[1] A perfect tree structure is uncommon in weakness/vulnerability taxonomies. This encouraged us to explore possible missing relationships.

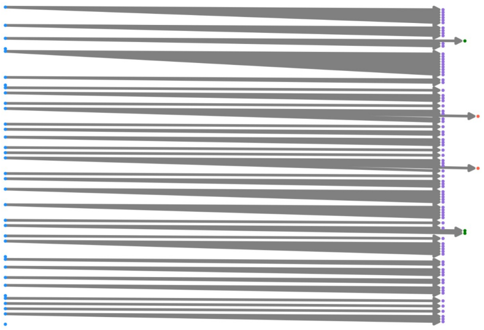

Fig. 1. CWE View 1003 (123 nodes, 87 edges)

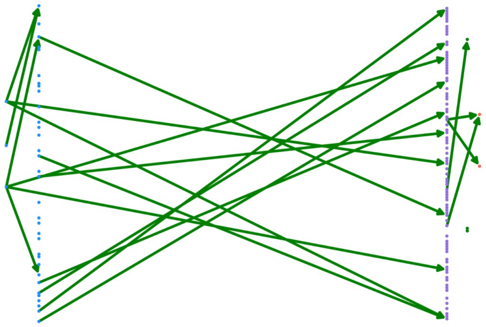

Fig. 2. CWE View 1003 Nodes with Direct Edges from Non-1003 Views (123 nodes, 19 edges)

column of class nodes to enhance visibility because they now have edges to other classes.

C. Indirect Edge Augmentation

Lastly, we create a new DAG (to be used temporarily for this section's analysis) by unifying the set of nodes in views 1003, 1000, and 699 and then adding edges based on the 'ChildOf' relationships specified in the three XML view files. This produces a DAG with 834 CWEs and 1046 edges. Then for each pair of nodes within view 1003, we determine if a path exists connecting them that uses at least one node not in view 1003. Each such discovered path can be used to add an edge to our foundational data structure DAG. These 29 'indirect' edges (that really represent paths using nodes not shown) can be seen in blue in Figure 3.

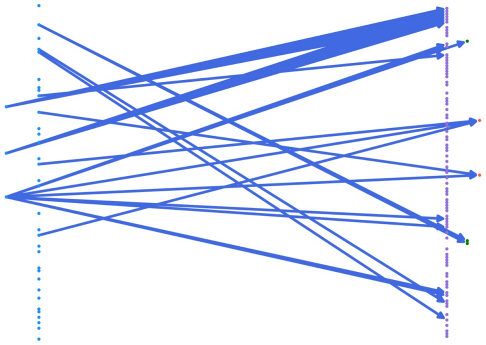

Fig. 3. CWE View 1003 Nodes with Edges Representing Paths from Non-1003 Views (123 nodes, 29 edges)

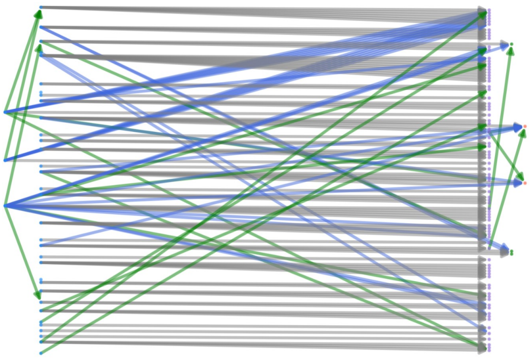

Fig. 4. Composite Graph of View 1003 with Direct Edges and Edges Representing Paths from Non-1003 Views (123 nodes, 135 edges)

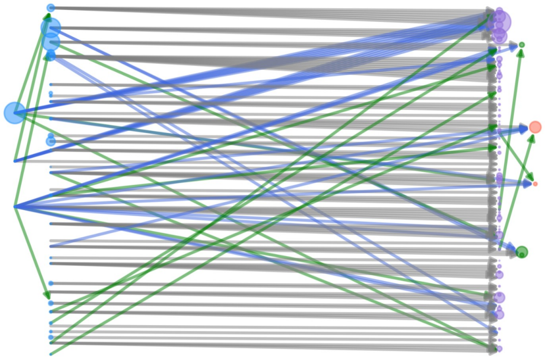

Fig. 5. View 1003 Nodes Adorned with NVD Data (no propagation)

D. Composite Directed Acyclic Graph

We now put together our DAG representing the 1003 view with the direct edge augmentation from Section III-B and the indirect edge augmentation from Section III-C. The resulting graph is shown in Figure 4. It has 123 nodes and 135 edges.

E. Node Adornment

The next step is to adorn the DAG with vulnerability analysis data from the NVD. We take each CVE in NVD that has one or more CWE mappings, and we label each relevant CWE node in the DAG with a vector containing the CVE name, the publish date, and the CVSS attribute information. Figure 5 shows this adornment for the CVEs published in 2019. Note that the size of each node now represents the number of vulnerability vectors mapped to that node.

F. Data Propagation

The edges within the DAG represent opportunities for propagating vector data between CWEs. Parent CWEs receive

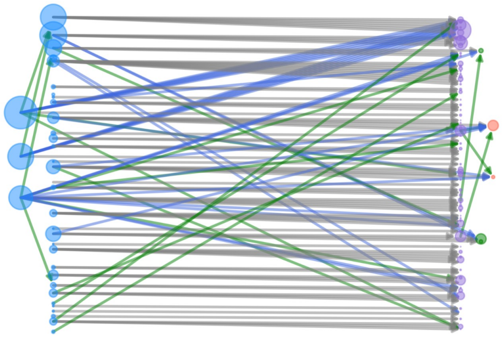

Fig. 6. View 1003 Nodes Adorned with NVD Data (with propagation)

the vectors of their children (with any duplicates being removed). This is because if a vector applies to a CWE then it by definition applies to its more general parent. Also, we discovered that NVD analysts only label a CVE with its most specific CWE. They do not label a CVE with a class if they can determine the applicable base, variant, or compound within that class. Figure 6 shows the DAG adorned with the 2019 vulnerability vectors propagated from children to parents. Note, by comparing figures 5 and 6, how without the propagation some classes get under counted (especially those with many popular bases that are the class' children).

IV. Metrics for Calculating Significance

The DAG in Figure 6 is what we use as the foundational data structure to calculate three simple metrics. The metrics we calculate on this DAG are normalized frequency, mean exploitability, and mean impact. These three metrics are defined below.

We start with a metric to count the number of CVEs mapped to each CWE. Let I designate the set of all CWEs and let J be the set of all CVEs. For CWE $i \in I$, let N_i be the number of CVEs mapped to i. We can write it as:

$$N_i = \sum_{j \in J} e_{ij}, \tag{1}$$

where

$$e_{ij} = \begin{cases} 1, & \text{if CVE } j \text{ is mapped to CWE } i, \\ 0, & \text{otherwise.} \end{cases} \tag{2}$$

A. Metric for normalized frequency (F_i)

$$F_i = \frac{N_i - \min\limits_{i' \in I}(N_{i'})}{\max\limits_{i' \in I}(N_{i'}) - \min\limits_{i' \in I}(N_{i'})}. \tag{3}$$

B. Metric for mean exploitability (Q_i)

Let q_j be the CVSS exploitability score for CVE j. We can write the average of the q_j in all CVEs mapped to CWE i as:

$$\overline{Q_i} = \frac{\sum_{j \in J} q_j e_{ij}}{N_i}. \tag{4}$$

C. Metric for mean impact (R_i)

Let r_j be the CVSS impact score CVE j. We can write the average of the r_j in all CVEs mapped to CWE i as:

$$\overline{R_i} = \frac{\sum_{j \in J} r_j e_{ij}}{N_i}. \tag{5}$$

V. Weaknesses in the Official CWE Equation

In September 2019, the official CWE website provided a metric for measuring the 'CWE Top 25 Most Dangerous Software Errors' [12]. It is an aggregate metric combining the normalized frequency of CVEs mapped to CWEs while using the CVSS severity calculated for each mapped CVE.

This metric, like ours, combines together CWE and NVD data, evaluating only the CWEs within the 1003 view. Differing from ours, it uses the raw NVD mappings (it doesn't perform any data propagation) and evaluates all CWE types together (i.e., classes, bases, variants, and compounds). The metric is described in [12], we summarize it below (leveraging two of our equations from section IV).

A. Official CWE Metric

We first need to define the mean CVSS score for some CWE i as $\overline{S_i}$. Let s_j be the CVSS base score for CVE j. We can write the average of the s_j in all CVEs mapped to CWE i as:

$$\overline{S_i} = \frac{\sum_{j \in J} s_j e_{ij}}{N_i}. \tag{6}$$

Now we define the official 'most dangerous' CWE score as D_i for some CWE i. Let F_i refer to equation 3 and let c_j be the CVSS score for the j-th CVE.

$$D_i = F_i * \frac{\overline{S_i} - \min\limits_{j \in J}(c_j)}{\max\limits_{j \in J}(c_j) - \min\limits_{j \in J}(c_j)} * 100. \tag{7}$$

B. Weakness 1: Undercounting Parent CWEs

Almost all CWE classes in view 1003 have children, as do a few bases. All CWEs that are parents then get under counted because CVEs that apply to them are often assigned to their children. The official CWE metric does not propagate CVE assignments from children to parents. Also, the NVD analysts assign only the most specific CWE to a CVE; they do not include the parents of marked CWEs. This artificially decreases the importance of CWEs that have children when using the official metric. Using the official CWE metric on the 2019 data, each CWE gets assigned a mean of 87.99 CVEs. Using the propagation proposed in this paper to avoid under counting parents, each CWE gets assigned a mean of 294.71 CVEs.

C. Weakness 2: Class Bias

The inclusion of all CWE types in the official metric (i.e., classes, bases, variants, and compounds) causes some classes to be unfairly promoted to being within the top lists. This is because classes are at a much higher level of abstraction and thus more CVEs will apply to them. Using the official metric, we find that there are 8 classes on the 2019 top 25 list (32 %) while there are 36 classes out of 123 CWEs in the 1003 view (29 %). While a bias is not particularly apparent here, the bias is muted because the classes are under counted due to weakness 1 (above). To correctly isolate and measure weakness 2, we remove weakness 1 by using the official metric but while performing data propagation from children to parents. Our regenerated 2019 official top 25 list then contains 16 classes (64 %); here the classes are vastly over represented since only 29 % of the CWEs in view 1003 are classes.

VI. Analysis

Our approach of propagating CVE data over the CWE taxonomies fills in data missing from the official CWE metric approach. This addresses weakness 1 described in Section V-B. Our approach a creating separate top lists for the two levels of CWE abstraction addresses weakness 2, described in Section V-C. Thus, we argue that our approach improves over the original. The question though is whether these improvements make any difference in the results.

Using our DAG and the three metrics, we calculated the most significant CWEs for 2019 at the two levels of abstraction. We now evaluate these results to verify that propagating analysis data over our DAG substantially changes the generated most significant software flaw lists. We also verify that our multiple metrics produce substantially different lists. To compare different rankings, we measure their distance using two related metrics: the Kendall's Tau and the Spearman's Footrule [7]. For two rankings l_1 and l_2, the Kendall's Tau $K(l_1, l_2)$ measures the number of pairs of elements in l_1 that are swapped in their relative positions in l_2. The Spearman's Footrule $F(l_1, l_2)$ measures the number of adjacent element swaps that would need to be performed in l_1 to convert it into l_2. It has been proven that $\forall l_1, l_2, K(l_1, l_2) \leq F(l_1, l_2) \leq 2K(l_1, l_2)$ [7].

Both approaches require that the rankings be of the same length and contain the same elements. Thus, when comparing rankings we use the full rankings of all CWEs observed in the data as opposed to comparing top X lists where X is some integer (using some X to limit list length usually results in lists that contain at least one distinct CWE). The number of observed class CWEs in our data was 36 and the number of non-class CWEs was 87. We performed an empirical study to determine K() and F() for random lists of these sizes using 100 000 trials. The results are shown in Table I.

TABLE I
Distance Between Random Rankings

	K()	F()
Length 36	315	432
Length 87	1870	2522

We first verify that propagating data over our DAG substantially changes the rankings. For each of our metrics, we calculate the full ranking using all available CWEs and then compare that against a ranking created using the same metric but without propagating data over our DAG. The results are shown in Table II. Overall, they show that the lists do change significantly when using the DAG to propagate data. Note that the distances are less for the non-class CWEs which is remarkable because those lists are more than twice as long as the class CWE lists (longer lists in general produce greater distances due to more elements possibly being out of place). However, this can be explained by noting that there are only 4 edges between the non-class CWEs which diminishes the effect of propagating data from children to parents. There are, on the other hand, 135 edges over which data can be propagated to the class CWEs.

We next verify that our multiple metrics produce substantially different lists. If this were not the case, then that would argue towards producing just a single list as opposed to multiple lists with different perspectives. Table III shows the results for the class CWE lists and Table IV shows the results for the non-class CWE lists. Overall, all the lists appear different. The mean exploitability lists have the most distinction from the other two. Comparing the mean exploitability and normalized frequencies lists for the class CWEs we get lists that are even more different than random (see Table I). Comparing the mean exploitability and the mean impact lists, they are almost as different as the random lists.

VII. Related Work

The NVD also provides CWE rating data. This is in the form of two visualizations that show the relative frequency between the observed CWEs per year and another that shows the actual frequency change for the most frequent CWEs [13]. This data is incorrect because it miscounts the frequencies of the CWEs that have children in the CWE taxonomies (because NVD only labels a CVE with its most specific CWE and this information is not propagated to its parents). Also, NVD doesn't distinguish between classes and bases/variants/compounds. The classes are larger categories biasing them to be very frequent, crowding out the bases that are less likely simply due to them being more specific.

VIII. Conclusion

The multiple CWE views can be evaluated as hierarchical taxonomies that reveal parent-child relationships between pairs of CWEs. The different perspectives for each view does not invalidate unifying them because in scoring a CWE as to its significance we want to know all applicable CVEs regardless of the particular method used to organize the CWEs hierarchically. View 1003 provides an obvious base taxonomy from which to start as it was designed to cover the CWEs most used by CVEs. However, its perfect tree structure indicates likely missing relationships. We find those relationships through evaluating the primary three CWE taxonomies (one of which we have to discard because it uses non-CWEs for its higher level classifications). We first find direct missing edges and then find indirect edges (those that represent paths traversing non-1003 view CWEs).

TABLE II
DISTANCE BETWEEN TOP LISTS CREATED USING RAW CWES VERSUS PROPAGATING DATA OVER THE CONSTRUCTED DAG

	Class CWEs		Non-Class CWEs	
	(list length of 36)		(list length of 87)	
	K()	F()	K()	F()
Normalized Frequency	213	324	115	228
Mean Exploitability	188	264	81	154
Mean Impact	175	256	82	164

TABLE III
DISTANCE BETWEEN TOP CLASS CWE LISTS CREATED USING DIFFERENT METRICS (WITH PROPAGATING DATA ON THE DAG)

	Normalized Frequency		Mean Exploitability		Mean Impact	
	Kendall Tau	Spearman	Kendall Tau	Spearman	Kendall Tau	Spearman
Normalized Frequency	0	0	357	488	213	290
Mean Exploitability			0	0	312	420
Mean Impact					0	0

TABLE IV
DISTANCE BETWEEN TOP NON-CLASS LISTS CREATED USING DIFFERENT METRICS (WITH PROPAGATING DATA ON THE DAG)

	Normalized Frequency		Mean Exploitability		Mean Impact	
	Kendall Tau	Spearman	Kendall Tau	Spearman	Kendall Tau	Spearman
Normalized Frequency	0	0	1281	1716	976	1350
Mean Exploitability			0	0	1527	1984
Mean Impact					0	0

The NVD is an ideal data source to analyze the CWEs because it both maps the CVEs to CWEs and also provides CVSS scores for each CVE. We adorned our unified DAG with the CVE information from NVD and propagated that information from children to parents. We then evaluated the DAG with three simple metrics; focusing separately on classes and bases/variants/compounds due to their very different levels of abstraction. We then generated top lists that provide the most significant CWEs relative to a particular perspective and abstraction. We analyzed those lists and discovered significant differences between them. This argues for the usefulness of and need for multiple top lists with different perspectives.

It is our hope that software developers and creators of software bug finding tools will use our approach to help prioritize finding and eliminating CWEs in their code. We hope in turn that this will help reduce the number and severity of security related flaws in software.

Abstract

Aging building clusters worldwide, especially in high seismic regions, will require a retrofit approach to improve the resilience of the built environment. One of the main challenges of retrofitting existing buildings is the associated cost. Fung et al. [1] develop a predictive modeling approach to estimating seismic retrofit costs. The predictive modeling approach uses historical data to predict retrofit costs for existing buildings based on observable building characteristics ("the features"). The advantages of this approach are that it is (1) cheap, (2) fast, and (3) can be applied to a single building or a large inventory of buildings. However, the approach relies on a linear model for prediction, which assumes a restrictive relationship between retrofit cost and the features. In this paper, we consider machine learning methods that can capture more complex, potentially nonlinear relationships between retrofit cost and the features. The paper considers ensemble methods (bagging and boosting) as well as neural networks and compares their performance to that of the linear model. The results show that a neural network provides the best performance in terms of prediction error. In applications, a user faces a tradeoff between accuracy and interpretability: while ensemble methods and deep neural networks may improve accuracy, they are not as easily interpretable as the linear model.

Keywords: seismic retrofit, risk reduction, resilience, retrofit cost estimation, building portfolio, prediction

Fung, Juan; Sattar, Siamak; Butry, David; McCabe, Steven. "Machine Learning Methods for Predicting Seismic Retrofit Costs." Paper presented at 17th World Conference on Earthquake Engineering, Sendai, JP. September 13, 2020 - September 18, 2020.

1. Introduction

Aging building clusters around the world, especially in high-seismicity regions, will require a retrofit approach to improve the resilience of the built environment. One of the main challenges of retrofitting existing buildings is the associated cost. The reliable estimation of retrofit cost is valuable for decision makers, especially in the planning stage of a potential construction project. Machine learning methods have the potential to accurately predict retrofit cost for a single building and, more importantly, for a large inventory of buildings.

Fung et al. [1] present a predictive modeling approach that predicts retrofit cost based on observable building characteristics (e.g., building age and size) and the target performance objective. However, the approach relies on a linear model that essentially assumes a linear relationship between the predictors and retrofit cost (in particular, a *generalized linear model*, or GLM). In this paper, we consider machine learning methods that can capture more complex and possibly nonlinear relationships (in particular, ensemble methods and neural networks). Such methods are useful only if they can perform better than the linear model. However, the tradeoff is a lack of interpretability: for more complex methods, it is often difficult to understand how the model arrives at a prediction. The paper considers whether the performance gain is sufficient to warrant lack of interpretability.

The use of machine learning methods in the retrofit cost prediction literature is not new. Jafarzadeh et al. [2] use linear regression and Jafarzadeh et al. [3] use artificial neural networks. However, a comparison between methodologies is not made. Nasrazadani et al. [4] use Bayesian linear regression. However, the main objective is not to accurately predict cost but rather to quantify uncertainty in covariate effects (e.g., lateral strength). In the broader context of construction cost prediction, Elfaki et al. [5] provide a literature review of "intelligent methods," including machine learning methods.

The paper is organized as follows. Section 2 presents a discussion of the machine learning methods used in this paper. The main results comparing performance of machine learning methods is presented in Sec. 3. Finally, Sec. 4 presents concluding remarks and directions for future research.

2. Machine Learning Methods

This section describes the machine learning methods used in this paper to predict seismic retrofit costs. It is worth noting that the methods covered are not intended to be exhaustive. Rather, the methods are chosen in order to illustrate the tradeoff between model complexity and performance. A more complete treatment of machine learning is beyond the scope of this paper. An excellent reference is Mitchell [6].

At a high level, machine learning is a set of methods that finds patterns in data [7]. There are two main types of machine learning methods: supervised learning, which is *predictive*, and unsupervised learning, which is *descriptive* [7]. The key difference is that supervised learning has access to an outcome of interest (e.g., retrofit cost) and the goal is to predict the outcome from the input data (e.g., building characteristics) [8]. In contrast, there is no explicit outcome of interest under unsupervised learning and the goal is to explore patterns in the input data (e.g., clusters or latent features) [8].

This paper deals with a supervised learning problem. In particular, retrofit cost prediction is a *regression* problem because the outcome of interest, retrofit cost, is real-valued. If the outcome of interest is categorical (e.g., high cost vs low cost), the supervised learning problem is *classification*. In supervised learning, the model learns about the relationship between the input data (or features) and the outcome of interest. See Hastie et al. [8] for a treatment of supervised learning problems.

More precisely, suppose you have a set of features X (the covariates, or explanatory variables) associated with an outcome Y (the dependent, or response, variable). There is some relationship between X and Y, say $Y = f(X)$, and you would like to "learn" that relationship in order to predict new values of the outcome when presented with new instances of the features, say, $Y^*_{new} = f(X_{new})$.

In practical terms, to learn the function f means to fit a model (e.g., a GLM or a neural network) to data. How well the model captures the relationship between features and outcome depends on two key factors. The first is that the "training data" used to fit the model, $\{(X_i, Y_i)\}_{i=1}^{n}$, is sufficiently rich to credibly estimate the parameters of the underlying model. This means that a large number of examples n is not sufficient; the quality of the training data also matters. The second is the model itself, which may require "tuning" (i.e., the choice of hyperparameters such as the number of layers in a neural network). These issues, which are beyond the scope of this paper, are covered extensively in Hastie et al. [8].

In the context of cost prediction, X includes building characteristics (such as building age and size), and retrofit characteristics (in particular, the performance objective). The outcome Y may represent the actual cost from a retrofit or the estimated cost (e.g., a design or bid estimate) for a potential retrofit. As in Fung et al. [1], this paper uses data collected for FEMA 156 [9]. The training data is discussed in more detail in Sec. 3 below.

