GHz) and the ideal spectrum of a Δ-Σ modulator with similar characteristics to the one used for the generation of the pattern of pulses. As can be seen from Fig. 3, the noise floor and the spurious tones of the JAWS and the calibrator/IVD signals are similar, which suggests that the various spurious tones and the noise floor in the spectrum are features of the digitizer.

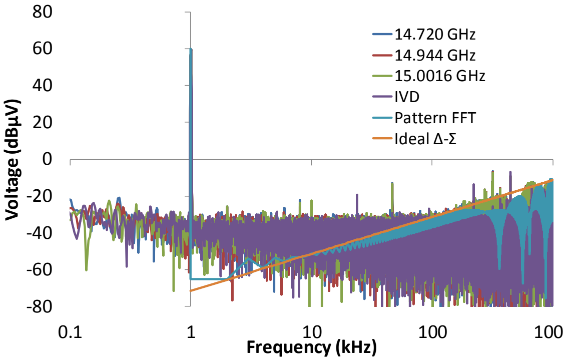

Fig. 3. Spectra of the four waveforms (1 mV at 1 kHz) produced by different means (see text for details).

The corrections of the lock-in amplifier were measured at a number of voltages in the range from 1 µV to 1 mV and at frequencies of 60 Hz, 200 Hz and 1 kHz. Figs. 4a and 4b show the results for 1 µV and 1 mV, respectively. For comparison, Figs. 4a and 4b also show the corrections of the same lock-in amplifier measured with a conventional lock-in amplifier calibration system consisting of a semiconductor source (Fluke 5700A) and an IVD (Sullivan 9700A). The results agree within the resolution of the lock-in amplifier.

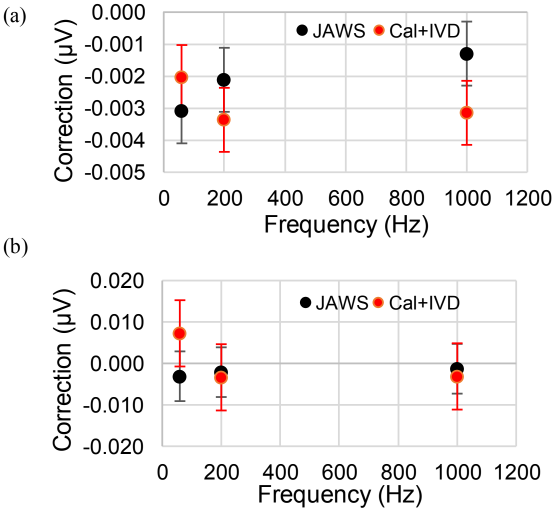

Fig. 4. Correction of the lock-in amplifier at (a) 1 µV and (b) 1 mV for different frequencies. The error bars show the resolution of the lock-in amplifier (1 nV and 0.1 µV, respectively) for the corresponding ranges.

Conclusion

The results presented in this summary show that the JAWS gives consistent results for the generation of low voltages from 1 µV to 1 mV at frequencies up to 1 kHz. The uncertainty analysis, to be presented at the conference, suggests that the dominant uncertainty component is the resolution of the lock-in amplifier under test.

ABSTRACT

Multidimensional coherent spectroscopy measures the third-order polarization response of a system to reveal microscopic electronic and many-body phenomena. Applied to semiconductor nanostructures, it can distinguish homogeneous and inhomogeneous broadening due to disorder or strain gradients, resolve coupling between transitions, and optically access transitions that are either non-radiating or outside the bandwidth of the pulses. Two tools often exploited in this versatile technique are (i) the ability to control the polarization of the excitation and emission and thus the optical selection rules, and (ii) the ability to capture the complex spectrum. Here, the polarization of pulses emerging from a multidimensional optical nonlinear spectrometer (MONSTR) and the resulting four-wave mixing emission are controlled automatically using variable retarders, such that multiple spectra are recorded during a single phase-stabilized scan. This improves the acquisition time by $\sim 3\times$ compared to running separate polarization scans. Importantly, only one phase ambiguity exists in the complex spectra across all sets of polarization states measured. This single ambiguity is resolved by comparing the initial spectrally resolved transient absorption to the complex four-wave mixing spectrum for collinear polarization and then applying it to all spectra. Here, the method is applied to a quantum well embedded in a semiconductor microcavity with an adjustable cavity-exciton detuning. The complex 2DCS spectra we report constitute the first measurements of detuning- and polarization-dependent exciton-polariton lineshape across the strong coupling regime.