To determine how well a model captures the relationship between features and outcome, we need to quantify the quality of the predictions the model produces. This requires the choice of a loss function, $L(Y, f(X))$, that penalizes errors in prediction [8]. In other words, the criterion for choosing f should be to *minimize prediction error*. In regression problems, the most common and convenient way to quantify prediction error is squared error loss (or mean squared error):

$$L(Y, f(X)) = E[(Y - f(X))^2] \tag{1}$$

In this paper, we use the square root of Eq. (1), the *root mean squared error* (RMSE). The criterion is used to estimate the parameters of the underlying model (e.g., the parameters in a GLM may be estimated by the Newton-Rhapson method that minimizes Eq. (1)). The "trained" model is the model with parameters chosen to minimize RMSE, which is estimated by computing the empirical loss function.

Once the model is trained, it should be validated to estimate how good it is at making predictions. The goal is to estimate how the model will perform (in terms of prediction error) on new data examples. A model may perform very well on the training data while performing very poorly on new data, a problem called overfitting [7]. For instance, we train a GLM on FEMA 156 data so that we can predict retrofit cost for a building that we are interested in retrofitting (in other words, a building that is not in the training data). Validation is the key step to assessing generalizability of a model. Performance is measured by estimating RMSE on data that is *not used to train the model*. Otherwise, RMSE estimates will be biased because the model already knows the data! When the training data is not very large, as in our case, cross-validation can provide unbiased estimates of RMSE [8].

In the following subsections, we describe the particular machine learning methods we use in this paper, including the least complex method: the linear regression model.

2.1 (Generalized) Linear Model

In classical linear regression, the outcome is typically assumed to follow a normal distribution. The generalized linear model (GLM) extends the classical linear regression model by allowing the outcome to follow any distribution in the exponential family, such as the normal, binomial, Poisson, and gamma distributions [10]. Depending on the outcome distribution, the GLM can be used for regression or classification problems (for instance, the binomial distribution yields logistic regression, a widely used statistical model for binary classification).

As the name suggests, the GLM is essentially linear. While the GLM is not strictly linear, it nevertheless imposes a restrictive structure on the relationship between features and outcome. One might wonder if this restriction somehow hurts performance, in terms of high prediction error. On the other hand, as discussed in Fung et al. [1], the GLM has several strengths: relative to a more complex model such as a neural network, it is both easier to train and easier to interpret. The latter is particularly important if the ultimate objective is not just to predict Y but to understand what features are driving the prediction.

2.2 Ensemble Methods: Bagging and Boosting Trees

Tree-based methods, such as Classification and Regression Trees (CART) are a very different type of model to the GLM. At a high level, a decision tree partitions the feature space into different segments and uses the mean value of the outcome corresponding to a chosen segment. For instance, if X represents building age, we partition X into two segments, say $X \leq 50$ and $X > 50$. Given X_{new}, we predict Y_{new} based on the mean value of Y in the segment that X_{new} belongs to. If X represents multiple features, say building age and building historic status, then partitioning is recursive as shown in Fig. 1 (hence the tree structure) [11].

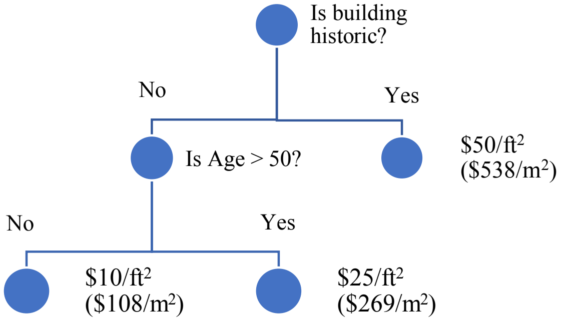

Fig. 1 – Example of a regression tree with two features: historic status of building and age of building. The terminal nodes represent predictions based on the mean retrofit cost in that branch of the tree. For instance, for a non-historic building that is over 50 years old, the predicted cost is $25 per square foot.

Representation of recursive partitioning as a tree makes these models interpretable, since they reflect the steps of a decision-making process. Moreover, the structure has the potential to easily capture interactions between features as well as non-linear relationships between features and outcome. Unfortunately, the hierarchical structure comes with a significant disadvantage: trees often have high variance [8]. Intuitively, this is because trees are highly sensitive to the partitioning rule, since any errors in the partitioning will be propagated down the tree. As a result, prediction error from a single tree can be large.

One way around these limitations is to combine the predictions of many trees. Ensemble methods leverage multiple individual algorithms to obtain better performance than each algorithm on its own. Two of the most common ensemble methods are *bagging* and *boosting*.

Bagging, short for bootstrap aggregating, resamples the training data (with replacement) B times, fitting the model to each of the B models and averaging the predictions across the B models. This process reduces the variance from fitting a single model to the training data without increasing the bias [12]. While bagging was originally applied to trees, the method can be applied to create an ensemble of any model. Bagging trees is robust to noise, outliers, and avoids overfitting. In this paper, we use *random forests*, a bagging method that additionally uses random subsamples of the features in order to reduce correlation across trees [13].

Boosting, on the other hand, fits a model sequentially M times to the training data. At each step m, the training data is reweighted based on the model's performance in the previous step, with the goal of focusing learning on the training examples that the model is predicting poorly, and at the last step M the final prediction is a weighted average of the M predictions [14]. Boosting was originally proposed for classification but has since been extended to regression. In contrast to bagging, boosted trees are not robust to noise or outliers. In this paper, we use a *gradient boosted model* (GBM), a boosting method that addresses some of the weaknesses of boosting, namely speed and robustness [15].

While boosting superficially resembles bagging, its objective makes the ensemble procedure very different. Boosting iteratively improves the performance of a "weak" learner (i.e., learner with high prediction error) to create a "strong" learner that has lower prediction error than the weak learners. Bagging, on the other hand, is a special case of model averaging: each model is fit independently of the others.

As is immediately obvious, the performance improvements provided by bagging and boosting come at a cost: combining multiple trees means the final "model" loses its interpretability. The question we ask in this paper is whether the improvement in performance (ie, lower prediction error) justifies the loss of interpretability: in other words, not just if such models are better but rather how much better.

2.3 Neural Networks

Another set of models that has recently received a lot of attention is the neural network. Neural networks are not new, however. The foundational theory dates back to the 1940s, with a mathematical model of how the brain processes complex information through the use of many simple neurons (hence the name) [18]. What is relatively novel is that the combination of large amounts of data and computing power in the early 21st century has allowed such previously intractable algorithms to be used broadly.

Despite the name and original motivation, neural networks have not been successful for plausibly modeling biological systems. Instead, neural networks have found success in statistical pattern recognition. The quintessential neural network is the feedforward neural network, or the multi-layer perceptron (MLP), essentially a "function approximation machine" [19]. A feedforward network learns a mapping $Y = f(X)$ by passing the inputs X through multiple hidden layers of neurons. Each layer finds a new representation of the features that is fed to the next layer, as shown in Fig. 1. Thus, the function f that is learned is simply a composition of many simpler functions. The term "feedforward" refers to information going in one direction (from inputs to output). If the output is fed back into the model, the network is called *recurrent*. Feedforward networks are most suitable for structured, tabular data [18].

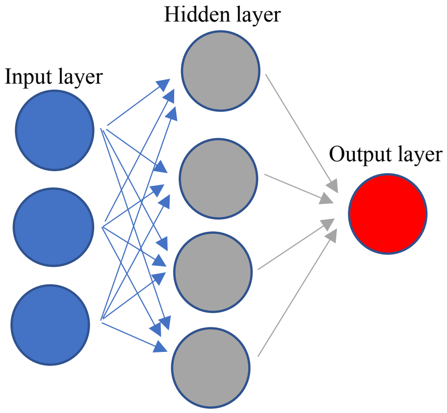

Fig. 2 – Example of a feedforward neural network with a single hidden layer. The input layer represents the features, which get passed on to the hidden layer. The hidden layer transforms the input features into a set of hidden features, which are passed on to the output layer to produce predictions. Note that the number of neurons in the hidden layer does not have to be the same as the number of features.

This simple idea belies the complexity of feedforward neural networks. The number of layers, including input layer, hidden layers, and output layer, defines the depth of the network. This is where the term deep learning originates. Moreover, the hidden layers can perform nonlinear transformations of the inputs and thus the network can learn a nonlinear and complex function f that is difficult to learn with a regression model.

Indeed, a neural network may be thought of as a nonlinear generalization of linear regression [8]; if the units in the hidden layers all perform an "identity" transformation, the entire model collapses to a linear regression model.

Estimation of the underlying parameters, however, requires solving a nonlinear, non-convex optimization problem. Fortunately, the gradients can be computed efficiently through *backpropagation* [18]. A thorough treatment of neural networks is far beyond the scope of this paper. For a deeper dive, see Goodfellow [19].

Like the ensemble methods discussed in Sec. 2.2, the complexity of a feedforward neural network makes interpretability (understanding how the algorithm produced a prediction) virtually impossible. Indeed, the impressive performance of neural networks has been criticized for coming at the expense of "black box learning." The interpretability problem has become a hot research topic in artificial intelligence (AI) more generally, as evidenced by the nascent field of Explainable AI; see Adadi and Berrada [20] for a survey.

3. The Training Data

In this section, we describe the training data used to predict seismic retrofit costs, originally collected for FEMA 156 [9]. The data is freely available online as part of FEMA's archived Seismic Rehabilitation Cost Estimator (SRCE) software (SRCE [16]). The data set includes retrofit cost and building characteristics for each of 1978 buildings in the United States and Canada. While the data set does not include primary building use, it nevertheless represents the most complete publicly available data set on seismic retrofit costs for North American buildings. The SRCE data is discussed in detail in Fung et al. [1].

In this paper, we use the features presented in Table 1. As shown in the Table, we focus on predicting *structural* retrofit cost (in particular, we predict the structural *unit* cost: structural cost per square foot). As we show in Fung et al. [1], predicting total retrofit cost is associated with much higher prediction error.

Table 1 – Description of the SRCE training data used in this paper

Variable	Definitions	Range of values
Structural retrofit cost	Cost to retrofit structural elements of a building, in millions of US dollars	[0.002, 157.161]
Area	Building floor area, in 1000ft$_2$ (93m$_2$)	[0.2, 1430.3]
Age	Building age, in years since construction	[2, 153]
Stories	Number of above and below ground stories	[1, 38]
Historic	Is building deemed historic?	Y, N
Occupancy	What happens to occupants during retrofit?	IP, TR, V
Seismicity	Site seismicity	L, M, H, VH
Performance objective	Retrofit target performance objective	LS, DC, IO
Building type	Building model type	See Table 2

Costs in the original SRCE data are normalized to average construction costs in California for 1993. Following Fung et al. [1], we normalize costs to US national average construction costs in 2016, using the Engineering News Record's Building Construction Index (BCI) [17]. It is worth noting that retrofit engineering practice has evolved since the SRCE data was collected, likely decreasing the rate of growth in retrofit costs relative to the growth in the material and labor costs represented in the BCI.

Historic is a binary variable denoting whether the building is deemed historic and, thus, requires special care to preserve historic elements of the building. Occupancy denotes whether occupants are left in-place (IP), temporarily relocated to another part of the building (TR), or completely vacated (V) during the retrofit. Seismicity is measured using peak ground acceleration (*pga*) with a 5 % chance of exceedance in 50 years and is grouped into four categories [1]. In principle, any measure that captures the variation in seismic exposure will work. The performance objectives in the SRCE data are Life Safety (LS), the most common target, Damage Control (DC), and Immediate Occupancy (IO). For definitions, see FEMA 156 [9].

Finally, Table 2 presents the 15 building types represented in the SRCE data. In the models, we group building types based on structural similarities [1]. Note that, by far, unreinforced masonry is the most highly represented building type (32 %), followed by concrete frame with infill walls (C3) and concrete shear wall (C2), each at about 18 %. More details on the SRCE data are given in Fung et al. [1].

Table 2 – Building groups, building types, and their fraction in the SRCE data

Group	Building type	Building type name	Fraction in data
1	URM	Unreinforced Masonry	31.85 %
2	W1	Wood Light Frame	3.28 %
	W2	Wood (Commercial or Industrial)	4.85 %
3	PC1	Precast Concrete Tilt Up Walls	3.34 %
	RM1	Reinforced Masonry with Metal or Wood Diaphragm	5.24 %
4	C1	Concrete Moment Frame	7.54 %
	C3	Concrete Frame with Infill Walls	18.22 %
5	S1	Steel Moment Frame	4.98 %
6	S2	Steel Braced Frame	2.29 %
	S3	Steel Light Frame	1.31 %
7	S5	Steel Frame with Infill Walls	7.86 %
8	C2	Concrete Shear Wall	17.96 %
	PC2	Precast Concrete Frame with Infill Walls	0.98 %
	RM2	Reinforced Masonry with Precast Concrete Diaphragm	0.85 %
	S4	Steel Frame with Concrete Walls	2.11 %

4. Results

This section presents the results of training five different models on the SRCE data. In particular, we consider a linear regression model, a generalized linear model (GLM), a bagging model (random forests), a boosting model (GBM), and a neural network model (MLP).

We train each of the five models on the SRCE data using K-fold cross-validation in order to estimate out-of-sample performance, with $K = 10$. K-fold cross-validation randomly splits the data into K mutually exclusive subsets, iteratively using each as a validation set while training the model on the remaining data. Out-of-sample prediction error is estimated by averaging RMSE across the K iterations. Hyperparameters (e.g., tree depth, number of hidden units) are chosen using random grid search. Table 3 presents out-of-sample prediction error estimates, as well as training error (that is, average RMSE from training a model), for each of the models. The results suggest that the neural network, GBM, and random forest outperform the linear regression models. In particular, the prediction error for the linear regression model is \$3/ft$_2$ (\$33/m$_2$) higher than for the neural network.

Table 3 – Out-of-sample prediction error estimates (validation error), with their standard deviation. Based on K-fold cross-validation with $K = 10$. The training error represents the minimization of the loss function (in this case, RMSE), used to estimate the model parameters. Values in 2016 USD per ft$_2$ (m$_2$).

Model	Validation error	Standard deviation	Training error
Neural network	34.99 (376.64)	9.16 (98.60)	28.66 (308.50)
GBM	35.07 (377.50)	9.67 (104.09)	13.48 (145.39)
Random forest	35.14 (378.26)	9.93 (106.89)	36.27 (390.42)
GLM	37.13 (399.68)	9.10 (97.95)	38.57 (415.18)
Linear regression	38.04 (409.47)	8.59 (92.47)	38.63 (415.82)

Does the \$3/ft$_2$ (\$33/m$_2$) reduction in prediction error justify the loss in interpretability? Ultimately, this is subjective and depends on the problem context and the extent of the retrofit in terms of square footage. For a building owner that only cares about obtaining the most accurate estimate, the tradeoff may be highly valuable. In particular, for a building owner facing a 10,000ft$_2$ (929m$_2$) project, the potential cost from larger error is \$30,000. In contrast, for a consultant or any other user that must be able to provide an explanation as to *why* the cost estimate is y, a GLM may be desirable as it provides transparency and interpretability as to what features are driving the cost estimate. In this case, a \$2/ft$_2$ (\$21/m$_2$) reduction in prediction error may not be so appealing, especially for a smaller retrofit project.

4.1 Model Details

For completeness, we now describe each of the model architectures. The GLM uses a gamma distribution for the outcome with a log link function, i.e., $\ln(E[Y|X]) = X\beta$ [1]. The neural network includes one hidden layer with 500 neurons, with a rectified linear unit (ReLU) activation function. (The activation function transforms the weighted sum of the input to the layer into an output for the next layer; the ReLU activation function is the standard activation function for MLPs as it typically achieves better performance than other functions due to its handling of the vanishing gradient problem. For more details, see Goodfellow et al. [19].) The number of hidden layers and neurons is chosen by random grid search.

The GBM and random forest models can best be described in terms of number of trees and tree depth (i.e., the number of splits an individual tree performs), which are hyperparameters chosen by random grid search. For the GBM, the number of trees (that is, the number of boosting iterations) is M=46, with a maximum depth of 14. This results in an average of 547 leaves (i.e., terminal or decision nodes), with the smallest tree having only 174 leaves. The random forest model fits 37 separate trees, with a maximum depth of 29. This results in an average of 690 leaves, with the smallest tree having 550 leaves.

Each of the five models employs a form of *regularization*, a technique used to avoid overfitting when training a model. For the linear regression model and the GLM, regularization takes the form of adding a penalty term to the objective function. Broadly, regularization penalizes model complexity. The linear regression model in Table 3 uses a quadratic penalty (this is commonly called ridge regression) [8]. The GLM, on the other hand, employs a linear penalty term (known as lasso). For the neural network, we use *dropout* for regularization [21]: in the hidden layer, 50% of the neurons are randomly dropped before passing the inputs to the activation function.

Regularization for ensembles of trees, on the other hand, is to a certain extent "built in." For GBM, the most straightforward method is to limit the number of boosting iterations M. For random forests, limiting tree depth is the easiest method of regularization. It is worth noting that in the random forest model trained in Table 3, all 37 trees have depth 29. For more advanced regularization techniques, see Hastie et al. [8].

It is worth noting that the neural network in Table 3 is not very deep, as it only contains a single hidden layer. A deeper neural network, with three hidden layers (each with 200 neurons, ReLU activation functions, and 40% dropout) performs worse than the neural network in Table 3, with out-of-sample prediction error of 37.28. While it does outperform the GLM and linear regression model, these results demonstrate that a more complex model is not always better.

5. Conclusion

In this paper, we considered the relative performance of machine learning methods, including linear regression models, ensembles of decision trees, and neural networks, as well as the tradeoff between prediction error and interpretability, in the context of predicting seismic retrofit costs. The results suggest that the gain in performance from more complex machine learning methods such as neural networks may not be significant to justify the loss of interpretability when a cost estimate may require some level of transparency. If the objective is to obtain an accurate estimate, especially when the building is very large, a neural network with a single hidden layer can reduce prediction error by \$3/ft$_2$ (\$33/m$_2$). Perhaps encouragingly, these results suggest that nonlinear relationships between features and the outcome are not hugely important for predicting retrofit cost.

It is worth noting that the ensemble methods we use combine the predictions of multiple "weak" learners in order to create a "strong" learner with better performance. An alternative ensemble method called *stacking* combines "strong" learners to create a "super learner" [22, 23]. An example of a super learner would be to stack random forests, GBMs, and neural networks into a single learner. Of course, the super learner would be inscrutable in terms of interpretability since each of the individual learners lacks interpretability. Nevertheless, it would be interesting to compare such a super learner to the models we consider in this paper. This is left for future work.

***Abstract* — The adapted Wheatstone bridge technique has been utilized at National Institute of Standards and Technology (NIST) and other National Metrology Institutes (NMIs) for high resistance measurements. In this work, we evaluate the suitability of a transimpedance amplifier (TIA) as a null detector for the adapted Wheatstone bridge to improve high resistance measurements. Initial resistance measurements using the TIA based null detector showed an order of magnitude improvement in the Type A uncertainty.**

***Index Terms* — High resistance measurement, low-current measurements, resistance standards, transimpedance amplifier.**

I. Introduction

At the National Institute of Standards and Technology (NIST) automated adapted Wheatstone bridges [1] are used for accurate high resistance measurements from 10 MΩ to 100 TΩ. An adapted Wheatstone bridge uses two voltage sources in place of the main resistance ratio arms of a conventional Wheatstone bridge. High value resistors (≥ 1 MΩ) are used in the other ratio arms. At the balance point, the resistance value of the unknown resistor can be calculated using the equation:

$$R_x = R_s(V_1/V_2) \tag{1}$$

Multiple variants of the adapted Wheatstone bridge have been developed at NIST [2]. To achieve a bridge balance, the adapted Wheatstone bridge uses a commercial electrometer as the current detector. Adapted Wheatstone bridges at NIST utilize current null detection [3]. The third generation of the adapted Wheatstone bridge implemented at NIST balances at a true null rather than $\pm\ 5000 \times 10^{-6}$ from null as the first and second generation of these bridges at NIST [4]. Balancing at a true null rather than at a null offset, combined with well calibrated voltage sources, provides scaling independent of Hamon transfer standards that use the substitution technique. In addition, these improvements to the bridge have allowed the extension of the measurement range to higher decades of resistance (> 10 TΩ) than Hamon transfer standards can achieve [5]. Balancing the bridge at a true null requires low current measurements in the pA range. The accuracy and the measurement noise of the commercial electrometer has been identified as a possible area of improvement to reduce Type A uncertainties of high resistance measurements. Hence, alternative methods of low current detection were examined.

II. Evaluation of a transimpedance amplifier

A transimpedance amplifier (TIA) converts low level current to measurable voltage. Thus, a TIA, combined with a precision multimeter, provides the means for accurate low current measurements. To examine the suitability of a TIA as a current null detector, a commercially available variable gain sub femto-Ampere current amplifier was evaluated. To use the TIA in the adapted Wheatstone bridge, a recently calibrated 8-1/2 digit multimeter was used as the voltage readout. The TIA of interest (Femto DDPCA300)[1] has 3 adjustable low pass filter settings ranging from full bandwidth, 0.7 Hz, and 0.1 Hz. The gain can be adjusted over a wide range from 10^4 up to 10^{13} V/A [6].

A. Linearity

Measurements were made to study the linearity of the TIA as a current detector. Prior current measurements made during the bridge balance have identified ±2 pA as the operational current range of the third generation adapted Wheatstone bridge with true null balancing. Using a source-meter as an input current source, the output voltage of the TIA was measured for a set of currents to within ±2 pA. The voltage output of the TIA was used to calculate the output current based on the transimpedance, which is then compared with the input current of the source-meter. For the specific current range of interest, gain settings above 10^{10} V/A showed a maximum deviation of 10 fA from the linear regression. Thus, gain settings above 10^{10} V/A were considered for successive tests.

B. Optimal Gain and Bandwidth

The 10^4 to 10^{13} V/A gain range of the TIA provides the means for high resolution current measurements for a wide measurement range (1 mA to sub-fA). However, considering the specific use case of the adapted Wheatstone bridge, the gain must be optimized for the specific current range of ±2 pA that is commonly measured during the bridge balance.

Using a source-meter as an input current source, the voltage output of the TIA was measured using an 8-1/2 digit multimeter. Sets of currents within ±2 pA was sourced for gain

[1] Certain commercial equipment, instruments, or materials are identified in this paper to foster understanding. Such identification does not imply recommendation or endorsement by the National Institute of Standards and Technology, nor does it imply that the materials or equipment identified are necessarily the best available for the purpose.

Payagala, Shamith; Dee, Alana; Jarrett, Dean G. "Evaluation of an alternative null detector for adapted Wheatstone bridge." Paper presented at Conference on Precision Electromagnetic Measurements, Denver, CO, US. August 22, 2020 - August 28, 2020.

settings 10^{10} V/A, 10^{11} V/A, and 10^{12} V/A respectively. For each gain setting, 160 voltage measurements were made using 100 power line cycles and the last 120 measurements are accounted for statistics. Based on the standard deviation of each set of voltage measurements, the 10^{10} V/A gain setting produced the lowest measurement noise from the three gain settings tested.

Similarly, the three bandwidth settings of the TIA were evaluated individually based on the measurement noise of a known input current. Using the same setup as the gain setting tests, the voltage output of the multimeter was recorded for a set of currents within ±2 pA. Using the 10^{10} V/A gain setting based on previous results, measurements were repeated for the three different bandwidth settings. Measurement results suggest that the lowest bandwidth setting of 0.1 Hz is the optimum case for DC low current measurements of the adapted Wheatstone bridge.

III. Improvements to the Bridge Measurements

The goal of using the TIA as a current detector is to reduce the systematic uncertainties of high resistance measurements. The third generation of the adapted Wheatstone bridge at NIST was modified to use the TIA, along with the 8-1/2 digit multimeter, as a null detection method. To study improvements of using the TIA as a null detector, a resistance ratio of 10:1 using well known 100 GΩ and 10 GΩ resistors were employed. A gain of 10^{10} V/A and a bandwidth of 0.1 Hz for the TIA was used based on the prior measurements.

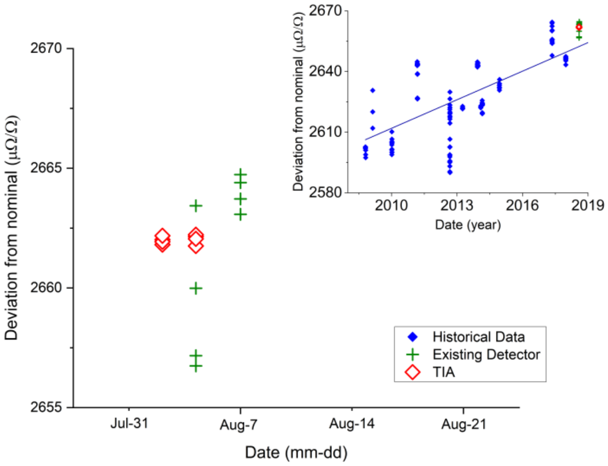

Fig. 1. 100 GΩ resistance measurement comparison between TIA and existing current detector. Historical data with a linear regression fit is shown in the inset.

To compare the repeatability and the accuracy of the TIA as a null detector, multiple resistance measurements were made using both TIA and the existing detector. Fig. 1 shows a set of data acquired using both detectors. Historical data for the 100 GΩ resistor that dates to 2008 are shown in the inset. A linear regression line based on the historical data was used to predict the value of the resistor at the time of the measurement. Data points in green (symbol +) using the existing detector has a standard deviation of 3.2 µΩ/Ω whereas the data points in red (symbol ◇) acquired by the TIA resulted in a standard deviation of 0.2 µΩ/Ω. The average of both sets of data has an agreement of 1 µΩ/Ω, implying both detectors produced comparable average resistance value while the TIA resulted in improved repeatability. Reported expanded uncertainty for 100 GΩ standard resistor is 50 µΩ/Ω [7].

During a resistance measurement, the balancing algorithm reverses the polarity of the voltage sources to reduce bridge offsets. Examining the currents resulted at bridge balance for both polarities, it was evident that the TIA produced significantly lower current offsets compared to the existing detector. The settling times were comparable for both detectors.

IV. Conclusion

A commercially available TIA was evaluated as a current null detector for the adapted Wheatstone bridge. Measurements made using a known current input yielded satisfactory linearity between the input and the TIA output. The optimum gain setting of 10^{10} V/A and the bandwidth of the TIA for the specific current range of interest ±2 pA was realized. Preliminary resistance measurement comparison between the TIA and the existing current detector suggests an order of magnitude improvement in the Type A uncertainty.

***Abstract*—This paper describes an over-the-air (OTA) calibration procedure for the impulse response of a 28-GHz phased-array antenna channel sounder. The silicon-germanium (SiGe) antenna board is composed from two 8x8 planar arrays; each array can generate a distinct beam in the vertical and horizontal polarizations that can be steered in both azimuth and elevation within ±50° and ±25°, respectively. As part of the calibration procedure, unique pre-distortion filters were designed per steer angle, achieving a peak-to-sidelobe ratio in the impulse response of up to 56.5 dB, with less than 1 dB variation across the steer angles. Critically, we show that performance degraded up to 10.1 dB when applying the pre-distortion filter designed at one steer angle to the other steer angles, underscoring the need for angle-specific filters. Finally, we show that performance between both polarizations is comparable thanks to the array symmetries in the fabrication process.**

Keywords—channel sounder; 5G wireless communications; propagation channel; calibration; wireless communication

I. Introduction

The millimeter-wave (mmWave) frequency bands are drawing attention amid growing interest for fifth-generation (5G) communications [1]. While these operating frequencies enable high-bandwidth and high-speed links, they suffer from greater propagation loss. To overcome the latter, phased-array antennas paired with beam-steering to achieve high-gain directional systems have been recently considered for 5G wireless networks [2].

Previously, channel sounders at the mmWave frequency bands of 28 GHz, 60 GHz, and 83 GHz based on time-multiplexed switched antenna arrays were developed by the National Institute of Standards and Technology (NIST) [3]-[4]. The calibration procedure to estimate and remove systematic distortions caused by the IF (Intermediate frequency) and RF (Radio frequency) sections of the system was based on a back-to-back method in which waveguide attenuators were directly connected between the transmitter (TX) and receiver (RX) after removing the antennas. When dealing with phased-array antennas, the back-to-back method cannot be applied because the RF components in the SiGe chips on the printed circuit board – which also distort the system impulse response – are not accessible through connectors. As such, OTA methods must be used instead.

In this paper, we extend the work in [5] to a 3D-steerable dual-polarized 28-GHz phased-array antenna. In Section II, the system architecture of the 28-GHz channel sounder is described following by the OTA calibration procedure and results in Section III. Lastly, the conclusion and the future work are described in Section IV.

II. Channel Sounder Architecture

Our 28-GHz dual-beam dual-polarized phased-array channel sounder is a correlation-based system using a pseudo-random noise (PN) code as the probing signal. Fig. 1 shows the schematic block diagram of the channel sounder calibration. An arbitrary waveform generator (AWG) at TX provides the binary phase shift keying modulated IF signal of 2.5 GHz using a PN code with degree of 11 (2047 chips). A chip rate of 1 Gbits/s with 2 GHz null-to-null bandwidth is used. The IF frequency is up-converted to RF with center frequency at 28.5 GHz. The received RF signal is down-converted back to IF of 2.5 GHz and digitized using an analog-to-digital converter (ADC) sampling at 10 Gsample/s. A single 10 MHz rubidium-disciplined crystal oscillator is used as the frequency reference. Two rubidium devices are used when channel sounding to enable untethered time synchronization of PN codes between TX and RX.

Details of the 28 GHz dual-beam dual-polarized phased-array in our system are described in detail in [6]. The array consists of 2x64 patch elements driven by sixteen 2x4 SiGe dual-beamformer transmit/receive (TRX) chips, placed on a low-cost printed-circuit board (PCB) and operated with 6 bits of phase control and 22 dB of gain control. The scan angle range of the array with vertical- (V) and horizontal- (H) polarized beams in the azimuth and elevation planes is ±50° and ±25°, respectively. Given the limited azimuthal scan range of each board, four boards – each scanning ±45° – are mounted at right angles with respect to each other in order to extend the total scan to an omni-directional view (360°). The array can generate V- and H-polarized beams simultaneously.

III. Impulse-response calibration

In order to obtain optimal performance, we calibrate the system impulse response through pre-distortion filtering to account for the hardware non-idealities of the channel sounder. As seen in previous work [4]-[5], the pre-distortion filter is designed in a multi-step procedure: In the first step, the ideal PN code is transmitted and the code distorted by the system is

Jun, Sung Yun; Caudill, Derek; Senic, Jelena; Gentile, Camillo; Chuang, Jack; Golmie, Nada T. "Over-The-Air Calibration of a Dual-Beam Dual-Polarized 28-GHz Phased-Array Channel Sounder." Paper presented at 2020 IEEE International Symposium on Antennas and Propagation and North American Radio Science Meeting, Montreal, CA. July 05, 2020 - July 10, 2020.

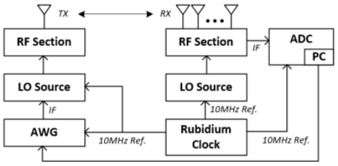

Fig. 1. Block diagram of the channel sounder calibration setup.

received; next, the received code is deconvolved from the ideal code, what we refer to as the *pre-distorted code*; finally, the pre-distorted code is sent instead of the ideal code so that what is received after distortion by the system is a quasi-ideal code. The calibration procedure was applied iteratively to deal with the non-linearities of the system; three iterations were necessary for convergence to optimal performance. Details of the calibration procedure can be found in [4].

Fig. 2 displays the OTA calibration set-up: It employs a scalar feed horn at the TX with 16.6 dBi gain and a phased-array board at the RX. The RX was placed in a semi-anechoic environment on a precision mechanical rotator with 1.6 m separation from the TX; the purpose of the rotator was to align the antenna boresights while investigating different phased-array steer angles. Fig. 3(a) displays the normalized power delay profile (PDP) with and without pre-distortion filtering for the V-polarized beam at 0° azimuth steer angle in the elevation plane and Fig. 3(b) for H-polarized beam; thanks to array symmetries in the fabrication process, the results for both polarizations are comparable. Calibration greatly reduced the peak Interval Of Discrimination (IOD_{pk}) between the correlation peak and the sidelobes: in the correlation tail, non-ideal spurious peaks were down at least 54.8 dB in both polarizations; also, the cross-polarization rejection between beams was measured as approximately 22.7 dB and 24.4 dB in V- and H-polarized beams, respectively.

Table I compares the IOD_{pk} for the response calibrated at several azimuth steer angles (in the elevation plane) versus the uncalibrated response: the IOD_{pk} is similar across the steer angles. In contrast, the pre-distortion filter designed at 0° azimuth steer angle was then applied to the other steer angles, what we refer to as a *semi-calibrated response*: the IOD_{pk} suffered by up 10.1 dB, suggesting that calibration per steer angle is essential. Cross-polarization rejection remained within 1 dB of original values.

IV. Conclusion and Future work

This paper presents results for the impulse-response calibration of a dual-beam dual-polarized 28-GHz phased-array channel sounder. The study shows that the results, expressed in terms of the peak-to-sidelobe correlation ratio, are essentially invariant across the various steer angles of the phased-array antenna so long as a unique calibration is performed per steer angle; in contrast, we show that when a single calibration is performed and merely applied to other steer angles, the ratio can suffer by up to 10.1 dB. Finally, we show that results are similar between the V- and H-polarized beams due to the array symmetries in the fabrication process. So far, we have only investigated performance with variation in the azimuth plane; in future work, we shall investigate joint variation in the azimuth and elevation planes.

***Abstract*—DC high resistance measurement capability between National Institute of Standards and Technology (NIST) and National Metrology Institute of Japan (NMIJ) has been evaluated using a NMIJ traveling dual source bridge. The NMIJ bridge determines the resistance ratio by measuring the voltage ratio using an 8.5 digit digital multimeter. Based on the same 1 MΩ standard resistor calibrated using a 2-terminal cryogenic current comparator, standard resistors from 10 MΩ to 10 GΩ were calibrated by 10:1 scaling measurements with both systems. The measurements at 10 GΩ agreed to less than 1 µΩ/Ω for both systems. Scaling from 10 GΩ to 100 TΩ is in progress.**

***Index Terms*—adapted Wheatstone bridge, dual source bridge, DC resistance standard, high resistance standard, small current measurement.**

I. Introduction

National Institute of Standards and Technology (NIST) and National Metrology Institute of Japan (NMIJ) have performed high resistance measurement comparisons for several years, which yielded good agreement within the expanded uncertainties ($k = 2$) for 10 TΩ and 100 TΩ [1]. For the high resistance measurement comparisons, the NMIJ traveling dual source bridge (DSB) was sent to NIST where high resistance measurements were performed with the NMIJ DSB and the third generation of the NIST adapted Wheatstone bridge (AWB). Both measurement systems are based on the method of the automated high resistance bridge proposed by Henderson [2] but use different hardware and calibration methods. The NMIJ traveling DSB relies on the linearity of an 8.5 digit digital multimeter [3], which measures the voltage ratio applied to standard resistors to calculate the resistance ratio. The NIST AWB #3 system uses well characterized voltage sources to apply a voltage corrections to derive the correct resistance ratio. The high resistance comparison was performed starting with a stable 1 MΩ standard resistor calibrated using the 2-terminal cryogenic current comparator bridge at NIST [4], [5]. This recently calibrated 1 MΩ resistor was used in both high resistance measurement systems as the initial reference. The comparison built up to 10 GΩ by repeating 10 : 1 ratio measurements, the calibrated 10 GΩ values of both systems agreed to within 1 µΩ/Ω. Scaling from 10 GΩ to 100 TΩ will be completed in the next several months. In this abstract, both measurement systems are introduced and the comparison results up to 10 GΩ are shown briefly.

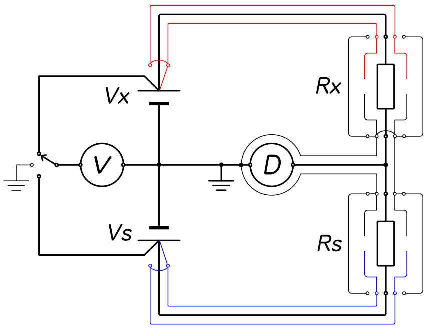

Fig. 1. Circuit diagram of the NMIJ traveling dual source bridge.

II. Measurement system

A. NMIJ Traveling High Resistance Bridge

Figure 1 shows the circuit diagram of the NMIJ bridge. It uses two 6.5 digit voltage sources (ADCMT 6166)[1], a current detector, a digital multimeter (Hewlett Packard 3458A) to measure the voltage ratio, and a switch box using latching relays. The latching relays were switched using a USB I/O device with LabVIEW software. All equipment is controlled by the laptop PC connected through a USB isolator to prevent noise problems. The flowing current between the neutral points of the bridge was converted to voltage using the transimpedanse amplifier (Femto DDPCA-300) and the output voltage was measured using a 7.5 digit digital multimeter (Keithley DMM7510). The low terminal of the DMM7510 was connected to the same ground as the chassis of all equipment that were connected via power cables grounded to the same node. An active guarding was implemented by applying V_x and V_s to the cable shields and the split guard of the resistance boxes as shown in Fig. 1 to shorten the settling time and to make the measurements more stable.

The bridge is balanced by adjusting V_s so that the current detector achieves null current. Then the voltage ratio was measured by measuring V_x and V_s with the 3458A. The detailed algorithm is shown below;

[1] Certain commercial equipment, instruments, or materials are identified in this paper to foster understanding. Such identification does not imply recommendation or endorsement by the National Institute of Standards and Technology, nor does it imply that the materials or equipment identified are necessarily the best available for the purpose.

Oe, Takehiko; Payagala, Shamith; Jarrett, Dean G.; Kaneko, Nobu-Hisa. "Evaluation of NMIJ Traveling Dual Source Bridge Using NIST Adapted Wheatstone Bridge." Paper presented at Conference on Precision Electromagnetic Measurements (CPEM), Denver, CO, US. August 24, 2020 - August 28, 2020.

1) Apply nominal ratio voltages (*e.g.* $V_\mathrm{x}/V_\mathrm{s} = +100\ \mathrm{V}/-10\ \mathrm{V}$) and the voltage V_s is adjusted to determine the bridge balance voltage ($V_{\mathrm{s}0+}$).
2) Repeat the same process for reversed polarity ($-100\ \mathrm{V}/+10\ \mathrm{V}$) and determine $V_{\mathrm{s}0-}$.
3) Adjust V_s based on $V_\mathrm{x}/V_\mathrm{s} = +100\ \mathrm{V}/(V_{\mathrm{s}0+}+V_\mathrm{off})$, then the flowing current is measured using the DDPCA-300 and the DMM7510. Next, the voltage ratio is measured using the 3458A. Here, the V_off is indicated voltage offset and the typical value is from 0.01 mV (1 µV/V of 10 V) to 1 mV (100 µV/V of 10 V).
4) 3) is repeated for $V_\mathrm{x}/V_\mathrm{s} = -100\ \mathrm{V}/(V_{\mathrm{s}0-}+V_\mathrm{off})$, $+100\ \mathrm{V}/(V_{\mathrm{s}0+}-V_\mathrm{off})$, and $-100\ \mathrm{V}/(V_{\mathrm{s}0-}-V_\mathrm{off})$.
5) 3) and 4) are repeated for indicated number of loop.

The output of the voltage source V_x was adjusted so that the absolute values of the voltage measured by the 3458A was exactly 100 V. We use the assumption that the absolute value of ±100 V is the same for both polarities. To measure the voltages V_x and V_s by the 3458A, the same voltage range was used for the 3458A to achieve an accurate voltage ratio. The 3458A input is connected to the ground during the current measurement and it is connected to V_x or V_s only during the voltage measurement. The voltage ratio measurement was performed before and after the current measurement to cancel the effect of the drift of the actual applied voltage.

B. NIST Adapted Wheatstone Bridge (AWB) #3

The NIST AWB#3 uses two FLUKE 57X0A calibrators as the stable voltage sources, and a Keithley 6430A as a current detector [6]-[8]. The output voltages of the 57X0As are calibrated annualy using a Measurement International 8000A/8001A automated Cutkosky binary voltage divider. The voltage corrections are applied at the time of measurement to V_x and V_s. Two versions of the control software were available (LabVIEW and Visual Basic) which showed similar results. The Visual Basic algorithm was used for the comparison since the settling time was the same as that of the AIST system. Detailed measurement algorithm is shown below:

1) The applied voltage to get the bridge balance ($V_{\mathrm{s}0+}$ and $V_{\mathrm{s}0-}$) is calculated from the predicted value of the R_s and R_x using the historical data.
2) $V_\mathrm{x}/V_\mathrm{s} = +100\ \mathrm{V}/(V_{\mathrm{s}0+}+V_\mathrm{off})$ is applied and the flowing current is measured using the 6430A. Here, the V_off is 5000 µV/V typically.
3) 2) is repeated for $V_\mathrm{x}/V_\mathrm{s} = -100\ \mathrm{V}/(V_{\mathrm{s}0-}+V_\mathrm{off})$, $+100\ \mathrm{V}/(V_{\mathrm{s}0+}-V_\mathrm{off})$, and $-100\ \mathrm{V}/(V_{\mathrm{s}0-}-V_\mathrm{off})$.
4) 2) and 3) are repeated for indicated number of loop.

The NMIJ traveling DSB adopts similar algorithm as the NIST AWB#3. The difference of the systems is that the NIST AWB#3 uses the predicted value to determine the V_s to get the bridge balance ($V_{\mathrm{s}0+}$ and $V_{\mathrm{s}0-}$), and the NMIJ DSB determines the values from the brief measurement at the beginning of the measurement.

III. Measurement results

Table I summarises the measured results by the NMIJ traveling DSB and the NIST AWB#3. The two middle columns show the measured relative resistance values, and the right column shows the difference of the two systems in µΩ/Ω. The same 1 MΩ value were used as the reference standard for the 10 MΩ measurement for both systems. For the higher resistance measurements, each system used its own calibrated value for the reference resistor (R_s) for each step, so the difference values show the accumulated error. The maximum difference of the resistance ratio was -0.3 µΩ/Ω in the 10 GΩ/1 GΩ measurement. The NMIJ's calibration and measurement capability (CMC) value for 10 GΩ in the key comparison data base (KCDB) is 6.3 µΩ/Ω and a difference of -0.6 µΩ/Ω is 10 % of it, based on this, the results were satisfactory.

TABLE I
Measured relative resistance value from 10 MΩ to 10 GΩ by the NIST AWB#3 and the NMIJ traveling DSB.

Nominal resistance value	NMIJ traveling DSB [µΩ/Ω]	NIST AWB #3 [µΩ/Ω]	Difference (NMIJ - NIST) [µΩ/Ω]
10 MΩ	17.4	17.5	-0.1
100 MΩ	23.2	23.3	-0.1
1 GΩ	-580.8	-580.5	-0.3
10 GΩ	4249.0	4249.6	-0.6

IV. Conclusion

We have performed the high resistance comparison from 10 MΩ to 10 GΩ by repeating 10:1 measurements. The calibrated 10 GΩ value determined from scaling with each system agreed within 1 µΩ/Ω, and it is sufficiently low to use the dual source bridge as a traveling standard. In the future, a comparison is going to be performed up to 100 TΩ and the NMIJ's voltage injection type Wheatstone system in Japan for the customer calibration [9] will be evaluated using the traveling DSB.

***Abstract* — Standards and Calibration Laboratory (SCL) setup in 2018 a liquid helium based programmable Josephson voltage standard (PJVS) developed by the National Institute of Standards and Technology (NIST). The system was validated by direct comparison with a NIST transportable PJVS system at 1.018 V, 4 V, 6 V, 8 V and 10 V. The difference between the systems was within 0.5 nV, with an expanded uncertainty of less than 2.2 nV (*k* = 2). In this paper, the setup and the results of the direct comparison method are presented.**

***Index Terms* — Programmable Josephson voltage standard, quantum voltage measurement, measurement uncertainty, Josephson voltage comparison.**

I. Introduction

In 1993, the Standards and Calibration Laboratory established the 1 V conventional Josephson array voltage standard (CJVS) as the primary standard of DC voltage for Hong Kong. Then the system was upgraded to 10 V in 1995. This conventional system was designed based on the National Institute of Standards and Technology (NIST) design. The system operates through a computer control interface "NISTVOLT" developed by NIST. The microwave signal was generated by a Gunn-diode oscillator at a frequency around 75 GHz. The SCL maintains 10 V Josephson array chips developed by both NIST and Physikalisch-Technische Bundesanstalt (PTB). The array chip was cooled by liquid helium stored in a 100 liter dewar.