Keywords: Multidimensional coherent spectroscopy, Coherent coupling of Exciton-Polariton, Phase corrected 2D Spectra, Four wave mixing

1. INTRODUCTION

Optical properties of semiconductor quantum wells (QW) are dominated by excitonic resonances at low temperature. Excitons are Coulomb bound electron-hole pairs. When such a QW is placed inside a planar semiconductor microcavity at the antinode of the resonant field of the cavity, the QW exciton strongly interacts with the cavity normal mode, resulting in the formation of a new quasiparticle, exciton-polaritons.[1] The single exciton line is replaced with lower polariton (LP) and upper polariton (UP) branches, with a splitting characterized by the vacuum Rabi splitting energy E_{VRS}. Exciton-polaritons are hybrid modes composed of an exciton-like part and a light-like cavity photon mode part. The energies of the LP and UP branches and how these parts are divided between them depends on the detuning (Δ) of the cavity mode with respect to the exciton energy. The detuning-dependent branch energies are depicted in Fig. 1(a). The exciton and photon fractions of the UP or LP branches are represented by Hopfield coefficients,[2] H_x and H_{cav}, respectively, which are shown in Fig. 1(b) as a function of the cavity detuning. In the present study, we employed two-dimensional coherent spectroscopy to investigate exciton-cavity coupling over a range of detuning values near the zero detuning of the cavity.

Two dimensional coherent spectroscopy (2DCS) is an enhanced version of transient four wave mixing (TFWM) which has been developed over the last two decades into an important tool for studying ultrafast coherent processes in semiconductor nanostructures.[3–8] Multidimensional spectroscopy has numerous advantages over linear

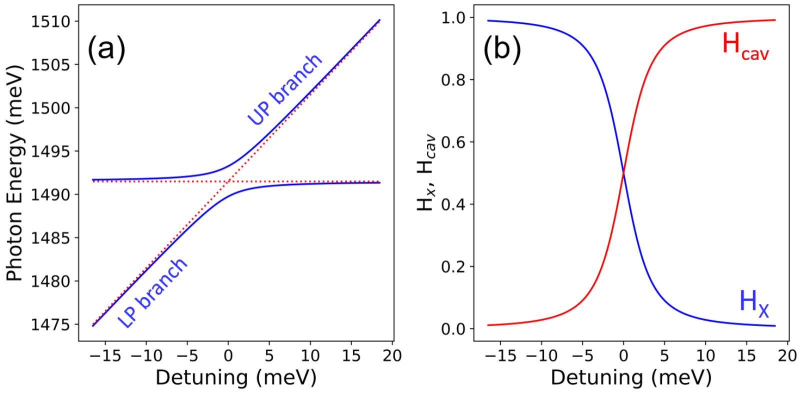

Figure 1. (a) Illustration of anticrossing of LP and UP branches in the semiconductor microcavity studied. The branch energies are shown as blue solid lines. The red dotted lines show the bare exciton (horizontal) and cavity mode (linear slope) energies in the absence of interaction. The splitting at zero detuning is the vacuum Rabi splitting E_{VRS}. (b) Hopfield coefficients of the UP branch plotted as a function of the cavity detuning. H_x and H_{cav} represent the exciton and photon fractions of the branch, such that $H_x + H_{cav} = 1$. H_x and H_{cav} are reversed for the LP branch.

spectroscopy techniques or conventional one dimensional time domain spectroscopy techniques as it correlates two time domains and represents the correlation spectra in a two dimensional map in the frequency domain. In a 2D spectrum, the resonant transition frequencies appear on the diagonal and any coupling between the resonances are revealed by the cross diagonal peaks. Another advantage of 2DCS is that homogeneous broadening can be easily isolated from inhomogeneous broadening a rephasing 2DCS scan. The homogeneous and inhomogeneous linewidths of a resonance can be directly obtained by finding cross-diagonal and diagonal slices of the resonance lineshape,[9] respectively, in a rephasing 2D spectrum. Polarization dependent 2DCS measurements isolate various quantum pathways and allow identification of many body interactions that contribute to the third order nonlinear response of the material.[10] Proper phasing of the 2D spectra allows extracting the signal phase. Previous work on quantum wells in microcavities reported magnitude 2D spectra, not fully phased spectra.[11–14]

In this proceeding, we present polarization-dependent complex 2D spectra, phased using spectrally-resolved transient absorption (SRTA) measurements. Real spectra of rephasing 2DCS for a range of cavity detuning values are measured as well as the polarization dependence for a single (near-zero) detuning. To our knowledge, this is the first report of phased 2DCS in microcavity samples and is the first step to understanding the full $\chi^{(3)}$ response of this strongly nonlinear optical system.

2. EXPERIMENTAL DETAILS

The experimental setup used in our study is well documented in Ref. 15 and will be only briefly described here. A 120 fs mode locked laser pulse from a Ti:sapphire oscillator with a repetition rate of 76 MHz is used as an input to a Multidimensional Optical Nonlinear SpecTrometeR (MONSTR)[16] instrument to generate four identical phase stabilized pulses. In Fig. 2(a), the pulse sequence for a rephasing scan is shown, where the phase conjugated pulse A* and pulse B are separated by time delay τ, and pulse B and pulse C are separated by time delay T. The beams are arranged in a box geometry, i.e. on the corner of a square, as shown in Fig. 2(b). The three excitation pulses, separated by two time delays τ and T, are focused on the sample mounted inside a liquid He cooled cryostat using a single lens and the resulting four-wave mixing (FWM) signal is emitted in the phase matching direction (along the fourth pulse). In a rephasing pulse sequence, the phase conjugated pulse arrives first on the sample followed by the other two pulses, and the FWM signal is emitted as a photon echo in the phase matched direction ($-k_A + k_B + k_C$, where k_i is the wavevector of excitation pulse i). The FWM signal is then collinearly combined with a phase stabilized local oscillator and the resulting spectral interferogram is dispersed into a grating spectrometer, and is then detected by a thermoelectrically cooled CCD. In this work,

rephasing 2D spectra were measured for four different polarization configurations and the time delay T is set to $\approx$ 50 fs. The polarizations of the incident laser pulses were controlled by liquid crystal variable retarders. In order to reduce artifacts caused by scattered light in the direction of the FWM signal, the phase of pump pulses A and B were phase cycled using two additional liquid crystal variable retarders. Phase cycling also improves the signal to noise ratio.

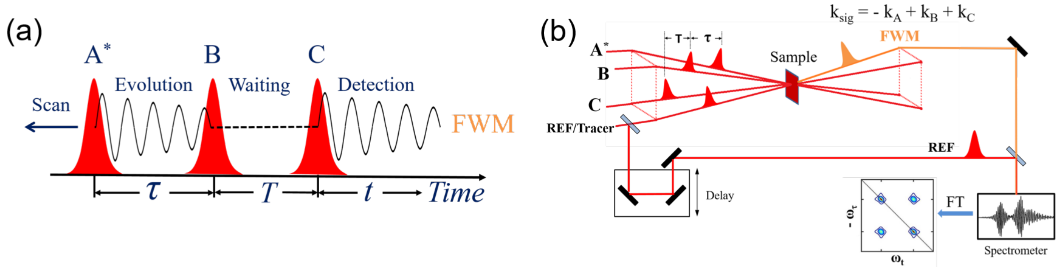

Figure 2. (a) Pulse sequence for a rephasing scan. (b) Pulse arrangement in the box geometry used in the experiment. The four-wave mixing (FWM) beam is emitted in a background-free, phase matching direction $-k_A + k_B + k_C$. The local oscillator (REF) is sent around the sample.

The microcavity sample used in our study was grown by molecular beam epitaxy on a GaAs substrate. The mirrors consist of GaAs/AlAs (14.5 and 12 bilayer) distributed Bragg reflectors separated by a wedged λ GaAs cavity, with a cavity mode close to 830 nm (1491 meV), the energy of the heavy hole exciton. A single 8 nm In$_{0.4}$Ga$_{0.96}$As QW is placed at the antinode of the cavity.[1,12] The sample has a vacuum Rabi splitting parameter $E_{\mathrm{VRS}} = 4$ meV. The cavity is slightly wedged, which allows us to vary the detuning by translating the sample in a direction perpendicular to the incident laser beams. Polaritons are very sensitive to the angle of incidence. In our experiment, the three excitation laser beams were incident on the sample at an external angle of approximately 7° to the normal.