The recent evolution of quantum voltage standard technology, namely the programmable Josephson voltage standard (PJVS), enables the generation of both dc voltage and stepwise approximated ac voltages for frequency up to around 1 kHz [1 – 2]. The PJVS system developed by NIST can produce intrinsically stable DC voltages up to 10 V at a microwave driving frequency of about 18-20 GHz.

In 2018, the SCL setup a new PJVS to upgrade the 25-year-old CJVS system. The performance of this SCL PJVS system was validated by direct comparison with a NIST transportable PJVS system, as shown in Fig. 1, and by indirect comparison with the in-service SCL CJVS system through the use of a set of Zener voltage standards.

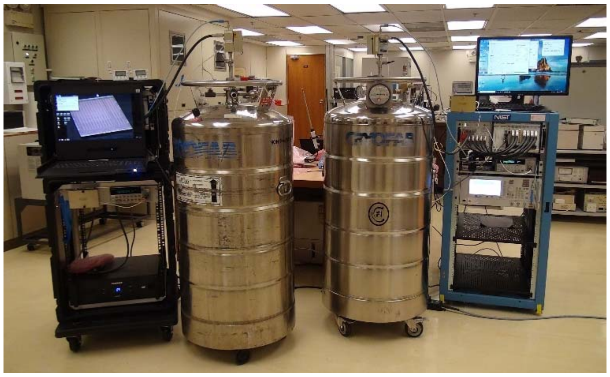

Fig. 1. Direct comparison between NIST transportable PJVS (left) and SCL PJVS (right)

II. PJVS Comparison Setup

A. SCL PJVS system

The SCL PJVS system is a liquid-helium-based system developed by NIST. The PJVS array has 23 subarrays ranging in size from 6 junctions up to 16 800 junctions. The total number of junctions with all subarrays in series is 248 312, such that the entire circuit is capable of generating 10 V with a driving frequency of approximately 20 GHz. The PJVS array bias electronics is a 24-channel current source that employ 16-bit DACs to supplies bias currents to the 23 subarrays. A microwave signal generator and a microwave power amplifier were installed to supply driving frequencies in the range of (18 – 20) GHz with sufficient power to drive all the subarrays. A digital nano-voltmeter was used as a null detector on its 1 mV range. The measurement range of the null detector was fixed to minimize noise and to avoid the change in gain when different ranges are used. The system operation is controlled by a NIST program.

B. NIST Transportable PJVS System

The NIST transportable PJVS system is similar in fundamental design and operation to the SCL PJVS system; however, the system has been implemented with a compact RF

Yang, S.; Cular, Stefan; Rufenacht, Alain; Burroughs, Charles J.; Dresselhaus, Paul; Benz, Samuel P.; Ng, M. "Direct DC Voltages Comparison between two Programmable Josephson Voltage Standards at SCL." Paper presented at 2020 Conference on Precision Electromagnetic Measurements (CPEM), Denver, CO, US. August 24, 2020 - August 28, 2020.

source and installed in rack cases for easy palletization and shipment. The system additionally has a frequency-to-voltage converter that enables easy operation from power supplied at any common line voltage and frequency without reconfiguration.

C. Measurement configuration at SCL

The measurement was conducted on site at the direct current laboratory of the SCL at Wan Chai, Hong Kong, China from March 12 to March 16, 2018. During the measurement, the frequency sources of both PJVS systems were locked to the same 10 MHz signal supplied by the RF laboratory of the SCL, which is traceable to the laboratory's cesium-beam frequency standards and is compared routinely with the BIPM through GPS common view comparison.

Various grounding conditions were tested prior to the start of comparisons. Both systems were connected to the same power outlet and grounded at a single point. Both systems were then verified to be stable during the course of measurement through the use of hourly quantum locking range [3] checks.

III. Measurement Results

A. Direct comparison results

Automated measurement was performed by the NIST program in the following order: 10 V, 1.018 V, 4 V, 6 V, 8 V and 0 V. At least 200 polarity pairs of measurement data were collected at each test voltage. The measured difference between the two PJVS systems and their expanded uncertainty at different test voltages are tabulated at Table I. Overall, the difference between the two systems was within 0.5 nV, with an expanded uncertainty of within 2.2 nV ($k = 2$).

Table I. Measured voltage differences

Test Voltage	Mean difference between PJVS systems	Expanded Uncertainty ($k = 2$)
10 V	0.2 nV	2.2 nV
8 V	0.2 nV	2.0 nV
6 V	0.4 nV	1.9 nV
4 V	0.3 nV	1.8 nV
1.018 V	-0.5 nV	1.8 nV

The uncertainty budget was intended to be conservative for this comparison and was composed of eight parameters with the three largest contributors being the digital null meter noise (0.8 nV), frequency sources (0.7 nV) and the null meter non-linearity (0.6 nV). In some direct JVS comparisons, through the use of a common 10 MHz signal and similar RF synthesizers, the frequency uncertainty is removed from the budget. However, for this comparison the sources were of different design and it was chosen to include the values.

B. Leakage resistance to ground measurement

For improved precision in direct PJVS comparison, NIST custom-made polytetrafluoroethylene (PTFE) isolated cables were used between the DACs and the amplifier board, and between the cryoprobe and the amplifier board [4]. The leakage current between two precision leads to ground were measured at 10 V using the same setup for the NIST–BIPM 10 V PJVS comparison [4 - 5]. The resulting leakage current to ground of the SCL PJVS system at 10 V is tabulated in Table II. The overall leakage resistance to ground can be calculated by the sum of the measured leakage current (144 pA), as it can be assumed that the system is virtually biased at the same voltage of 10 V. The corresponding leakage resistance to ground of the SCL PJVS system was 69 GΩ, which is much better than the required leakage resistance specification of 25 GΩ.

Table II. Measured leakage Current to ground at 10 V

Configuration	Leakage current to ground
(+) side to ground	105 pA
(-) side to ground	39 pA
Overall	144 pA

IV. Conclusion

The on-site comparison of two PJVS systems was conducted at SCL for five voltages. The overall result was a difference of 0.2 nV with an expanded uncertainty of 2.2 nV ($k = 2$) at 10 V. This comparison with a transportable PJVS system demonstrated nano-volt level uncertainties. Uncertainties were decreased through the use of low-leakage custom PTFE insulated cables.

Working Fluid Screening for Ocean Thermal Energy Conversion (OTEC) Applications

Ian BELL[(a)]

[(a)]National Institute of Standards and Technology
Boulder, CO, 80305, USA, ian.bell@nist.gov

ABSTRACT

Ocean Thermal Energy Conversion (OTEC) is among the small number of renewable energy production systems that can provide base load capacity. Ammonia has long been proposed and tested as a working fluid for these systems. *Are there any other superior fluids from a purely thermodynamic standpoint?* This question was probed based on the use of highly accurate thermodynamic equations of state, and a few other possible working fluids have been identified, but many candidates have disqualifying features: acute toxicity, high global warming potential, high ozone depletion potential, extreme flammability or very low condensing pressures. No identified fluids were obviously superior to ammonia, though CO_2 and water deserve further study.

Keywords: Ocean Thermal Energy, Rankine Cycle, Renewable Energy.

1. INTRODUCTION

While there are significant technical and cost challenges with OTEC systems that have limited their application, a comprehensive study of working fluids for OTEC applications has not been carried out thus far. Existing studies (Yoon, et al., 2014; Sun, et al., 2012; Moore & Martin, 2008) have usually studied only a few working fluids at a time, and here the goal is to test a broader palette of working fluids, relaxing some of the current constraints on suitability of working fluids for this application. A rather comprehensive review of OTEC systems is available on Wikipedia.

One major challenge with OTEC is the curse of the second law -- the small temperature difference between the surface water and the subsurface water limits the maximum efficiency possible to that of a Carnot cycle given by $\eta_{\rm Carnot} = 1 - T_l/T_h$, where T_l is the low temperature reservoir and T_h the high temperature reservoir. Large thermocline gradients allow for temperature differences greater than 20 K in the equatorial Pacific Ocean between the sea surface and the water at a depth of 1 km, but generally, the temperature differences are much smaller. A typical assumption (surface seawater: 25 °C, subsurface seawater: 5°C), yields a Carnot efficiency of 6.7%; all thermodynamically feasible systems will operate at a fraction of this efficiency.

2. ANALYSIS

2.1. Cycle Modeling

The component modelling employed in this study is intentionally simplified, with the focus placed on the thermodynamics of the OTEC cycle. The OTEC system is embodied by a conventional closed four component Rankine cycle, in which subsurface seawater cools the condenser and surface water heats the evaporator. Figure 1 shows the overall schematic. The modeling assumptions are that: a) the pressure drop in the heat exchangers are negligible (reasonable as plate or shell-and-tube heat exchangers are likely to be used) b) fixed outlet pinch from boiler of 1 K c) fixed outlet pinch of 1 K in condenser d) fixed overall isentropic efficiency in pump and turbine (including motor and generator losses, respectively) of 0.8 e) inlet seawater to boiler at 25 °C, inlet seawater to condenser at 5 °C.

The only adjustable parameters in the cycle optimization are the superheat at the outlet of the boiler (which controls the evaporation saturation temperature), and the subcooling at the outlet of the condenser (which controls the condensation saturation temperature). These two temperature differences are allowed to float in

Bell, Ian. "Working Fluid Screening for Ocean Thermal Energy Conversion (OTEC) Applications." Paper presented at IIR International Rankine 2020 Conference - Heating, Cooling and Power Generation, Glasgow, UK, Glasgow, UK. July 26, 2020 - July 29, 2020.

the range 0.1 K to 10 K, and Figure 2 makes clear that these temperature differences should be as small as possible to minimize heat transfer irreversibilities, as expected. Therefore the two temperature difference terms were set to 0.1 K.

In the seawater loop, the pressure drops in the seawater pipes were assumed to be zero. This assumption is certainly invalid, but the assumption is employed for all working fluids, so as to make that part of the analysis a fair comparison between fluids.

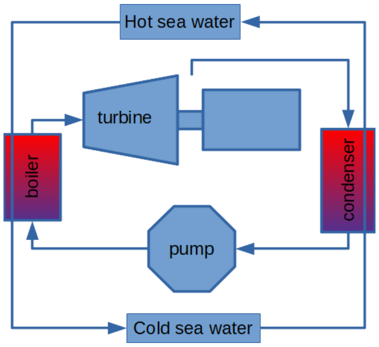

Figure 1 Schematic of OTEC system

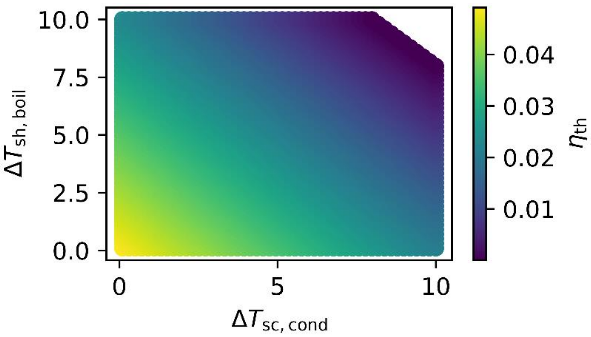

Figure 2 Thermal efficiency of ammonia OTEC system as function of temperature differences in HX

2.2. Thermodynamic Modeling and Constraints

The thermodynamic properties were obtained from the NIST REFPROP library, version 10.0 (Lemmon, et al., 2018) and REFPROP was called by CoolProp (Bell, et al., 2014); the cycle model was written in Python. REFPROP implements the thermodynamic models that are deemed to be the most reliable in the literature. Due to space constraints the references for each equation of state cannot be included; please see the documentation for REFPROP for more information. In the first screening, all fluids were included, even some fluids that are clearly unsuitable for OTEC application (e.g., very toxic species like hydrogen sulfide). There are approximately 150 fluids included in REFPROP. Recent studies (McLinden, et al., 2017) have shown that there are few chemical compounds that would make suitable working fluids for air conditioning applications, and similar constraints apply here too.

One constraint that is sometimes invoked in working fluid selection for Rankine cycles is that the condenser saturation pressure should be above atmospheric pressure. This constraint eliminates associating fluids like water and alcohols, but these associating fluids are excellent working fluids from a thermodynamic standpoint, so that constraint was relaxed here. Furthermore, fluids with large global warming potential (GWP) or non-zero ozone depletion potential (ODP) might be legislatively constrained in the present or the future, but they were also allowed through the initial screening. Fluids known to be toxic were also included.

2.3. Screening results

Given the simplicity of the cycle modelling, only a few figures of merit can be considered, among which are the thermal efficiency and the volumetric output power. As should perhaps not be surprising, and in agreement with existing studies, one of the best working fluids for this application is ammonia. Therefore, the results for all other fluids are considered in relation to ammonia. The thermal efficiency quantifies how much output power can be obtained for a given input thermal input heat from the hot seawater, and also quantifies how close to the Carnot limit the cycle is able to approach.

In this very simplified cycle model, the ammonia thermal efficiency is 4.9%, or 0.7 times the Carnot thermal efficiency. The inclusion of additional loss parameters (e.g., pressure drop in the seawater pipes), and increased irreversibilities in heat transfer, mechanical systems, and electro-mechanical conversion would have the effect of further reducing the thermal efficiency of the system, highlighting the challenge of designing OTEC systems that have competitive economics with technologies like photovoltaics or wind power, even though those technologies are fundamentally intermittent while OTEC has the promise of base load generation.

The volumetric output power (VOP), defined as the mass-specific output power times a density gives some indication of the relative size of components that would be required. For instance, in the context of cooling systems, it indicates how large the compressor would need to be (Bell, et al., 2019), and similar arguments apply here. A very large volumetric output power indicates that the pipes could be designed with a reasonable pressure drop for a given output capacity and also gives some rough indication of how large the heat exchangers would need to be to ensure a feasible pressure drop in them. The quantity VOP is tightly linked with the operating pressure of the system -- higher-pressure working fluids will result in higher densities at all points in the cycle, and therefore, higher volumetric output power. In this study, the volumetric output power was determined based on the density of the working fluid at the inlet to the turbine.

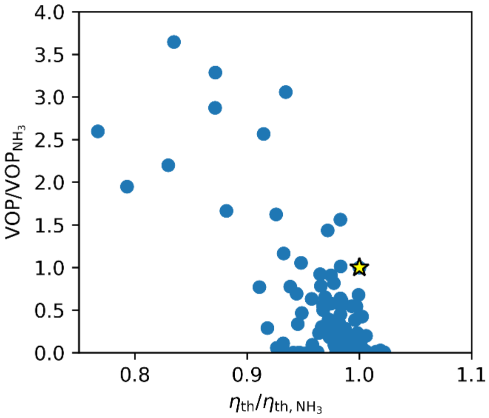

Figure 3 Scatter plot of normalized VOP versus normalized η_{th} for candidate working fluids in REFPROP 10.0. The star indicates ammonia (NH_3)

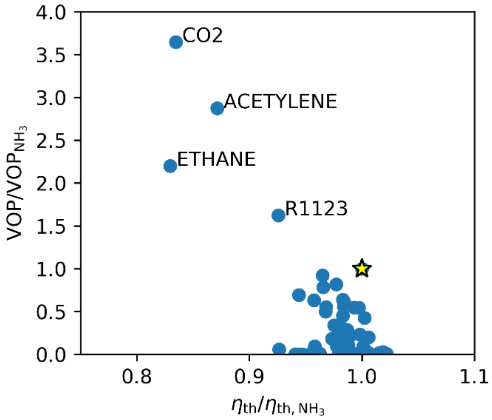

Figure 4 Scatter plot as in Figure 3, but screened for toxicity, GWP, and ODP

Figure 3 shows a scatter plot of the normalized volumetric output power and normalized thermal efficiency for OTEC systems, with each metric normalized by the value for ammonia. In this screening there are no working fluids that have simultaneously a larger volumetric output power and higher thermal efficiency than ammonia, but if either of the figures of merit are relaxed, some new candidate working fluids emerge. Fluids which are acutely toxic (e.g, chlorine, vinyl chloride, ethylene oxide) would not be suitable working fluids because of the danger to any humans or animals that might become exposed to the fluid during manufacture or service. A similar argument applies to fluids with high ODP. The screening was now limited to fluids without known acute toxicity, having an ODP less than 10, and having a global warming potential less than 100. If the GWP or ODP was not known, the fluid was retained. The updated version of Figure 3 with these screening criteria applied is presented in Figure 4.

Of the fluids with higher VOP than ammonia, the only one that seems like a promising candidate is CO_2. Two candidates are extremely flammable (acetylene and ethane), and the other (R-1123) doesn't offer a markedly improved VOP than ammonia. Carbon dioxide has not been discussed as a candidate working fluid for OTEC applications, perhaps because its critical temperature is rather low (31 °C), but that has not precluded the recent interest in supercritical CO_2 power cycles. Indeed, while the working pressures for CO_2 would be approximately 8 times higher than ammonia in the condenser (circa 40 bar versus circa 5 bar), this comes with an upside: high working pressures mean that the impact of pressure drop is less significant, CO_2 has excellent heat transfer properties, and the heat exchangers could be made rather compact, potentially improving the economics, which are generally dire for OTEC as compared with other renewable power generation technologies.

The VOP is intimately tied to the fluid through its working pressure, which are in turn tied to the range of seawater temperatures. The thermal efficiency shows a weaker dependence on the fluid -- the band of predicted

Bell, Ian. "Working Fluid Screening for Ocean Thermal Energy Conversion (OTEC) Applications." Paper presented at IIR International Rankine 2020 Conference - Heating, Cooling and Power Generation, Glasgow, UK, Glasgow, UK. July 26, 2020 - July 29, 2020.

VOP varies over a few orders of magnitude while the values of η_{th} do not vary nearly as widely. Thus once a decision has been made about the acceptable band of VOP, a more detailed study of component sizing and modelling can begin.

2.4. Discussion

Overall the predicted thermal efficiencies do not vary too widely among fluids, and the origin of the behaviour merits a brief comment. One of the assumptions invoked in the cycle modelling is that the pinching in the heat exchangers occurs at the outlet of the heat exchanger in both cases. As the seawater flow rates and temperature changes are not constrained in the cycle model, a simplifying assumption in the analysis here is that the seawater flow rates are infinite, which guarantees that the limiting capacitance is on the working fluid side, and therefore, the cycle can be schematically shown in temperature entropy coordinates (for ammonia in this case) as in Figure 5. This figure explains why the thermodynamic models for fluids operating well below their critical temperature consistently result in a similar thermal efficiency -- the dominant irreversibility in the cycle is that of heat transfer over a finite temperature difference in the boiler and the condenser, and if the condensing and boiling temperatures are fixed (as they are in this model), this loss will be roughly constant as a percentage of the output power for all fluids.

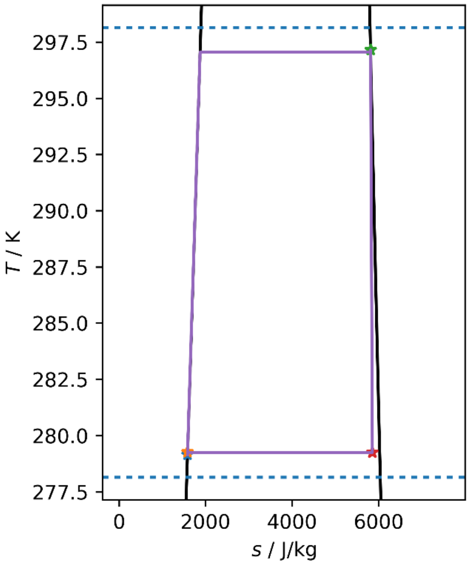

Figure 5 T-s plot for ammonia with cycle overlaid.

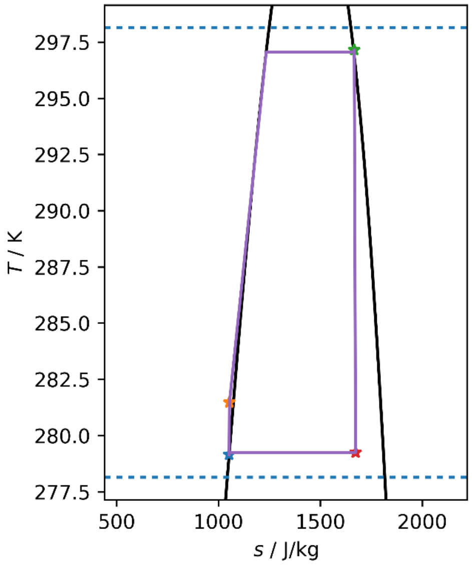

Figure 6 T-s plot for CO_2 with cycle overlaid.

The story is a bit different for CO_2; as shown in Figure 6, CO_2 boils at a pressure quite close to its critical pressure, and as a result, the thermal efficiency is lower because the cycle is more trapezoidal in these coordinates, deviating from the ideal rectangular Carnot cycle even more than fluids operating at lower pressures.

2.5. Summary

Table 1 summarizes the results for the fluids that survived the toxicity, GWP, and ODP screenings. A further screening was that the fluid should have a VOP that is at least one tenth of that of water. Many of the fluids are flammable (some are *very* flammable), and a predictive method could be used to estimate the flammability for the fluorinated species (Linteris, et al., 2019) if it were desired to include flammability in the screening.

Table 1 Fluids that survived the screening, sorted by VOP. Given names are the REFPROP identifier for each species.

Bell, Ian. "Working Fluid Screening for Ocean Thermal Energy Conversion (OTEC) Applications." Paper presented at IIR International Rankine 2020 Conference - Heating, Cooling and Power Generation, Glasgow, UK, Glasgow, UK. July 26, 2020 - July 29, 2020.

3. CONCLUSIONS

The major conclusion of this study is that even after the most comprehensive fluid screening to date, there are no working fluids for ocean thermal energy conversion systems identified that are obviously superior to ammonia. Water and other associating fluids provide a slightly higher thermal efficiency, but their major downside is that the required components would be physically much larger than for ammonia. On the other hand, carbon dioxide appears to be an interesting fluid for this application due to its high working pressures, reasonable toxicity, and low GWP.