Because of the strong interaction of the microcavity with the light, the optical density and dispersion of the sample is much higher than a typical semiconductor sample. As a result, the all-optical phasing technique often used with the MONSTR did not reliably work. Instead, we measure the spectrally-resolved transient absorption (SRTA) spectrum for the VVVV polarization configuration at the beginning of each scan. This spectrum is the same as a slice of the phased 2D spectrum, which allows us to fit it to find the global phase for that polarization.[17,18] Because we use liquid crystal variable retarders to polarize the beams and capture data for each polarization configuration on every step in the 2D scan, we can apply the known polarization-dependent phase imparted on the beams, which allows us to set the global phase of each polarization configuration measured.[15] Phased complex two-dimensional coherent spectra (2DCS) for common polarization configurations were recorded for a GaAs multiple quantum well sample for comparison to previous work.[10,15]

3. RESULTS AND DISCUSSION

Magnitude-only 2D spectra for this microcavity sample were presented in Refs. 12 and 14. In Ref. 15, preliminary phased polarization-dependent 2D spectra were presented for $\Delta = -6.0$ meV, where the lower branch is primarily light-like and the upper branch is primarily exciton-like. It was found that the diagonal peak corresponding to the exciton-like branch had the same dispersive lineshape as seen for the heavy hole exciton in a bare quantum well sample.[10] However, the sign of the biexciton feature was opposite what is seen in a bare quantum well sample. Here we present phased 2D spectra for values of detuning nearer the avoided crossing ($\Delta \approx 0$) and show how the phased 2D spectrum evolves with Δ.

Figure 3 depicts the rephasing amplitude (a-d) and real part (e-h) of the 2D spectrum for four different polarization configurations at near zero detuning ($\Delta \approx 0.05$ meV). Here, VVVV, VHHV, $\sigma^+\sigma^+\sigma^+\sigma^+$, and $\sigma^-\sigma^-\sigma^+\sigma^+$ represent the co-linear, cross-linear, co-circular, and cross-circular polarization configurations, respectively with first three letters representing the polarizations of the first three pulses, while the fourth letter corresponds to the emission polarization. The lower and upper polariton branch energies on the diagonal are labeled as LP and UP, respectively. Cross-peaks corresponding to couplings between the branches are labeled as UP-LP and LP-UP.

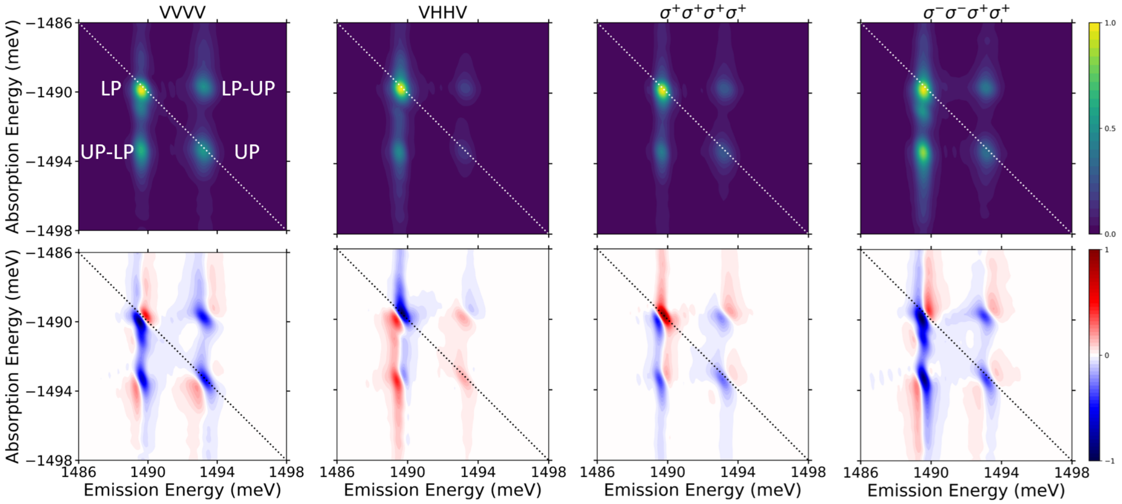

Figure 3. Polarization dependent rephasing 2D Spectra at near zero detuning, $\Delta \approx 0.05$ (meV). (a)-(h) The magnitude and the real part of the complex 2D spectra are shown in the top and bottom rows, respectively. VVVV, VHHV, $\sigma^+\sigma^+\sigma^+\sigma^+$, and $\sigma^-\sigma^-\sigma^+\sigma^+$ represent the co-linear, cross-linear, co-circular, and cross-circular polarization configurations, respectively.