An important limitation of this study is that it involves solely thermodynamic optimization, not combined thermo-economic optimization (Quoilin, et al., 2011), which would almost certainly shift the optimal fluids from the screening. Most importantly, the heat exchanger analysis assumed a constant pinch temperature at the outlet of the working fluid. Achieving this fixed pinch would require widely varying heat exchanger configurations, and accordingly varying capital expenditure.

***Abstract* — We report on the first international comparison in ultrafast waveform metrology. To this end, the frequency and time responses of a photodiode with a nominal bandwidth of 100 GHz have been measured by several National Metrology Institutes during the last two years. An overall good agreement between the different measurement techniques is obtained. However, certain features in the frequency- and time-domain responses are not reproduced by all NMIs, calling for additional studies and comparisons.**

***Index Terms* — Waveform metrology, photodiodes, electro-optic sampling, ultrashort voltage pulses.**

I. Introduction

Ever increasing data rates in modern communication schemes pose the need for traceable measurements of electrical waveforms at mm-wave frequencies. Such *ultrafast waveform metrology* is currently developed at several National Metrology Institutes (NMIs) [1,2,3]. However, up to now, no detailed comparison of the different measurement procedures has been performed.

In this work, we report on the first international comparison in ultrafast waveform metrology. The device under test (DUT) is a photodiode (PD) with a nominal bandwidth of 100 GHz (u2t XPDV4120R)[1] with a coaxial 1.0-mm female connector and a 1-m long fiber for optical input at 1550 nm. NMIs from China (Beijing Institute of Radio Metrology and Measurement, BIRMM and National Institute of Metrology, NIM), USA (National Institute of Standards and Technology, NIST), and Germany (Physikalisch-Technische Bundesanstalt, PTB) took part in this comparison, whose measurements started in spring 2018 and ended in summer 2019.

II. Experimental Setups

The different NMIs use different measurement procedures, all of which are based on electro-optic sampling (EOS), employing femtosecond lasers with a center wavelength of 1550 nm and an optical pulse duration ranging between 100 and 250 fs. The basic measurement scheme, which is common to all participants, is briefly described in the following; differences between the NMIs are only indicated due to space limitations.

The femtosecond laser beam is split into optical excitation and sampling beams. The excitation beam excites the 1.0 mm coaxially-connectorized photodiode, which generates an electrical pulse. This pulse is coupled by the wafer probe onto a coplanar waveguide (CPW) fabricated on an electro-optic substrate (BIRMM and PTB: GaAs, NIM and NIST: $LiTaO_3$, note that also the dimensions of the CPW differ). The optical sampling beam is used to reconstruct the repetitive electrical waveform generated by the PD at the reference plane of the CPW. For this purpose, different EOS schemes are employed [4,5].

To calculate the electrical waveform at the PD's coaxial connector from the voltage measured by the EOS system, a change in reference plane is necessary. This requires vector network analysis (VNA) to characterize the reflection coefficients of the PD, the CPW and the wafer probe. For this purpose, NIM and NIST employ a conventional VNA [2,4], while BIRMM and PTB employ laser-based VNA [5].

There are numerous sources of uncertainty in the measurements, which differ between the EOS systems. To propagate these uncertainty contributions to the electrical waveform at the PD's coaxial connector, NIST uses the NIST

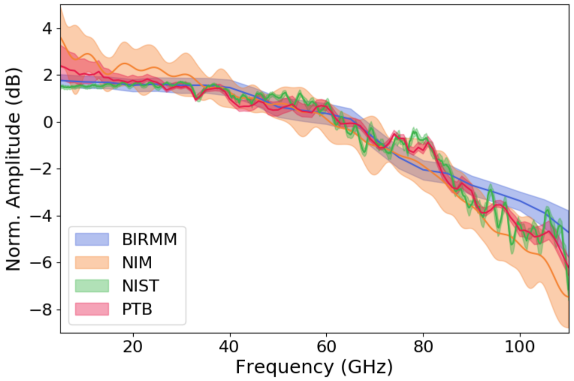

Fig. 1. Frequency-domain amplitude response of the DUT obtained by the different groups. The solid lines and semi-transparent regions denote the best estimates and the coverage intervals, respectively.

[1] Manufacturers name and model are listed here to specify the experimental configuration and do not imply an endorsement. Other makes or model may work as well or better.

Microwave Uncertainty Framework [2], BIRMM, NIM, and PTB use Monte-Carlo simulations [3].

IV. DISCUSSION AND CONCLUSIONS

In all measurements, the PD was biased with 2 V and the optical power was adjusted such that each excitation pulse created a charge of approximately $4 \cdot 10^{-14}$ C. To account for the different pulse durations of the excitation pulses, each NMI specified the photodiode response for a delta-pulse excitation.

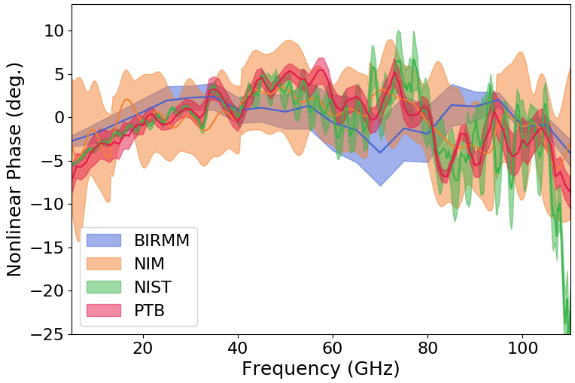

Fig. 2. Frequency-domain phase response of the DUT obtained by the different groups. The solid lines and semi-transparent regions denote the best estimates and the coverage intervals, respectively.

Figure 1 shows the amplitude of the frequency domain responses of the different NMIs. The amplitude spectra were normalized to the average amplitude values in the range from 10 GHz to 100 GHz. It should be noted that differences in time record length between the various NMIs and the choice to interpolate data results in a variety of effects on the presented data including differing frequency step (resolution) and overall smoothness. Furthermore, zero-padding the time record outside of the window around the main pulse can result in a non-physical result by missing any reflections (energy) in the measurement system. An overall good agreement exists with an increased spread between the different results below 20 GHz and above 90 GHz.

The frequency-domain phase responses are shown in Fig. 2. A linear contribution (obtained from linear regression of the phase values in the range from 10 GHz to 100 GHz) was subtracted from the phase values beforehand. Overall, there is very good agreement on the phase with minor difference starting to present above 70 GHz.

Finally, the time-domain responses are plotted in Fig. 3. Here, all pulses have been normalized to one with their maxima centered at 0 ps. The NIST data is not presented here because the traditional network analysis techniques only allow for calibration up to 110 GHz, limiting the ability to inverse FFT data with the same higher frequency content. Similar to the frequency-domain data, there is an overall good agreement with small differences in rise and fall times of the main pulse as well as small discrepancies in the features seen after the main pulse.

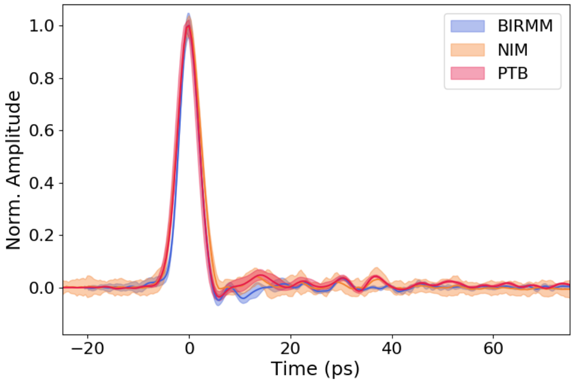

Fig. 3. Time-domain response of the DUT obtained by the different groups. The solid lines and semi-transparent regions denote the best estimates and the coverage intervals, respectively.

Methods for comparing time-dependent measurements are still in their infancy [6] and a more detailed statistical analysis is beyond the scope of this abstract.

In summary, the results of this first comparison look promising, although some features in the frequency- and time-domain responses were not reproduced by all NMIs. Yet, the topic of ultrafast waveform metrology is still in an early stage and additional comparisons will be made to establish better confidence in such measurements.

Photodiode Calibration Comparison between Electro-Optic Sampling and Heterodyne Measurements up to 75 GHz

Ari Feldman, Jeffrey Jargon, Tasshi Dennis, and Paul Hale
National Institute of Standards and Technology, Boulder, CO USA
ari.feldman@nist.gov

***Abstract* — We present the comparison of a photodiode's measured frequency response calibrated with an electro-optic sampling system and a heterodyne system up to 75 GHz, along with the systems' respective 95% confidence intervals. A brief description of each system and its known sources of uncertainties are provided. The two systems agree to within their respective uncertainties at most frequencies.**

***Index Terms* — Calibration, comparison, electro-optic sampling, heterodyne, measurement, photodiode.**

I. Introduction

The electro-optic sampling (EOS) system at NIST [1, 2] is the United States' primary standard for high-speed waveform calibration and is traceable to the SI through fundamental physics. A photodiode calibrated using this system serves as a time- and frequency-domain transfer standard and allows for subsequent calibrations of high-speed oscilloscopes, electronic comb generators, and high-speed modulated signals [3]. Check-standard photodiodes are frequently measured to verify self-consistent operation of the EOS system, however an external comparison to an independently traceable measurement can help verify the measurement.

At NIST, an independently traceable heterodyne measurement system has been used to measure the magnitude response of photodiodes up to 50 GHz [4, 5]. The beat between two single-frequency lasers defines the excitation of the photodiode. While the EOS system is capable of measuring frequencies up to 110 GHz, the low frequency response is limited below 600 MHz, whereas the heterodyne system provides measurements approaching DC.

Each measurement system has its own set of challenges transforming measured quantities to a calibrated response. The EOS measurement requires that (1) the photodiode operate in the linear regime for excitation with pulsed light; (2) the on-wafer coplanar resistor structures be well characterized; (3) the laboratory environment be stable during measurements; and (4) the probe be de-embedded from the measurement. The heterodyne system relies on a set of calibrated, low-power, diode-based RF power meters to cover the measurement frequency range. For both measurements, calibrated scattering-parameters of the photodiode and connecting devices must be measured and propagated through the photodiode calibration [3].

A previous comparison was presented in [4, 5] but was limited to 50 GHz and didn't include measurement uncertainty. To validate the EOS closer to the frequency of 110 GHz, here we present the comparison of a photodiode calibrated with the EOS and heterodyne measurements up to 75 GHz [6], the highest frequency to date performed at NIST, along with their respective uncertainty estimates. A similar comparison was performed at NPL [7]. In the following sections, we provide a brief description of each system and its major sources of uncertainties, and results of the measurement comparison.

II. Electro-Optic Sampling System

NIST's EOS system is comprised of a 1550 nm mode-locked, erbium-doped fiber laser that emits a series of short optical pulses on the order of 100 fs in duration [1, 2, 3] with a 10 MHz repetition rate. The linearly-polarized output is split into optical excitation and sampling beams. The excitation beam excites the 1.0 mm coaxially-connectorized photodiode, which generates an electrical pulse. This electrical pulse is coupled by the wafer probe onto a coplanar waveguide (CPW) fabricated on an electro-optic LiTaO3 substrate. The optical sampling beam reconstructs the repetitive electrical waveform generated by the photodiode at the on-wafer reference plane in the CPW. This is accomplished by passing the sampling beam through a variable optical delay, polarizing it, and passing it through one of the gaps of the terminated CPW. Since the substrate is electro-optic, the electric field between the CPW conductors changes the birefringence of the crystal, altering the polarization of the optical sampling beam passing through it. A polarizing beam splitter and balanced photoreceiver detects this change, which is proportional to the electric field in the CPW at the instant the optical pulse arrives. This process does not perturb the electrical signal on the CPW. Sweeping the relative delay of the sampling beam allows us to map the voltage at the reference plane in the CPW as a function of time.

To calculate the electrical waveform at the photodiode's coaxial connector from the voltage measured in the CPW by the EOS system, a change in reference plane is required. This requires a VNA to characterize the reflection coefficients of the photodiode and an on-wafer resistor as well as the scattering-parameters (*S*-parameters) of the probe head. The *S*-parameters are then used to determine the impedance levels in the measurement system and determine the frequency-domain voltage the photodiode would generate across a 50 Ω load. The frequency-domain results can then be Fourier-transformed to traceably characterize temporal- and frequency-domain instruments up to 110 GHz, the single-mode limit of the 1.0 mm coaxial connectors of the system.

Feldman, Ari; Jargon, Jeffrey; Dennis, Tasshi; Hale, Paul D. "Photodiode Calibration Comparison between Electro-Optic Sampling and Heterodyne Measurements up to 75 GHz." Paper presented at Conference on Precision Electromagnetic Measurements, Denver, CO, US. August 24, 2020 - August 28, 2020.

There are numerous sources of uncertainty in the EOS system beyond the impedance corrections, including optical reflections from the surfaces of the LiTaO3 wafer, field penetration into the LiTaO3 wafer, the radius of the optical sampling beam, finite temporal widths of the optical sampling and excitation pulses, and measurement repeatability. Correlated uncertainty is propagated through the chain of calibrations using the NIST Microwave Uncertainty Framework [8].

III. Heterodyne System

The NIST heterodyne system for measuring the magnitude of the frequency response of photodiodes operates at frequencies up to 75 GHz. Two single-mode fiber lasers having up to 1 nm of continuous wavelength tuning and a linewidth specification of <1 kHz are combined with free-space optics. The use of free-space optics rather than fiber components reduces the wavelength and polarization dependence of the coupled beams.

After passing through polarizing isolators, fiber-pigtailed collimators are used to collect and deliver the polarized light to the fiber-coupled photodiode under test and the photoreceiver used for frequency measurement. Polarizing and mode-matching the beams in a single-mode fiber is critical to ensuring that the modulation of the light incident on the photodiode is precisely calculable. Adjustable rotary attenuators are used to equalize the power delivered by each laser, as monitored by the photodiode bias current. Tuning of the heterodyne beat frequency between the lasers is performed by controlling the operating temperature of the lasers [4].

The frequency of the heterodyne signal up to 50 GHz is detected by use of an amplified photoreceiver and electrical spectrum analyzer. Above 50 GHz the operating wavelength of each laser is monitored with interferometer-based wavelength meters and the difference frequency is determined.

Aside from impedance corrections, the major sources of uncertainty in the heterodyne system include power meter range scaling, bias current measurement, power sensor noise, and measurement repeatability.

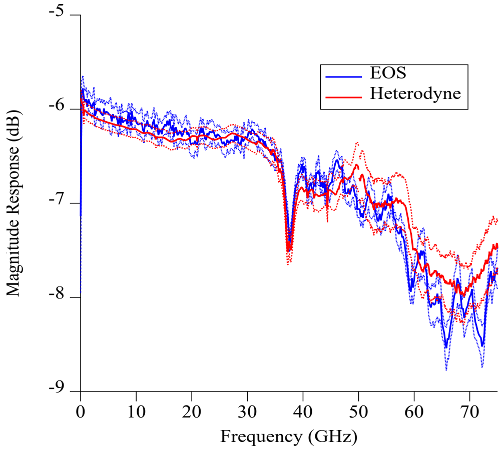

Fig. 1. Comparison of EOS and heterodyne measurements.

IV. Measurement Comparison

The magnitude of the frequency response of a 110 GHz photodiode as measured by the EOS and heterodyne techniques is presented in Fig. 1. The two methods correspond closely in defining the roll-off of the response, with most points agreeing to within their uncertainties. The points that do not agree could be attributed to repeatability of the on-wafer and coaxial connections and calibrations. The EOS measurement indicates more structure despite having a much coarser frequency resolution (200 MHz) relative to the heterodyne measurement (30 MHz). We chose not to connect the two heterodyne curves at 50 GHz, which resulted from the two methods of measuring the beat frequency and different RF power sensors.

The results presented is our best comparison of the methods so far and suggests areas for making meaningful improvements. For the EOS method, improving the frequency resolution from increased range and precision of the delay sweep could reduce distortions in the measured response. The EOS method relies on impedance corrections for the wafer, probe, and photodiode which introduce additional components of uncertainty. The value of the heterodyne method comes from its simplicity and known modulation but relies heavily on the calibrated RF power sensor efficiencies as well as the impedance corrections to isolate the response of the photodiode. The maximum frequency of the heterodyne measurement is limited by the sensitivity of available power sensors to 75 GHz.

V. Conclusion

We presented a comparison of a photodiode's frequency response measured with both EOS and heterodyne methods up to 75 GHz, along with their estimated uncertainties. The results compare favorably while indicating areas for improvement which could result in better agreement.

Abstract — **The frequency dependence of the quantized Hall resistance at alternating current results from capacitive losses inside the sample as well as between the sample and external parts. In this joint effort, we report on ac quantum Hall measurements of a graphene-based Hall bar using superconducting contacts and a novel contact design approach.**

Index Terms **— electrical measurement standards, ac quantized Hall resistance, epitaxial graphene.**

I. Introduction

The fundamental nature of the quantum Hall effect allows for the realization of an electrical standard for the direct current (dc) resistance as well as for the impedance, capacitance, and inductance [1]–[3]. To accelerate the worldwide adoption of these techniques, National metrology institutes are investigating the deviation of the quantized Hall resistance (QHR) at alternating current (ac) from the value measured at dc. Parasitic capacitances were identified to be the reason for the observed offsets, which can be compensated using externally applied shields [4].

In this paper, we report on a joint effort of the PTB and the NIST to characterize an epitaxial graphene-based Hall bar using superconducting contacts and an optimized contact geometry to identify measurement conditions and sample characteristics that are critical to the measurement precision [5].

II. DC Measurements

Figure 1(a) shows the sample design, the measurement configuration and dominating parallel capacitances under ac conditions. The magnetotransport properties at direct current were pre-characterized using a current source and a nano voltmeter for magnetic flux densities between $B = 0$ T to $B = 12$ T. Figure 1(b) shows that due to the low carrier density of $n = 6.6\times10^{10}$ cm^{-2}, the resistance plateau started at around $B = 1$ T and the longitudinal resistance, measured with current reversal to reject thermal voltages, was within the setups the noise floor for $B > 2$ T. The sample was then characterized with a cryogenic current comparator at $B = 7$ T. The longitudinal resistance was found to be (465 ± 1.5) µΩ on the low potential side and (694 ± 1.5) µΩ on the high potential side (type A uncertainty $k = 1$).

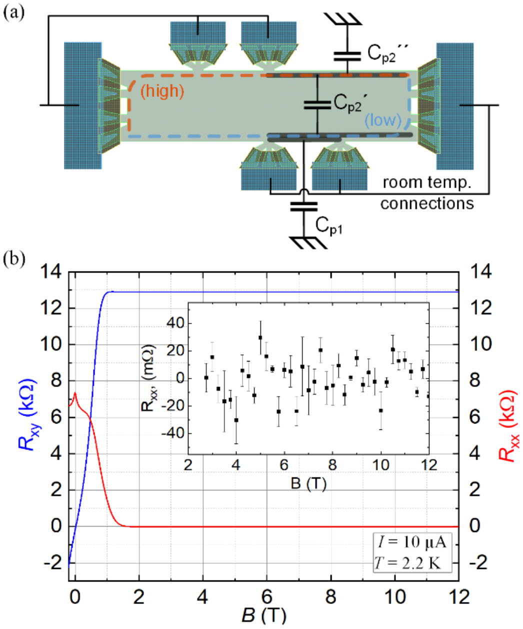

Fig. 1. (a) The drawing shows the sample design as well as indicates the origin of parallel capacitances of the Hall and longitudinal resistance measurements at ac. (b) Characterization of dc magneto transport properties. The carrier density n and mobility μ are 6.6×10^{10} cm^{-2} and 12883 cm²/Vs, respectively. The inset indicates a vanishing of the longitudinal resistance at magnetic flux densities around $B = 2$ T. The error bars represent the standard deviation determined from three measurements.

III. AC Measurements

The deviation of the Hall resistance at ac from the dc value R_H shows a linear frequency dependence with a slope of (81.7 ± 1.5) × 10^{-9} / kHz (see Fig.2, top). The parallel capacitance C_{p2} (bottom) is measured at the pair of Hall contacts and is

"Graphene quantum Hall effect devices for AC and DC resistance metrology." Paper presented at 2020 Conference on Precision Electromagnetic Measurements(CPEM 2020), Denver, CO, US. August 24, 2020 - August 28, 2020.

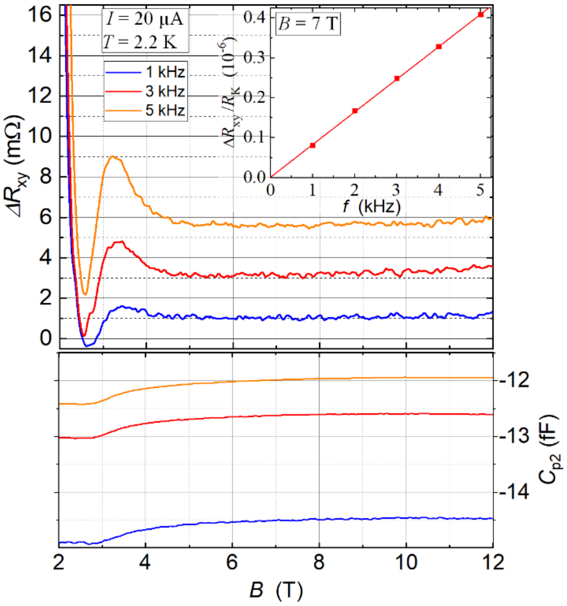

Fig. 2. The deviation of the Hall resistance ΔR_{xy} at ac from the dc value R_H (top) with a slope of 81.7 ± 1.5 × 10^{-9} /kHz (see inset) and corresponding magetocapacitance measurements (bottom).

composed of the two components C_{p2}' and C_{p2}'' where C_{p2} = C_{p2}'- C_{p2}''. While the absolute value of C_{p2} has a large uncertainty of 58 fF, the shape of the magnetic field dependence can still be precisely measured. The graph shows that C_{p2} increases in the beginning of the resistance plateau and becomes mostly flat for $B \geq$ 6T, reflecting the changes in the areas of compressible and incompressible states inside the QHR sample and a dominating contribution from C_{p2}'' compared to C_{p2}'. Figure 3 shows the frequency dependence of the longitudinal resistance (top) and the parallel capacitance C_{p1} (bottom) measured at the same contact pair. The upwards bending of the longitudinal resistance curves at higher magnetic flux densities and the absence of a clear flat region indicates a non-zero longitudinal resistance at f = 0 Hz in agreement with the results of the cryogenic current comparator. Interestingly, the increase of the longitudinal resistance at higher magnetic fields seems to be associated with an increase of C_{p1}.