The detuning dependence of the amplitude spectra we measure are consistent with previous results on this sample,[12] so we focus here on the real part spectra. Fig. 4 shows the real part of the rephasing spectrum for Δ values ranging from -3.27 meV to 3.37 meV.

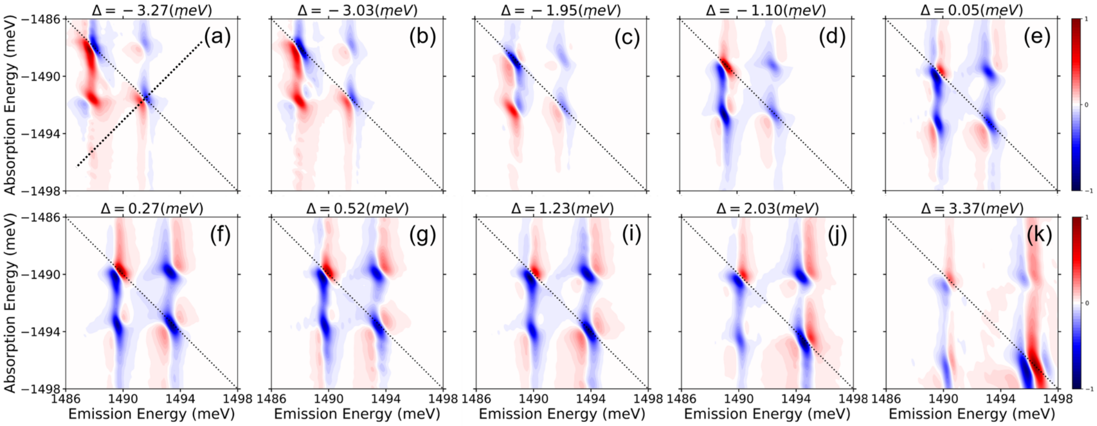

Figure 4. (a)-(j) Real Part of the rephasing 2D Spectra for different detuning values (Δ) in the range of -3.27 meV to 3.37 meV, (shown on top of each spectrum), for co-linear polarization configuration. Each spectrum is normalized to the maximum of the two diagonal resonances.

We find that the phase of the spectrum evolves approximately smoothly as we change the detuning parameter, as expected. This can be seen most clearly in Fig. 5, which shows line outs of the 2D spectra as a function of Δ.

A detailed analysis of the phased spectra and comparison to theoretical models will be explored in future work.

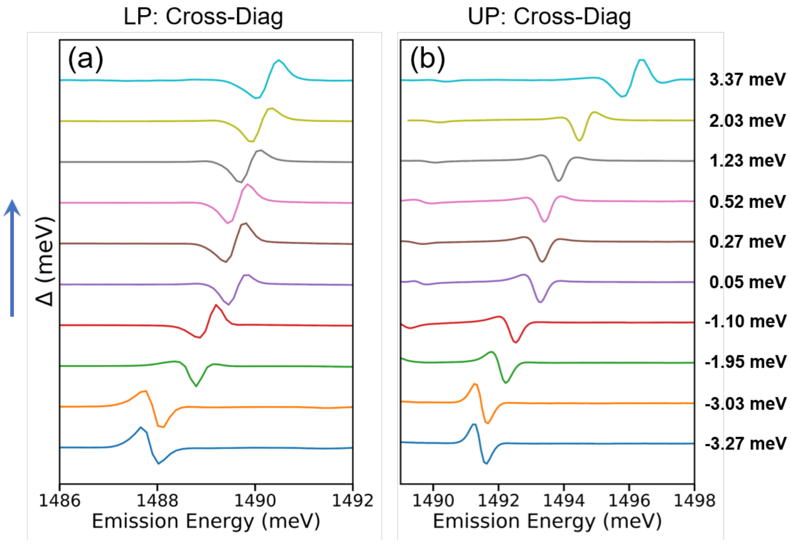

Figure 5. Cross-diagonal profile of real part 2D spectra of LP and UP as a function of detuning.

4. CONCLUSION

In summary, we have measured the response of a microcavity using multidimensional optical coherent spectroscopy. We investigate the coherent coupling between the exciton-like and cavity like normal modes in a semiconductor microcavity as a function of the detuning of the cavity. A full set of polarization dependent 2D spectra with co-linear, cross-linear, co-circular, and cross-circular polarization configuration were collected and phased with the help of spectrally-resolved transient absorption (SRTA) measurements. We observe the phase of the upper and lower polariton branches evolve gradually as a function of detuning.

***Abstract*—The Common Weakness Enumeration (CWE) is a prominent list of software weakness types. This list is used by vulnerability databases to describe the underlying security flaws within analyzed vulnerabilities. This linkage opens the possibility of using the analysis of software vulnerabilities to identify the most significant weaknesses that enable those vulnerabilities. We accomplish this through creating mashup views combining CWE weakness taxonomies with vulnerability analysis data. The resulting graphs have CWEs as nodes, edges derived from multiple CWE taxonomies, and nodes adorned with vulnerability analysis information (propagated from children to parents). Using these graphs, we develop a suite of metrics to identify the most significant weakness types (using the perspectives of frequency, impact, exploitability, and overall severity).**

***Index Terms*—Metrics, Software flaws, Vulnerabilities**

I. Introduction

The Common Weakness Enumeration (CWE) [1] [2] is a prominent list of software weakness types. It is maintained by the MITRE corporation, funded by the United States (U.S.) government, and developed with the participation of 55 organizations. The CWE list contains 808 weaknesses organized by multiple views. Views are 'hierarchical representations' of CWEs (i.e., taxonomies) serving different communities with different perspectives on the data.

A specific view, 1003, was created to support the labelling of publicly disclosed software vulnerabilities ('potential weaknesses within sources that handle public, third-party vulnerability information'). It contains 123 software flaws. The National Vulnerability Database (NVD) [3] and other vulnerability databases and security tools use view 1003 to describe the underlying security flaws within analyzed vulnerabilities. 98.8 % of the 12 760 fully analyzed vulnerabilities published by NVD in 2019 were able to be mapped to view 1003, demonstrating its applicability and coverage.

This linkage of vulnerability analysis to the view 1003 CWEs opens the possibility of using the NVD analysis of software vulnerabilities to identify the most significant weaknesses that enable those vulnerabilities. In this work, we accomplish this through creating mashup views combining the following resources:

- the multiple primary taxonomies of the CWE (views 1003, 1000, 699, and 1008),
- the Common Vulnerabilities and Exposures (CVE) [4] enumeration of publicly disclosed software vulnerabilities,
- the NVD mapping of CVEs to view 1003 CWEs, and
- the NVD measurements of each CVE using the Common Vulnerability Scoring System (CVSS) [5] [6]. This calculates the exploitability, impact, and overall severity of each CVE outside of any particular deployment context.

The result of creating mashups of this data are graphs that have CWEs as nodes. The edges between the nodes are extracted from the parent-child relationships between the multiple CWE taxonomies. And the nodes are labelled with CVE and CVSS information (propagated backwards along the edges). We apply to these graphs a suite of simple metrics that we developed to identify the most 'significant' weakness types. We evaluate significance from multiple perspectives using metrics focused on the following areas: frequency, impact, and exploitability. In doing this we evaluate the CWEs in two distinct groups to take into account the varying levels of abstraction of the CWEs.

We create most significant weakness lists for each metric for the CVE vulnerabilities published in 2019 (not provided due to space limitations). We then analyze the differences between these six lists (3 metrics * 2 sets of CWE types) using two algorithms for comparing differences between ordered lists (Kendall's Tau and the Spearman's footrule variant [7]). We find that different weaknesses tend to emerge as the most significant depending upon the perspective, the metric used, and the CWE type. Note that we use simple low level metrics for our perspectives. This is because there is no ground truth for aggregating those metrics; equations in security that aggregate simple metrics are often practically useful but less scientifically defensible.

Finally, we note that the CWE already has an official metric to identify the 'most dangerous' CWEs. It aggregates both frequency and severity with severity itself being an aggregate metric combining exploitability and impact. We discover weaknesses with this official metric that leads to the under counting of certain CWEs.

We recommend that software developers and creators of software bug finding tools use our approach to prioritize finding and eliminating these most significant weaknesses to

Mell, Peter; Gueye, Assane. "A Suite of Metrics for Calculating the Most Significant Security Relevant Software Flaw Types." Paper presented at 2020 IEEE 44th Annual Computers, Software, and Applications Conference (COMPSAC), Madrid, ES. July 13, 2020 - July 17, 2020.

reduce the number and severity of security related flaws in software.

II. Background

As mashup research, our approach combines multiple resources. These are briefly described and referenced here.