IV. Conclusion and Outlook

The applied sample design resulted in a Hall resistance with a positive frequency dependence. Previously published ac QHR measurements using graphene Hall bars [6] showed a positive frequency dependence in the case of much larger sample dimensions (e.g. 2600 μm × 800 μm) and higher current. By further investigating the frequency dependence with respect to the charge carrier density and the applied current as well as by applying the double-shield technique, we are aiming to find favorable conditions for precise ac QHR measurements.

ABSTRACT

This study investigates the thermal conductivity of 17-4PH stainless steel powder that was encapsulated within specimens with different internal geometries in laser powder bed fusion (L-PBF) additive manufacturing (AM). The objective is to evaluate the effect of the internal geometry of the specimens on the measurement of the powder thermal conductivity and to compare the thermal properties amongst the 17-4PH and two additional powder materials used in L-PBF. Continued from the previous work [1], three new cone configurations in the hollow specimens were designed and fabricated in an L-PBF system. The thermal conductivity of the internal powder was indirectly measured using an experimental-numerical approach, combined with laser-flash testing, finite element (FE) heat transfer modeling and multivariate inverse method. The results reveal that the thermal conductivity of 17-4PH powder ranges from 0.67 W/(m·K) to 1.34 W/(m·K) at 100 °C to 500 °C, and varies with the internal geometry of the specimens. In addition, the measurement of the hollow specimen with a convex cone seems to be a more reliable evaluation. Further, the thermal conductivity ratio of the powder to the solid counterpart of 17-4PH approximately ranges from 3.9 % to 5.5 % at tested temperatures, which is similar to the results obtained from the nickel-based super alloy 625 (IN625) and Ti-6Al-4V (Ti64) powders measured in a previous study.

Keywords: Laser powder-bed fusion; laser flash; finite element modeling; inverse method; powder thermal conductivity; 17-4PH stainless steel

1. INTRODUCTION

Powder bed fusion (PBF) additive manufacturing (AM) is ever-increasingly investigated and widely adopted in recent years because of its capability to fabricate solid freeform shaped parts and high quality products for a wide range of applications. During the building process, metallic powder is spread onto the building plate and successive layers of powder are selectively fused by a high-energy heat source [2]. The thermal transfer between the melted part and the surrounding powder bed have a profound impact on the temperature gradient and the solidification rate, which in turn, gives rise to a substantial influence on the grain growth and microstructural morphology [3-6] and resultant mechanical properties of the final part [7, 8]. In addition, the powder bed acts as a support for overhanging structures in PBF, but also acts as a thermal insulator. This creates localized overheating, dependent on the relative amount of solid compared to powder material near the melt pool [9, 10]. Owing to the high cost of PBF equipment and materials, researchers seek assistance from the computational approaches to understand the thermal behavior in PBF processes, and consequentially to improve the fabrication processes and part quality. A key input for building these simulations is the thermal properties of the powder bed, which are essential to achieve reliable computational predictions.

Spread by the recoater and infiltrated by an inert gas environment in PBF, the powder bed can be regarded as a mixture of gas-infiltrated particles with a specific packing density. The individual properties of the metal powder, gas, and packing density can be combined to form an assumed continuum or singular material. For decades, many have recognized the dominant role of conduction in the heat transfer in heterogeneous gas-solid systems in different types of application processes, such as chemical reactors [11, 12], drying systems [13] and heat exchangers [14]. It has been reported that many factors can be critical, such as volume fraction, contacts between particles, infiltrated gas types and gas pressure [15-22]. For example, Yagi et al. [18] established a model of heat transfer in packed bed with

motionless gas. They raised theoretical equations to predict the effective thermal conductivities of a gas-powder packed bed system and concluded that the radiant heat transfer is more effective when the temperature is higher than 400 °C. Wakao and Vortmeyer [20] claimed that the effective thermal conductivity of packed beds with stagnant gas is primarily affected by the conductivity of the packed bed and radiation in the gas-solid system, as well as the contact conductivity between particles. A discrete element method in granular material heat transfer was developed by Vargas and McCarthy [22], which considered the effect of stress and contact heterogeneities on the pressure distribution in the stacked particles. On the other hand, Wei et al. [23] and Bala et al. [24] presented an experimental method to measure the thermal conductivities of metallic powders, and the latter pointed out that the gas infiltrating has an effect to the heat dissipation of the powder bed.

Recent studies by Cheng et al. [25] and Zhang et al. [1, 26] estimated the thermal conductivity of metallic powder using a hybrid laser flash experiment and numerical heat transfer simulation. In that work, the authors designed a hollow specimen to encapsulate powder during fabrication to maintain the in-situ powder bed conditions. Using an inverse heat transfer approach, the thermal properties of the encapsulated powder could be extracted from the laser flash measurement results. Herein, except for the thermal conductivity and powder porosity, the contact conductance between powder and the specimen shell was also critical to the heat transfer analyses and evaluated as an output. Additionally, a critical finding in those studies was that the powder thermal conductivity obtained by this method seems to be varied for different internal geometries of specimens. It was noted that a gap exist between the internal powder and the top shell of the specimen, which adversely affects heat flow through the specimen. Although this finding provides an insight of measurement uncertainty potentially related to the specimen geometry, quantitative understanding of the specimen internal geometry effect on the powder thermal property analysis is still lacking.

To continue the previous work, the objective is to design addition specimen geometries to investigate their effects on the measurement of powder thermal properties. In addition, the contact conductance between the powder and internal surfaces of specimen shell with different geometries are of interest. Furthermore, the experimental-numerical approach is extended to investigate the temperature-dependent thermal conductivity of 17-4PH stainless steel powder. A comparison of powder thermal conductivity and porosity with two additional powder materials: nickel-based super alloy 625 (IN625) and Ti-6Al-4V (Ti64), presents different results in a tested temperature range of 100 °C to 500 °C.

2. EXPERIMENTAL DETAILS

The test specimens were designed hollow discs that enclosed powder, thus maintaining the as-fabricated powder conditions. As indicated in [25], a cone feature can reduce the gap and improve the contact condition between the powder and internal upper shell, and therefore, increase the accuracy of simulation. However, the follow-up investigation in [1] showed inconsistent measured thermal conductivity of metallic powder, including IN625 and Ti64 materials, at specimens with three different internal geometries. To clarify the effect of the internal geometry of the specimens, the three shaped internal geometries were also tested in this study for estimating the powder properties of 17-4PH powder. In addition, 3 developed geometric features were designed as shown in Figure 1, including (1) top cone with a height of 1 mm (1Cone-1.0), (2) spherical cap with a height of 1 mm (Convex), and (3) concave, rotated cap with the height of 1 mm (Concave). These three novel specimens only vary the top internal geometry and keep the same bottom geometry to test the contact conditions between the powder and the top shell, specifically.

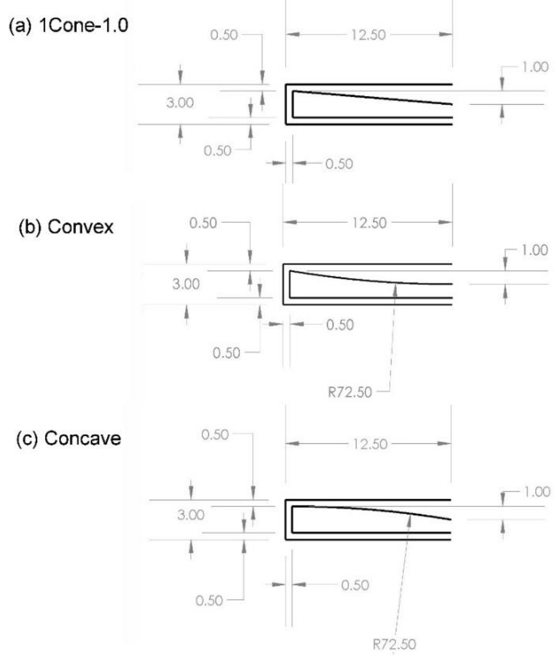

FIGURE 1: SYMMETRICAL CROSS-SECTION VIEW OF DIFFERENT SPECIMEN DESIGNS SHOWING INTERNAL GEOMETRY (UNIT: MM)

In this study, 17-4PH stainless steel supplied by LPW Technology[2] was used for specimen fabrication by an EOSINT M270 L-PBF system. The build orientation for the specimens

[2] Certain commercial equipment, instruments, or materials are identified in this paper in order to specify the experimental procedure adequately. Such identification is not intended to imply recommendation or endorsement by the National Institute of Standards and Technology, nor is it intended to imply that the materials or equipment identified are necessarily the best available for the purpose.

was along the diameter direction (along the horizontal axis in Figure 1) to reduce the necessity of support structure. The machine recommended process parameters for 17-4PH solids were used, resulting in a scan speed of 1000 mm/s, a laser power of 195 W, hatch spacing of 100 µm, and a layer thickness of 20 µm. There was no laser exposure within the internal hollow region to encapsulate loose powder. In addition, a N_2 inert gas environment was employed during fabrication.

A DLF-1200 laser flash system from TA Instruments was utilized to acquire thermograms from each sample, which indicate the time-dependent temperature rise measured via pyrometer on one side of the sample resulting from an applied laser pulse on the other. Thermal diffusivity values, representing the homogeneous properties of the entire sample, are extracted using Clark-Taylor method [27] in this study. Before testing, a graphite coating was uniformly sprayed on the sample surface to maximize the absorption of the laser pulse. The sample was then put into the chamber sitting in a sample holder. During testing, the ambient temperature in the chamber, which also sets the sample temperature, was a user-defined preset. When the environment and sample temperatures reach steady-state and equilibrium, a 3 ms laser pulse of 25 J was applied to the bottom of the specimen over a uniformly distributed, circular region of 22 mm diameter. An infrared pyrometer received the voltage signal from the top of the specimen from a round region with a diameter of about 9.6 mm for 60 s. The time-dependent voltage signal, called a thermogram, was then obtained and normalized for use in the inverse-heat transfer simulation. Three samples for each type of internal geometry and three laser pulses for each sample were conducted in the laser flash system for a repeatability investigation at each preset temperature. The tested temperatures ranged from 25 °C to 500 °C.

3. Test sample system and FE model

Test samples used in the FE model were dimensionally equal to the real test components, which were assumed homogeneous materials in the modeling. The mesh for the sample system consists of 10-node quadratic heat transfer tetrahedron bricks, with the mesh sizes of 0.5 mm for the specimen and 0.7 mm for the holder, respectively. The total heat flux applied to the bottom surface of the specimen was simplified as a uniform distribution. The heat transfer takes place through three mechanisms: (1) heat conduction in the specimen, (2) heat conduction between the specimen and the holder, and (3) heat loss due to convection and thermal radiation from the sample system to the surrounding environment. The ambient temperature in the modeling was set the same as the actual experimental environment. Further details on the FE model construction are provided in [1].

To calculate the thermal properties of the internal powder, there existed five unknowns in the FE model: (1) the specimen-holder contact conductance (k_p), (2) powder density (ρ), (3) powder thermal conductivity (k), (4) the contact conductance between the powder and the top solid shell (k_t), and (5) the contact conductance between the powder and the bottom solid shell (k_b). Two major steps were conducted to estimate the five unknowns. First, the solid sample system was simulated and measured to analyze the k_p, in order to simplify the model and reduce the computational workload. Then, the k_p in the solid sample system was assumed the same values in the powder-enclosed sample system at each corresponding temperature, and utilized as a known parameter in the latter model. Next, the remaining four unknowns related to the powder were estimated using an experimental-numerical inverse heat transfer method, originally derived in [28], and applied to the laser flash system as described in [25]. To optimize the estimated powder properties, the multivariate inverse method was adopted to evaluate a set of unknown properties in each iteration and reduce the difference between the simulation and experimental results.

4. RESULTS AND DISCUSSION

4.1 Laser flash experimental results

The specimens with different internal geometries were measured in the laser flash system at environment temperature range of 25 °C to 500 °C. Figure 2 shows the effective homogeneous sample thermal diffusivity on the three new designed specimen geometries, which are obtained from the laser flash instrument using the Clark-Taylor analytical model. The resulting diffusivity ascends with the rising temperature from 25 °C to 300 °C, and then a plateau occurs when the temperature continues increasing until 400 °C, and then a slight increase at 500 °C. The values range from 0.0018 cm^2/s to 0.0025 cm^2/s at 25 °C. In addition, at each temperature, the Convex specimens provide highest thermal diffusivity among the three types of specimens due to the largest solid to powder mass ratio, followed by 1Cone-1.0 and Concave, successively.

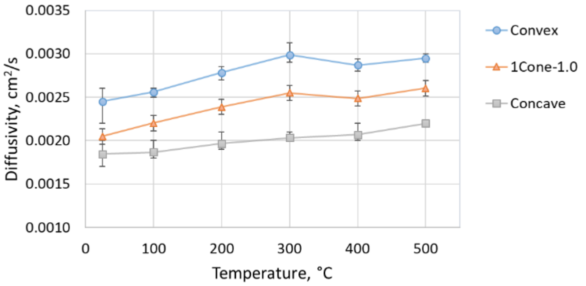

FIGURE 2: COMPARISON OF HOMOGENEOUS TOTAL SAMPLE THERMAL DIFFUSIVITY OF SAMPLES WITH DIFFERENT INTERNAL GEOMETRIES

Furthermore, the time-response thermograms (normalized pyrometer voltage) were obtained from the experiments. Figure 3 (a) shows the thermograms at five tested temperatures of Concave specimens as an example. It can be noted that the plots shift to the left gradually with an increasing temperature; the peak temperature occurs sooner, from 22 s at 100 °C to 16 s at 500 °C, indicating an increase in sample thermal diffusivity. Besides, at a certain temperature, the thermogram of the Convex specimen exhibits a faster heating rate than the other two, and the Concave shows the slowest, corresponding to the thermal diffusivities shown in Figure 2. An example of the comparison between the three cone geometrical specimens at 200 °C is shown in Figure 3 (b).

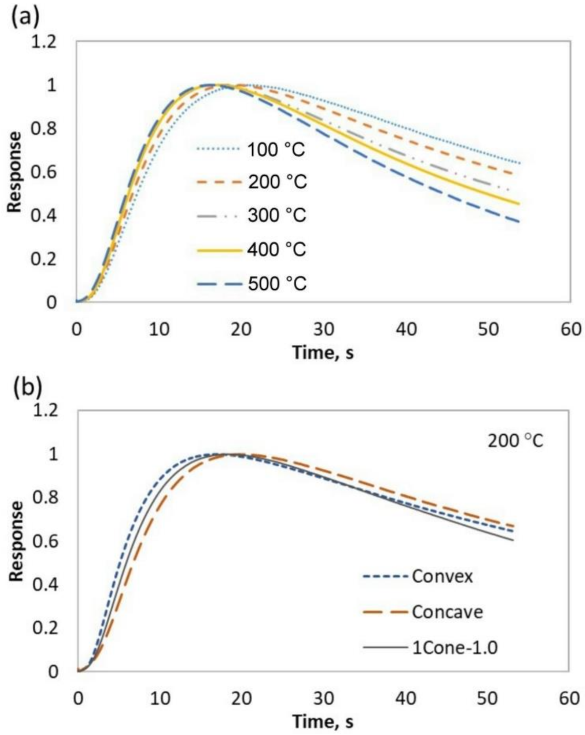

FIGURE 3: EXPERIMENTAL THERMOGRAMS FOR (A) CONCAVE SPECIMENS AT TESTED TEMPERATURES; AND (B) THREE TYPES OF SPECIMENS AT 200 °C

4.2 Simulation results

The FE model was established using measured dimension of the as-built specimens fabricated by L-PBF, and the material properties of the specimens were employed using the information of solid 17-4PH material [29, 30] in Figure 4. Radiation heat loss boundaries assumed an emissivity for 17-4PH of 0.2 [31], and the convection coefficient was estimated as 10 W/(m^2·K) [25]. In addition, the alumina sample holder was included in the modeling and applied the material properties of alumina [32-34].

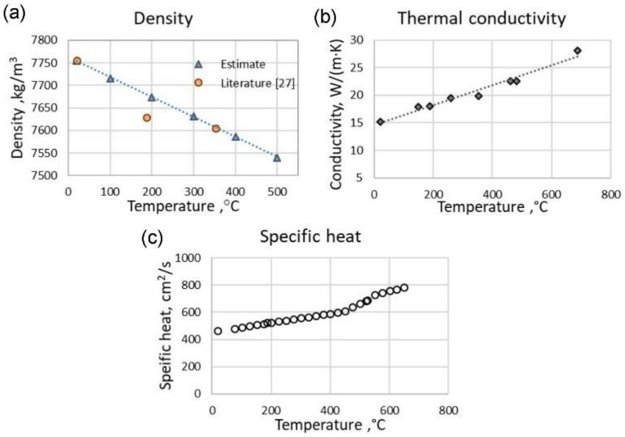

FIGURE 4: SOLID MATERIAL PROPERTIES FOR 17-4PH USED FOR SHELL STRUCTURE IN THE FINITE ELEMENT MODELS [29, 30].

4.2.1 Powder thermal conductivity with different cone geometries

The extracted powder thermal conductivity using the inverse heat transfer method applied to the three new cone designs and is shown in Figure 5. The powder conductivity achieved ranges from 0.65 W/(m·K) to 1.34 W/(m·K), and displays a linear increase with temperature. Additionally, the Convex specimen presents about 0.22 W/(m·K) to 0.31 W/(m·K) higher thermal conductivity than Concave at corresponding temperatures, with the 1Cone-1.0 model located in the middle of the range.

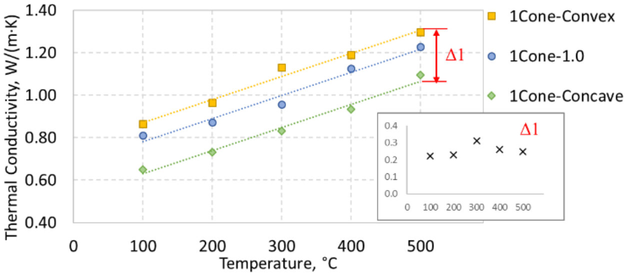

FIGURE 5: POWDER THERMAL CONDUCTIVITY COMPARISON IN 3 NEW CONE GEOMETRIES (INLAYED PLOT USES THE SAME COORNIDATE UNITS WITH THE MAJOR PLOT)

The powder thermal conductivity using the three models in [1] is shown in Figure 6. Similar to the other three models and the two materials in [1], the powder thermal conductivity also exhibits nearly linear to the temperature. Meanwhile, the two models of 2Cone-0.25 (2 cones 0.25 mm thick) and 1Cone-0.5 present similar simulation results that are generally lower than 2Cone-0.5 model. The difference (Δ2) between 2Cone-0.5 specimen and the other two is in a range of 0.10 W/(m·K) to 0.19 W/(m·K). It is indicated that the difference with new cone configurations generally shows 35 % wider (Δ1>Δ2).

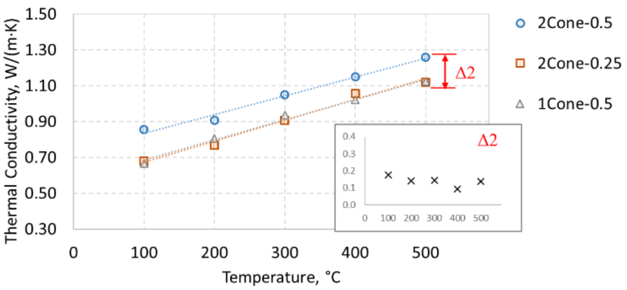

FIGURE 6: POWDER THERMAL CONDUCTIVITY COMPARISON IN 2CONE-0.5, 2CONE-0.25 AND 1CONE-0.5 MODELS (INLAYED PLOT USES THE SAME COORNIDATE UNITS WITH THE MAJOR PLOT)

4.2.2 Analysis of powder conductivity ratio ($\Delta k/k_{ref}$) vs. cone volume ratio ($\Delta V/V_{ref}$) upon the reference model

Stemming from the apparent specimen geometry effect, further investigation on powder thermal conductivity of 17-4PH powder results are analyzed in this section. The cone volume (V) was estimated by taking the difference between the measured mass of the sample, and that of a hypothetical hollow disk of the same external geomery, but 0.5 mm thick skin (and no cone structure). For example, the cone volume of 1Cone-0.5 model was calculated using the cone geometry with a cone height of 0.5 mm. To compare between the different specimens, 1Cone-1.0 specimen was set as the reference (named as “ref”). A measurement criterion was set as a ratio of $\Delta k/k_{ref}$, where k_{ref} is the thermal conductivity of the reference specimen, and Δk equals the objective conductivity value subtracted by that of the reference at the corresponding temperature. Likewise, the volume ratio ($\Delta V/V_{ref}$) is defined based upon the cone volume of the reference. The $\Delta k/k_{ref}$ ratio vs. $\Delta V/V_{ref}$ ratio was plotted in Figure 7. At 100 °C, it is noticed that $\Delta k/k_{ref}$ ratios of 2Cone-0.25 and 1Cone-0.5 are close at about 16% to 17 %. Concave has a distinguishable (2%) lower $\Delta k/k_{ref}$ ratio despite little difference in $\Delta V/V_{ref}$. Additionally, compared to the reference, 2Cone-0.5 shows higher $\Delta k/k_{ref}$ with about 3 % variation. On the other hand, unlike to the three models with smaller cone volume, the Convex model shows about only 6 % $\Delta k/k_{ref}$ above the x-axis, while the cone volume is about 1.5 times of the reference specimen. Similar quantitative analysis at 100 °C shows the unbalanced $\Delta k/k_{ref}$ ratio at both sides of the y-axis although the $\Delta k/k_{ref}$ ratio for smaller cone models exhibits smaller difference than those at 500 °C. Therefore, such a non-linear correlation between $\Delta k/k_{ref}$ ratio, and reduced difference in this ratio with different cone geometries at higher $\Delta V/V_{ref}$ ratio indicates more reliability of the powder conductivity measurement at a higher cone volume level, such as for the Convex specimens.

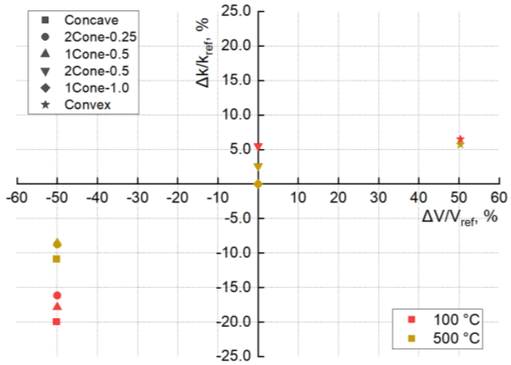

FIGURE 7: $\Delta K/K_{REF}$ VS. CONE VOLUME RATIO AT 100 °C AND 500 °C

4.2.3 Powder thermal conductivity in different materials

Normalized by the solid thermal conductivity (k_s) of the respective powder materials, the powder thermal conductivity ratio (k/k_s) with respect to the fabricated materials in 2Cone-0.5 samples is compared in Figure 8. It can be noticed that the k/k_s ratio of IN625 powder shows a temperature-dependent descent with from 6.9 % to 5.2 %. In contrast, 17-4PH powder exhibits a range of 5.0 % to 5.7 % and a slightly increasing trend with an increasing temperature from 100 °C to 500 °C while the resultant difference between both end temperatures appears insignificant. On the other hand, Ti64 powder keeps an approximately constant k/k_s ratio at all tested temperatures, and the value of the ratio is close to that of 17-4PH powder, which is about 5%.

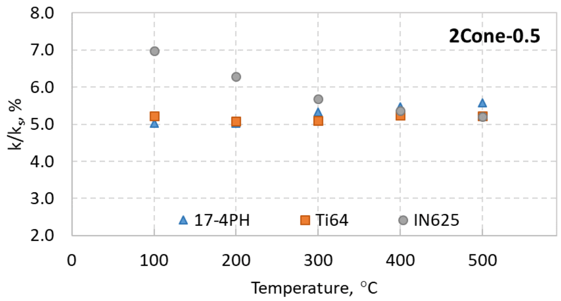

FIGURE 8: COMPARISON OF TEMPERATURE-DEPENDENT K/K_S RATIO IN 2CONE-0.5 MM MODEL WITH THREE MATERIALS.

Similar to 2Cone-0.5 model, IN625 powder still exhibits a descending k/k_s ratio and 17-4PH powder shows a slightly increasing k/k_s in both of 1Cone-0.5 and 2Cone-0.25 models from 100 °C to 500 °C. However, in both models, Ti64 powder shows an approximately 0.5% decreasing k/k_s ratio. In addition, the k/k_s ratio for the models of 1Cone-0.5 and 2Cone-0.25 in the three powder materials generally reduces 1% or so due to the internal cone configuration effect. Figure 9 shows the temperature-dependent k/k_s ratio for 2Cone-0.25 models with three powder materials.

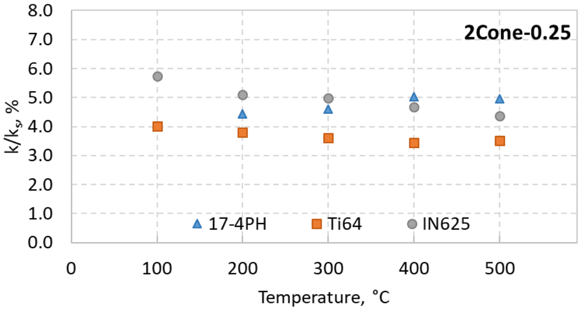

FIGURE 9: COMPARISON OF TEMPERATURE-DEPENDENT K/KS RATIO IN 2CONE-0.25 SPECIMEN WITH THREE MATERIALS

4.2.4 Thermal contact conductance comparison

It has been recognized that the contact conductance is a function of several parameters, such as contacting interface geometry, surface roughness, temperature, interfacial pressure, etc. [35-39]. In the multivariate inverse method, as another two outputs from the simulation, thermal contact conductance between the powder and solid shell on the top and at the bottom are principal parameters interfering with heat transfer in the powder-enclosed specimens. Among the three new specimen geometries, the top and bottom contact conductance are compared in Figure 10. It is noticed that the bottom contact conductance values vary little between the three specimens at each temperature, but overall increase with temperature. The reason for the similar bottom conductance could be that the three specimens have the same bottom geometry. Besides, the bottom contact conductance in all three specimens shows a temperature-dependent increase from 100 °C to 300 °C. Subsequently, there exists a slight retrogression at 400 °C and then a rebound at 500 °C. This trend was also observed for the measured total sample homogeneous thermal diffusivity in Figure 2, indicating this contact conductance may either be a major contributor to the total diffusivity, or may be similarly affected by intrinsic temperature dependence of the material thermal properties.

On the other hand, for the top contact conductance, Convex exhibits apparent higher values than the other two specimens at all tested temperatures; wherein, 1Cone-1.0 shows a higher or similar (at 500 °C) values than Concave. Likewise, at 400 °C, a retrogression or stagnation occurs at 400 °C for all three specimens, followed by an increasing at 500 °C.

Moreover, the contact conductance (top and bottom) were compared between Ti64, IN625 and 17-4PH, and an example of 2Cone-0.25 for the three materials is shown in Figure 11. It can be seen that the bottom contact conductance for all three materials are generally higher than that on the top of the internal powder and solid shell. This is considered to result from a gap that exists between the top shell and the internal powder, interfering the heat transfer through the specimens. Additionally, the retrogression also occurs in 17-4PH 2Cone-0.25 specimen at 400 °C, while such a phenomenon is not found in the other two materials.

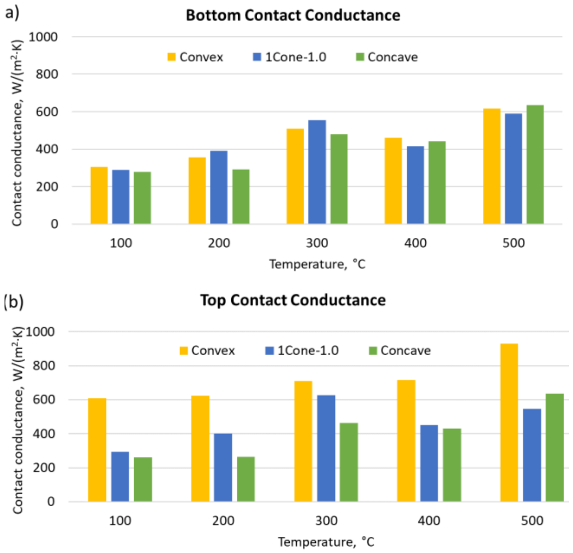

FIGURE 10: SIMULATED CONTACT CONDUCTANCE (A) AT THE BOTTOM, AND (B) ON THE TOP OF THE INTERNAL POWDER AND SOLID SHELL

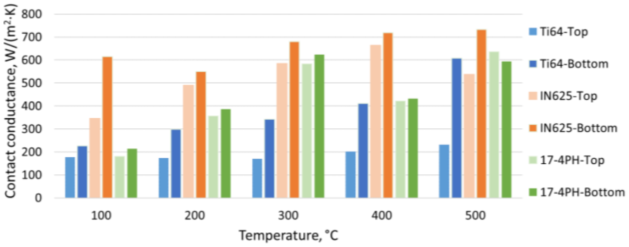

FIGURE 11: CONTACT CONDUCTANCE EVALUATION IN THREE MATERIALS

4.2.5 HEAT TRANSFER IN SPECIMENS

As the transient heat flux is exposed at the bottom of the specimens, the heat flux dissipates through the bottom shell towards the internal powder, and a lower temperature band occurs along the contact surfaces of the three specimens. It is observed that at t = 2.183 s, the internal powder takes heat, spreading upwards slowly due to limited heat transfer at the contact region, with the center region leading higher temperature and dissipation around the center. Additionally, the side shell provides more ability to carry heat to the upper shell, and thus the powder about the edge shows higher temperature for the three specimens. However, apparently, Convex gives a faster thermal flow passing through, followed by 1Cone-1.0 and Concave in an order. At t = 24.863 s, the heat transfer reaches steady state in Convex, and nearly so in Concave and 1Cone-1.0 specimens.

The corresponding heat flux distribution in the middle cut-off areas of the 3 internal powders is shown in Figure 12. At t = 0.011 s, the heat flux starts showing up at the bottom of the internal powders in the three specimens, and not obviously different in values. As the heat is outspreading, heat flux vectors of approximately 6.7 W/m^2 occasionally occurs around the central powder at about 0.1 s in all three specimens. Sequentially, at t = 2.183 s, the energy flows increase in the powder, and the middle portion of the powder shows a higher heat flow rate. Compared to the other two cone featured internal powders, the Concave specimen exhibits a narrower region specifying high heat flux value between 4.0 W/m^2 and 5.0 W/m^2, as the double-arrows are shown in Figure 12.

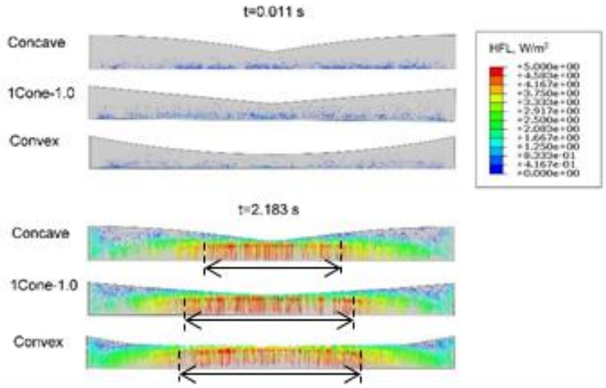

FIGURE 12: HEAT FLUX DISTRIBUTION IN POWDERS IN THREE CONE FEATURED SPECIMENS AT DIFFERENT TIMES

On the other hand, at t = 2.183 s, the heat flux exhibits significantly different on the top of the outer shells with different cone configurations, as shown in Figure 13. In Convex specimen, the heat flux displays a higher value, approximately 2.5 W/m^2 at the boundary that contacts the internal powder, and gradually reduces to none upwards but increases laterally toward outside. The heat flux in the top shells of 1Cone-1.0 and Concave specimens also exhibits the similar transition, but the heat flux at the bottom boundaries is lower than that in Convex. The bottom shells for the three cone featured specimens display insignificant differences. Beyond the range of the heat flux value of interest, the heat flux vectors in the solid shells follow the path along the geometries, and the magnitudes can reach nearly 57 W/m^2 on the side and peripheral of the bottom in the three specimens.

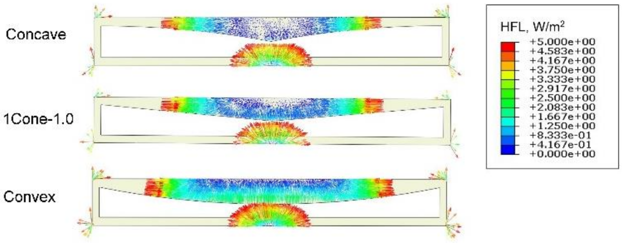

FIGURE 13: HEAT FLUX DISTRIBUTION IN OUTER SHELLS IN THE THREE CONE FEATURED SPECIMENS AT T=2.183 S

In addition, it has been known that the heat flux passing through two contacting objects can be measured as a function of the contact conductance between the two neighboring objects and their temperature gradient. The findings of the heat flux distributed in the shells demonstrate the corresponding tendency of the contact conductance in the three specimens, indicating that the top contact conductance in the Convex specimen exhibits significantly higher than those in 1Cone-1.0 and Concave specimens; although the bottom contact conductance in the three specimens does not vary apparently.

5. CONCLUSIONS

In the present study, hollow specimens were designed with various internal geometries and fabricated with powder enclosed using 17-4PH stainless steel in an L-PBF system. The as-built specimens were tested in a laser-flash equipment to measure the thermal diffusivity up to 500 °C. Then, the combined experimental-numerical simulation was carried out to evaluate the thermal conductivity of the internal powder at 100 °C to 500 °C. An internal geometry effect on the measurement of the metallic powder thermal properties has been analyzed. The contact conditions between the internal powder and the top shell of the specimens exhibited variation between different internal geometrical specimens, which may have resulted in various heat transfer behaviors. The detailed experimental and simulated results are concluded as follows:

- Thermal diffusivity for the 17-4PH specimens with different internal geometries varies from 0.0018 cm^2/s to 0.0025 cm^2/s at 25 °C; wherein, Convex shows the highest values, followed by 1Cone-1.0 and Concave in a descending order at all tested temperatures. As noticed, the thermal diffusivity increases from the room temperature until a plateau at 400 °C, and subsequently increases slightly at 500 °C.
- For each cone configuration specimen, time-response thermograms show an increasing heating rate as temperature rises, with the curves shift to the left, indicative of the rise in sample thermal diffusivity.
- The powder thermal conductivity of 17-4PH is measured ranging from 0.65 W/(m·K) to 1.34 W/(m·K) at 100 °C to 500 °C and displays a linear temperature-dependent tendency for each cone configuration. Specimen geometry has an effect on the powder conductivity evaluation, showing that Convex gives the highest values, and Concave, 1Cone-0.5 and 2Cone-0.25 exhibit similarly lowest.
- As a function of the cone volume, thermal conductivity ratio shows increase with cone volume, although a compromise occurs at the largest cone volume (Convex), and thus appears a non-linear correlation.
- 17-4PH is represented a conductivity ratio of 5.0 % to 5.7 % for 2Cone-0.5 and 4.0 % to 5.0 % for 2Cone-0.25, respectively, which are comparable with Ti64 and IN625 powders at the tested temperatures.
- The bottom contact conductance exhibits similar for the same bottom geometry in different specimens. However, there is variation of the top contact conductance upon

different cone geometries, for example, Convex shows significantly higher top contact conductance. Additionally, the retrogression for both contact conductance in 17-4PH specimens was noticed at 400 °C while this is not the case for Ti64 and IN625.

- Heat flux vectors in the powder of the Convex specimen at t = 2.183 s occurred in a larger region than those in 1Cone-1.0 and Concave specimens. The maximum heat flux value is approximately 5 W/m^2.
- Heat flux in the three cone featured specimens demonstrated the measurement of contact conductance between the internal powder and the outer shell from the developed experimental-numerical approach. Higher top contact conductance in Convex was evaluated than Concave and 1Cone-1.0 specimens, while similar bottom contact conductance was found in the three specimens.

***Abstract* — This paper presents precision measurements with a prototype cryogen-liquid-free DC Josephson voltage standard that produces a 1 V maximum output. Its cryostat is sufficiently compact that it can be operated on a bench close to devices under test. Compared to the National Institute of Standards and Technology (NIST) programmable Josephson voltage standard (PJVS), this bench-top Josephson voltage standard (BJVS) has a smaller cryostat (only 25 % of the volume), the Josephson junction array circuit is less complex and has only 10 % as many junctions, simpler bias electronics, and reduced mechanical cooling requirements. Direct voltage comparison between the BJVS and the PJVS achieved a relative agreement of 5 × 10^{-10} at 1 V. With the recent redefinition of the International System of Units (SI), the BJVS becomes a primary realization the unit volt, requiring only access to a standard single-phase power outlet and a GPS signal (SI second).**

***Index Terms* — Digital-analog conversion, Josephson arrays, standards, superconducting integrated circuits, voltage measurement.**

I. Introduction

The dissemination of dc voltage from primary to secondary laboratories is nowadays exclusively dependent on the stability of Zener voltage standards. Although the uncertainty achieved with commercial Zener voltage standards is sufficient for most electrical instrument calibration, the intrinsic drift of Zener references requires their periodic calibration with a Josephson voltage standard (JVS) [1]. The Zener calibration with a PJVS is performed at a primary standards laboratory and requires shipping the Zener artifact. With the redefinition of International System of Units (SI), all Josephson voltage standards become a primary realization of the unit volt [2]. In this paper, we present a prototype of a simplified compact bench-top JVS (BJVS) designed to realize the unit volt. The maximum output voltage of the BJVS was chosen to be 1 V, but a small number of fixed voltages are realizable. The main advantages of the 1 V BJVS (Fig. 1) are the reduced complexity and cost of the bias electronics, higher fabrication yield of the BJVS array circuit (having fewer junctions than the 10 V programmable Josephson voltage standard (PJVS)), and the ability to run the cryogenic compressor from a standard single-phase power outlet. This more compact and easily deployable 1 V BJVS can realize the unit volt directly, such as at secondary standards laboratories, eliminating *de facto* multiple calibration measurements, typical of past traceability chains. The BJVS can also be implemented as a primary voltage reference for Kibble balances, which are now key instruments for the realization of the mass scale with the newly redefined SI, or as a traveling primary standard for interlaboratory comparisons.

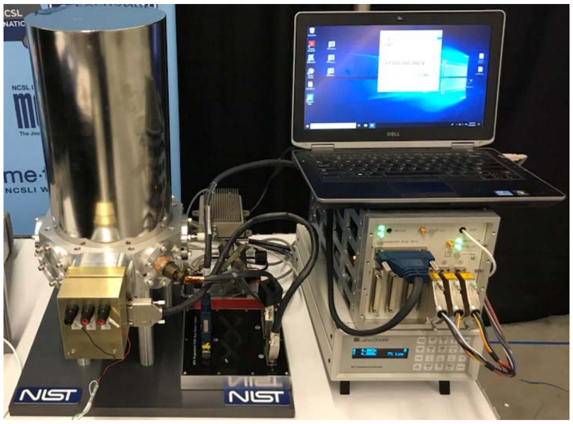

Fig. 1. Cryocooled 1 V bench-top Josephson voltage standard (air-cooled compressor not shown).

II. Bench-Top Josephson Voltage Standard

The BJVS circuit consists of 34 320 Josephson junctions (JJ) biased at a fixed microwave bias frequency of 14.090 8464 GHz. The JJ series array is subdivided into three subarrays of 3 432 JJs, 13 728 JJs, and 17 160 JJs, each generating, when biased on the n=±1 Shapiro step, ±0.1 V, ±0.4 V and ±0.5 V, respectively. The JJ array circuit is mounted on the 4 K cold stage of a Gifford-McMahon cryocooler. The cooling capacity of the cryogenic system is ~150 mW at 4 K, when operated with a single-phase-powered, air-cooled compressor. This cooling capacity is three-times the 50 mW cooling power required to operate the prototype circuit (JJ critical current: $I_c \cong 6.5$ mA at 4 K). A commercial temperature controller coupled to a 50 Ω heater is implemented to maintain the temperature of the device at 4 K. For the bias current sources, we used four channels of a low-cost compact commercial 16-bit digital-to-analog converter (±10 V), as well as four of the 24 current amplifier channels of our PJVS bias electronics amplifier board. A low-cost 24-bit (±0.5 V) analog-to-digital converter module is used to measure the chip output voltage, tune the bias-current operating range, and verify the

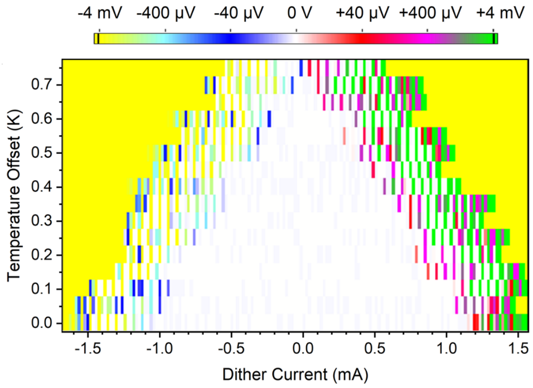

Fig. 2. Quantum locking range for the +0.5 V + (–0.4 V–0.1 V) subarray bias configuration as a function of the dither current and the temperature of the coldhead (referenced from 4 K).

quantum locking range of the BJVS. The microwave frequency is generated by a low-cost compact USB-powered synthesizer having a 100 Hz frequency resolution. The synthesizer is locked to an external 10 MHz reference (NIST primary frequency reference or GPS locked oscillator). The software was adapted to run the BJVS bias electronics while maintaining all the self-checks, diagnostic, and automatic tuning functions previously implemented with the NIST 10 V PJVS.

III. Quantum Locking Range

To measure the quantum locking range (QLR) with the best voltage resolution, the three subarrays are biased in the +0.5 V + (–0.4 V–0.1 V) = 0 V configuration. The white area (Fig. 2) shows the QLR domain as a function of both the dither current and the coldhead temperature. Unlike the 10 V PJVS system [3], the coldhead of BJVS is not fitted with a helium buffer tank, leading to an increase in the temperature oscillations (~240 mK), which are visible at the edges of the QLR by the band of successive voltage variations. Despite the correspondingly small ±0.5 mA bias current margin reduction associated with temperature oscillations, the QLR at 4 K remains larger than 2 mA.

IV. Direct JVS Comparison

We performed a direct comparison at 1 V between the BJVS and the PJVS. A digital nanovoltmeter (DNVM) measured the residual voltage difference. The low and high sides of the DNVM were connected respectively to the low side of the BJVS and the low side of the PJVS. The high sides of both JVS systems were connected in series. The low voltage tap of the BJVS was grounded on-chip through the current bias lead. In this configuration, only the leakage current contribution of the PJVS [4] contributed to a voltage error, but with an overall PJVS leakage resistance >150 GΩ [5], the leakage current-to-ground error contribution to this voltage comparison is insignificant. The measured leakage resistance of the BJVS was 90 GΩ. A single dataset measurement of $\Delta V = V_{\mathrm{BJVS}} - V_{\mathrm{PJVS}}$ consisted of four groups of 15 DNVM readings, where the polarity of both arrays was reversed after every group to remove the thermal offset. All the comparison measurements were performed by applying a dither current sequence (0, +0.2, –0.2) mA in both JVS systems to verify the QLRs [4]. We measured ΔV with two different types of microwave frequency synthesizers on the BJVS system (Table I). If we assume that all the voltage error ($\Delta V = -0.51$ nV) is due to the finite frequency resolution of the compact synthesizer, then its frequency error is ~7 Hz at 14.090 8464 GHz, despite being locked to the same 10 MHz reference as the PJVS synthesizer. With the standard synthesizer replacing the compact synthesizer in the BJVS, this error does not appear and ΔV becomes comparable to the minimum voltage that a typical DNVM can resolve.