A. Common Weakness Enumeration

Our research is primarily focused on the Common Weakness Enumeration (CWE) [8], a 'community-developed list of common software security weaknesses'. 'It serves as a common language, a measuring stick for software security tools, and as a baseline for weakness identification, mitigation, and prevention efforts' [9]. The 808 software weaknesses within the enumeration are referred to as CWEs where each is named CWE-X with X being some integer. Each CWE is characterized as either a class, base, variant, or compound. Classes are the highest level of abstraction, followed by bases, and then by variants. Compounds are relatively rare and are combinations of multiple bases and/or variants. In our work we evaluate classes separately from bases, variants, and compounds, given that the classes have a much higher level of abstraction.

Besides the CWE weaknesses, there are also 295 categories and 38 views. Confusingly, these are also considered CWEs; for simplification we use the name CWE to refer only to the weakness CWEs. The categories are used to organize the CWEs within select views (this is not used in our research). The views are hierarchical organizations of a subset of CWEs according to some perspective (essentially a taxonomy). The three primary taxonomies are the 'Research Concepts' (view 1000), 'Development Concepts' (view 699), and 'Architectural Concepts' (view 1008). This last view, 1008, was not useful to our work and is not used because it doesn't provide a hierarchy of CWEs but instead uses the categories to group CWEs. The view 1003 designed for vulnerability databases, mentioned previously, is called 'CWE Weaknesses for Simplified Mapping of Published Vulnerabilities View' and is the core data structure upon which our work builds.

B. Common Vulnerabilities and Exposures

The set of software vulnerabilities used for this research come from the Common Vulnerabilities and Exposures (CVE) program, maintained by the MITRE corporation. 'CVE is a list of entries—each containing an identification number, a description, and at least one public reference—for publicly known cybersecurity vulnerabilities' [4] [10].

C. Common Vulnerability Scoring System

The Common Vulnerability Scoring System 'provides a way to capture the principal characteristics of a vulnerability and produce a numerical score reflecting its severity' [11]. It provides equations for calculating a vulnerability's base score (inherent risk outside of any particular environment), temporal score (changing risk over time), and environmental score (risk within a particular environment). We use the base score, which is composed of two sub-scores that calculate the exploitability and impact of a vulnerability. It is maintained by the Forum of Incident Response and Security Teams (FIRST). The detailed specification for CVSS version 3.1 is available at [5].

D. National Vulnerability Database

The National Vulnerability Database (NVD) is 'the U.S. government repository of standards based vulnerability management data' [3]. It is maintained by the U.S. National Institute of Standards and Technology. We use its scoring of CVEs with CVSS scores and its mapping of the CVEs to view 1003 CWEs.

III. Foundational Data Structures

This section describes how we generate the foundational data structure used by our metrics to calculate the most significant security relevant software flaw types. We generate a directed acyclic graph (DAG) of CWEs that we will use to propagate CWE analysis data between the CWEs.

A. View 1003 Graph

We begin with the set of CWEs in CWE view 1003 since that is the set that was adopted by the NVD (and is the set identified by MITRE as most applicable to CVE vulnerabilities). We then form a graph of the view 1003 nodes through extracting the 'ChildOf' relationships in the CWE view 1003 Extensible Markup Language (XML) file. Other kinds of relationships are provided in the XML file but we don't use them because none of them definitively indicate the parent child relationship needed to construct edges in our graph (for example, 'CanPrecede'). The result is a rooted tree[1] with the root being CWE 1003, the nodes at distance one from the root being classes, and the nodes at distance 2 being bases, variants, and compounds. We remove the root as we are only interested in the classes, bases, variants, and compounds. The resulting DAG has 123 nodes and 87 edges, shown in Figure 1. On the left side are the 36 class nodes in blue. The majority of class nodes have edges to bases, variants, or compounds, but five do not. On the right side, the largest grouping of nodes in a single column in purple represents the 82 bases. Moved slightly to the right and in green are the 3 variants. Moved even farther to the right in orange are the 2 compounds.

B. Direct Edge Augmentation

We next augment our view 1003 DAG with edges extracted from the 'ChildOf' relationships specified within other CWE view XML files. For this we use both the CWE research and development concepts views (essentially alternate taxonomies). We can do this because for our metrics we aren't focused on a particular type of child-parent relationship, we just want to know that a child-parent relationship definitively exists between some pair of CWEs in the view 1003 set. This analysis adds 19 edges, shown in green in Figure 2. Note that we move three of the class nodes slightly left of the main