Table I: Results of the BJVS-PJVS comparison at 1 V

Synthesizer Type	Synthesizer Resolution	Dataset size	Mean of ΔV (nV)	Type A Unc. k=1 (nV)
Compact	100 Hz	524	**–0.51**	0.37
Standard	1 mHz	357	**–0.14**	0.37

V. Conclusion

The 1 V BJVS is designed as a compact, cost-effective primary voltage standard, for use anywhere with access to a GPS signal needed to establish the traceability of the SI second. With lower complexity and cost compared to the PJVS systems, this BJVS may become a key instrument to disseminate DC voltage at secondary laboratories, shrinking or eliminating the existing traceability chain while improving measurement uncertainty (relative agreement of 5 × 10^{-10} at 1 V). Despite its reduced voltage output, programmability, and tunability (due to fixed frequency), the BJVS ability to generate 1 V and 100 mV enables calibration of a 10:1 voltage divider, which can be combined with the BJVS to extend the input range to 10 V and thereby also enable calibration of 10 V Zener outputs.

***Abstract*— Efficient and accurate simulation methods are of increasing importance in the design and evaluation of factory communication systems. Model-based simulation methods are based on formal models that govern the interactions between components and subsystems in the systems that are being simulated. The formal models facilitate systematic integration across the system, and enable powerful methods for analysis and optimization of system performance. However conventional simulation approaches utilize communication channel models that do not fully reflect the characteristics and diversity of industrial communication channels. To help bridge this gap, we develop in this paper new methods for channel model construction for link-layer simulation that systematically incorporate field measurements of wireless communication channels from industrial networks, and derive corresponding channel modeling library components. The generated library components capture channel characteristics in the form of lookup tables, which can be flexibly integrated into system-level simulators or co-simulation tools. We integrate our new table-generation methods into a model-based co-simulator that jointly simulates the interactions among process flows, physical layouts of workcells, and communication channels in factory systems that are integrated with wireless networks. Experimental results using our lookup-table-augmented co-simulator demonstrate the utility of the proposed methods for flexibly and accurately integrating realistic industrial network channel conditions into simulation processes.**

I. Introduction

The integration of wireless communication capabilities into factory systems is of increasing interest due to the important potential advantages brought about by wireless communications technology in factory environments [1]. This integration leads to highly complex design spaces, which involve interactions among process flow algorithms, factory workcell layouts, and wireless communication networks. We refer to these design spaces as *wireless-integrated factory system* (*WIFS*) design spaces. Due the high complexity of WIFS design spaces, simulation methods are of great importance for designing new systems, and for investigating modifications, such as upgrades, to existing systems. Effective simulation tools enable rapid evaluation and comparison of alternative system designs, thereby facilitating the process of iterative design and system performance optimization.

A limitation in conventional simulation approaches used in navigating WIFS design spaces is that they are based on communication channel models that do not fully reflect the characteristics and diversity of industrial communication channels. Many network simulation tools have been developed whose capabilities are useful to aid in exploring WIFS design spaces. Popular examples include NS-3, OMNeT++, and Cloonix, which provide sophisticated capabilities for network simulation. However, these simulators apply channel abstractions at the physical layer — e.g., by utilizing mathematical equations associated with different channel models or synthetic (simulated) data that is derived from delay profiles obtained from third-party sources, such as the IEEE 802.11 Wireless LAN Working Group (see Section II. WIFS simulation approaches that employ such methods may fail to provide accurate assessment of system-level performance because they do not precisely incorporate characteristics of actual industrial wireless communication channels — for example, harsh conditions that arise due to the vibration of machinery, and the presence of metal objects and obstacles (e.g., see [2]).

In this paper, we develop new methods for integrating realistic models of wireless factory communication network channels into simulation tools and associated WIFS design space exploration processes. More specifically, we introduce an approach to link layer simulation that systematically incorporates data from field measurements. Our link layer simulation approach produces signal-to-noise ratio (SNR) to packet-error-rate (PER) conversion tables, which can be integrated into co-simulation tools for WIFS design space exploration. The resulting integration allows the co-simulation tools to assess factory system performance characteristics (e.g., real-time communication performance, communication reliability, factory production throughput, and workcell energy consumption) more accurately in the context of the reference networks from which the field measurements were taken.

To demonstrate our proposed new approach to integrating field measurements into WIFS design space exploration, we employ a recently-introduced co-simulation tool called *Tau Lide Factory Sim* (*TLFS*), which enables model-based representation and simulation of factory process-flows and systematic integration of its process-flow simulation models with arbitrary discrete event tools for network simulation [3]. We extend TLFS with an extensible channel library that can be populated with different SNR-to-PER lookup tables, such as those generated by our proposed link layer simulation

Geng, Jing; Li, Honglei; Hany, Mohamed; Liu, Yongkang; Candell, Rick; Bhattacharyya, Shuvra. "Integrating Field Measurements into a Model-Based Simulator for Industrial Communication Networks." Paper presented at 16th IEEE International Conference on Factory Communication Systems, Porto, PT. April 27, 2020 - April 29, 2020.

approach. Through experiments, we demonstrate the utility of plugging in SNR-to-PER conversion tables generated from our new link layer simulation tool into TLFS through the new channel library extension. This utility includes both simulation results that more accurately incorporate actual industrial network characteristics, and faster simulation speed, which is enabled by the use of lookup tables as opposed to computational methods.

Although we demonstrate the contributions in this paper using the TLFS co-simulation tools, the utility of the proposed methods is not specific to TLFS. The proposed link layer simulator and the SNR-to-PER tables that it produces can readily be integrated into other network simulators or process-flow / network co-simulation frameworks to extend those tools with more accurate and customizable models for industrial wireless networks.

The remainder of this paper is organized as follows. Section II discusses related work on modeling and simulation of industrial communication networks, and summarizes the contribution of this paper in the context of the related work. Section III presents our new methods for field measurement integration, link layer simulation, and channel characterization library construction. Section III also presents our approach for integrating channel characterization libraries into the TLFS simulation tool, which we use to validate and demonstrate the methods of this paper. Section IV presents experiments involving the results of applying our proposed link layer simulation methods, and results of applying TLFS extended with channel characterizations that are generated using results from these simulation methods. Finally, Section V summarizes the contributions of the paper.

II. Related Work

A large body of work in the literature covers modeling and simulation for cyber-physical systems that are integrated with wireless communication capabilities. These works include two major directions — one that focuses on communication channel modeling for different types of channels, and another that focuses on link layer or system-level simulation that utilizes new channel models or off-the-shelf models, such as those available in MATLAB.

Many approaches have been proposed to model wireless communication channels involving different path loss models, small scale fading models, noise figures, etc. For example, the IEEE 802.11 Wireless LAN Working Group proposes channel models based on a set of WLAN channel prototypes, which model the signal delay profiles for different environments under different indoor/open space line-of-sight (LOS) and non-LOS (NLOS) scenarios (e.g., see [4]). A related class of models is the set of SISO models developed by Medbo and Schramm [5]. However, channel models such as these do not precisely reflect signal transmission in industrial wireless environments. For example, they do not capture harsh characteristics of industrial environments, such as those due to complex surroundings involving vibrating machines and metal structures, which in turn lead to significant multi-path effects, electromagnetic resonance, and other complicating factors (e.g., see [2]).

A variety of works has also investigated channel modeling under more complex communication environments. For example, Abbas et al. present an evaluation of vehicle-to-vehicle communication channel parameters through a detailed comparison between simulations and measurements [6]. Peil et al. use measurements to develop wireless propagation characteristics in an industrial environment, and then use these characteristics to derive a channel model [7].

Other works on modeling and simulation emphasize system-level evaluation based on novel applications of existing simulation frameworks. For example, Liu et al. apply the OMNeT++ simulation library to develop an integrated framework for factory process control simulation and wireless network simulation [8]. Patidar et al. [9] apply link layer simulation to improve the physical layer abstraction. Their approach uses channel profiles proposed from the IEEE WLAN Working Group [4]. Li et al. present a WIFS-oriented design space exploration tool that utilizes TLFS together with channel models that are available in the NS-3 simulation platform [10].

The key distinguishing aspect of our contribution in this paper, compared to the body of literature summarized above, is its focus on coupling the derivation of accurate channel characterizations for industrial wireless environments with system-level co-simulation processes for WIFS design space exploration. This is achieved through a new link layer simulation approach that utilizes field measurements from actual industrial wireless channels, and encapsulation of the resulting channel characterizations through a channel library, which is designed to plug into higher-level co-simulation processes.

III. Approach

In this section, we present our approach for constructing channel models that incorporate the characteristics of industrial wireless networks through field measurements, and applying the derived channel models to enable more realistic co-simulation between factory process flows and wireless communication networks in networked, smart factory environments. We refer to this type of co-simulation as *networked process flow* simulation. The field measurements used in our approach capture channel impulse responses (CIRs) from actual industrial wireless communication environments.

We demonstrate our approach through extensive experiments in Section IV. The field data used in these experiments is publicly available, and was collected from a measurement campaign performed by the U.S. National Institute of Standards and Technology (NIST) [11], [12]. Specifically, we use field data collected in this campaign from an automotive factory site. The field data employed in our experiments is in the form of one large MAT file (approximately 5 GB), which contains all of the measured CIRs from the automotive factory. The MAT file includes the physical location associated with each measured CIR, as well as the IQ data and duration for each CIR signal. The MAT file also includes metadata associated with the measurements, such as the file name, antenna information, and frequency.

In our approach, the measured CIRs are input to a link layer simulator, which in turn produces a PER/SNR table that can be used to efficiently and accurately characterize the communication environment of interest for a higher-level simulator, such as a networked process flow simulator. The approach is extensible so that different wireless environments can be characterized using different PER/SNR tables, which are collected in the form of a channel library, as mentioned in Section I. A channel library populated with tables derived from multiple wireless environments enables comparison of a given factory/network configuration across different environments, as well as comparison of alternative configurations for a given environment.

To model a communication channel, we need to consider factors that include the channel gain, fading, multipath characteristics, and noise, as illustrated in Fig. 1. In our approach, these factors are taken into account by deriving channel models based on the CIR measurement data that is collected from the given factory environment.

Fig. 2 illustrates our link layer simulator, which processes field measurements in the form of CIRs, and produces PER/SNR tables. Our simulator takes as input a set of M location-specific channel impulse responses (CIRs) $C_1, C_2, \ldots, C_M$. Each C_i is associated with a distinct physical location p_i in the factory environment from which measurements are taken. Each CIR C_i is input in the form of an array A_i such that for each sample index j, $A_i[j]$ gives the value of the jth sample in the corresponding CIR signal. The time associated with each of these signal samples can easily be derived by dividing the sample index by the sample rate of the measured signal.

The simulator involves two phases of operation: *model construction* and *simulation*. The horizontal dashed line in Fig. 2 shows the separation of these phases. In the remainder of this section, we describe the different blocks shown in Fig. 2, as well as the operation of the simulation phase.

A. Pre-processing

The Pre-processing block transforms the set of location-specific CIRs $S_c = \{C_1, C_2, \ldots, C_M\}$ into a more compact, *refined* set of location-specific CIRs $S_r = \{R_1, R_2, \ldots, R_N\}$ that are more useful for further analysis than the original set S_c. Here $N \ll M$ since in typical measurement scenarios, M may be very large, and a much smaller value of N is needed for efficient channel library generation as well as for efficient networked factory simulation by tools that use the channel library. To compress across the set of CIRs, we select 1 out every D successive locations that are visited in the measurement process, where D is a parameter of the Pre-processing block. In our experiments, we use $D = 60$.

We also apply pre-processing operations to each individual CIR. In particular, to each CIR, we apply operations for filtering out noise; compression (intra-CIR compression) to reduce the number of samples; and deriving parameters, such as the delay spread and Rician K factor, that compactly characterize each of the CIRs. We apply intra-CIR compression to reduce the computational and memory cost of applying the CIR data. For intra-CIR compression, we first determine the first signal sample whose value exceeds a predetermined threshold, and then extract this sample together with the following 127 samples. The thresholding operation here is performed to ensure that we discard any prefix in the signal that falls within the noise floor, which is assumed not to be part of the desired impulse response. We retain the extracted 128 samples to represent the CIR more compactly and discard all of the other samples. In this context, 128 can be viewed as a particular setting that we use for the *block size* parameter associated with intra-CIR compression in our link layer simulator.

In general, appropriate settings for pre-processing parameters, such as the inter-CIR compression factor and block size parameter, are heavily dependent on the field measurement process. Systematic methods for setting pre-processing parameters based on measurement-process parameters is an interesting direction for future work.

B. Clustering

The Clustering block in Fig. 2 applies the clustering algorithm developed by Kashef et al. [13] to partition the set

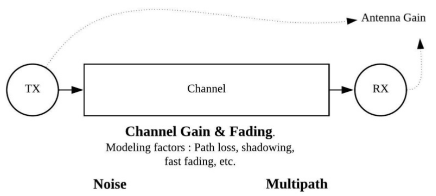

Fig. 1. An illustration of factors needed to model a communication channel.

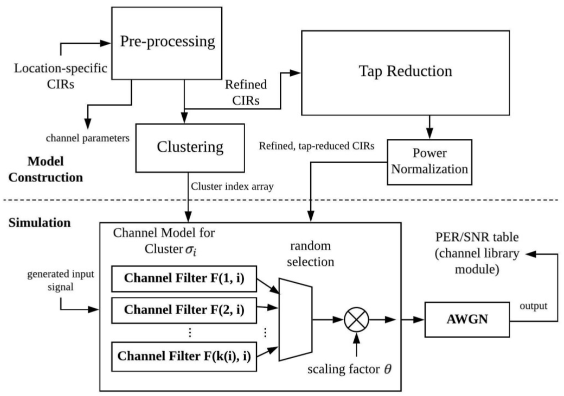

Fig. 2. An illustration of our proposed approach to link layer simulation and channel library generation.

of refined of CIRs into subsets $\sigma_1, \sigma_2, \ldots, \sigma_p$, where all of the CIRs within a given subset σ_i have similar characteristics. Each of the subsets σ_i is referred to as a *cluster* of refined CIRs. After the clustering process is applied, each refined CIR R_i has associated with it a unique cluster, which we denote as $\Sigma(R_i)$. Each cluster σ_i can be expressed as a set $\sigma_i = \{s_{i,1}, s_{i,2}, \ldots, s_{i,k(i)}\}$ of refined CIRs, where $k(i)$ represents the cardinality of (number of elements in) $\sigma(i)$, and $\Sigma(s_{i,j}) = \sigma_i$ for $j = 1, 2, \ldots, k(i)$.

The clustering block also creates a simple data structure, called the *cluster index array*, which maps indices of refined CIRs into indices of the clusters that contain them. Clustering helps to greatly reduce the complexity (number of generated PER/SNR tables) of the output of the link layer simulator, and the corresponding input that is operated on by the networked process flow simulators that utilize this data. This reduction in complexity translates into improved simulation speed during networked process flow simulation, as well as a more streamlined process for creating and storing the channel library. The reduction in complexity is achieved while preserving key characteristics of the original (unclustered) set of refined CIRs based on properties of Kashef's clustering algorithm.

C. Tap Reduction and Power Normalization

The tap reduction block converts each refined CIR R_i into a more compact tapped delay profile T_i using the algorithm of Mehlfuhrer and Rupp [14]. This is done, as with the inter-CIR and intra-CIR compression processes described above, to reduce model complexity in a way that does not substantially diminish the utility of the model. The number of taps in each of the T_is is a parameter of the tap reduction block that controls the complexity/accuracy trade-off of the tap-reduced CIR form. We refer to this as the *reduced tap count parameter* of our link layer simulator. In our experiments, we use 18 as the value of this parameter.

The output of the tap reduction process is post-processed by a simple power normalization block, as shown in Fig. 2. This block converts the taps to a form in which the sum of their squares equals unity. This normalization is performed to provide a channel profile without any path loss.

D. Construction of Cluster-Level Channel Models

Each cluster σ_i derived by the clustering block is converted during the model construction phase into a channel model, as illustrated by the block in Fig. 2 that is labeled Channel Model for Cluster σ_i. This block consists of a bank of filters $F(1,i), F(2,i), \ldots, F(k(i),i)$, where, as defined in Section III-B, $k(i)$ is the number of CIRs in cluster σ_i. Each $F(j,i)$ is the tap-reduced, power-normalized form of the refined CIR $s_{j,i}$.

Fig. 3 illustrates an example of a single filter $F(j,i)$ based on data from field measurements, and our reduced tap count parameter setting of 18. Section IV provides more details about the field measurement data that we have employed in our examples and experiments. The simulation model consists of $(k(1) + k(2) + \ldots k(p))$ such filters, where the filters are grouped into their corresponding clusters.

E. Simulation of the Constructed Channel Model

We use MATLAB to prototype our link layer simulator using the simulation model construction approach illustrated in the top part of Fig. 2. As a starting point for the prototype, we use the MATLAB WLAN toolbox, which contains channel modeling capabilities based on models proposed by Erceg et al. [4]. We then make various modifications and extensions to realize the proposed new simulation capabilities for bridging field measurements to networked process flow simulation.

First, we bypass the multipath features and fading profile from the MATLAB simulation. Instead, in our simulation approach, the multipath and fast fading effects are modeled through clusters and filters derived from the field measurements. For large scale fading, we apply the two-slope path-loss model proposed in by Damsaz et al. [15]. This is achieved in the simulation by scaling the filter response with a scaling factor θ whose value varies during simulation based on a randomly determined shadowing parameter. During simulation, applying this scaling factor is equivalent to multiplying the filter output by θ, as illustrated by the multiplication block shown in the lower part of Fig. 2.

In our approach, the link layer simulator is used to create a channel library module associated with a given factory environment. Each channel library module is populated with a set of PER/SNR tables, where one table is produced corresponding to each cluster. Different communication system parameters (e.g., the modulation and coding scheme or MCS) may be varied to produce a parameterized set of tables. In this case, for each set Γ of relevant parameter settings/combinations, link layer simulations are executed to derive the PER/SNR tables (table-subset) associated with Γ. Then the desired table-subset can be selected and used as input during networked process flow simulation.

To generate the table-subset for a given cluster σ_i and a given set of communication system parameters, the channel model for σ_i — based on the associated filters $F(1,i), F(2,i), \ldots, F(k(i),i)$ — is constructed as the core of the simulation model, as shown in the bottom part of Fig. 2. The simulation constructs physical layer service data unit (PSDU) signals from a stream of randomly-generated

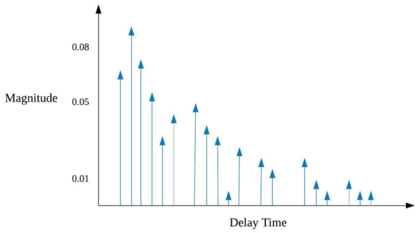

Fig. 3. An example of a single filter based on data from field measurements.

packets. The PSDU signals are passed through the channel model for σ_i to calculate the packet error rate.

For each packet, one of the $k(i)$ channel filters is selected randomly from $\phi_i = \{F(1,i), F(2,i), \ldots, F(k(i),i)\}$. This random selection allows us to incorporate the transient performance of the communication channel into the simulation in a realistic manner. The simulation to determine the packet error rate is run over a large number of packets and for a specific SNR value. This process is repeated over different SNR values to obtain the PER/SNR table for cluster σ_i.

The random selection from the set of filters ϕ_i is represented by the randomly-controlled switch that is connected to the output of the channel filters in Fig. 2. The output of the switch is connected to a multiplication block to simulate large scale fading, as described above.

Fig. 4 illustrates the use of the filter set ϕ_i to model a communication channel based on the corresponding cluster σ_i.

F. Integration with Networked Process Flow Simulation

As described in Section I, we use the TLFS tool for networked process flow simulation to demonstrate the utilization of a channel library produced from our link layer simulation approach. The model-based architecture of TLFS facilitates its extension with novel capabilities, such as those presented in this paper for channel modeling. Fig. 5 illustrates the high-level architecture of a TLFS-based networked process flow simulation together with the new TLFS extension to utilize channel libraries that are provided by external tools, such as our link layer simulator.

Here, the factory process flow is modeled (by the simulation tool user) as a dataflow graph, as illustrated in the bottom left part of Fig. 5. The dataflow graph illustration here incorporates various *actors* (dataflow-based functional components) that are useful for simulating factory process flows in TLFS. The actors labeled M and R represent a machine and a rail, respectively, while the actor labeled C is a controller actor that models the control of a set of machine and rail components. The dataflow graph also contains a number of send interface actors (SIAs) and receive interface actors (RIAs) which provide model-based interfaces between the process flow (dataflow) model and the communication network (discrete event) model.

The model-based architecture of TLFS makes it possible to plug in different network simulators to enable co-simulation between such simulators and the dataflow-based process flow simulator within TLFS. In our experiments, we utilize the popular NS-3 [16] simulator as the network simulator, as illustrated by the lower right part of Fig. 5. The blocks labeled NN and AP in this part of the figure respectively represent models for network nodes and an access point. In the extended version of TLFS illustrated in Fig. 5, we configure the network simulation to bypass the PER modeling features built-in to NS-3 and utilize instead the PER/SNR tables provided by the channel library.

For more details on the TLFS-based modeling and co-simulation methods illustrated in Fig. 5, see [3].

IV. Experiments

In this section, we present experiments that demonstrate the utility of our proposed linked layer simulation approach and its integration with networked process flow simulation.

A. Field Measurement Dataset

For the set of field-measurements that are input our link layer simulation experiments, we apply CIR measurements that have been obtained from a measurement campaign performed by NIST, as mentioned in Section III. Details of the measurement techniques involved in this campaign are presented by Candell et al. [11]. We specifically use the field data collected in this campaign from an automotive factory site. Among the different sites surveyed in the measurement campaign, the automotive factory most closely matches the factory production environment context to which this paper is most oriented. All of the field data is archived online [12].

Applying Kashef's clustering technique [13] on the CIR data from the automotive plant, after pre-processing, yields a total four clusters. Fig. 6 shows the *representative CIR* that is derived from each of the four clusters. The representative

Fig. 4. An illustration of the use of the filter set ϕ_i to model a channel based on cluster σ_i.

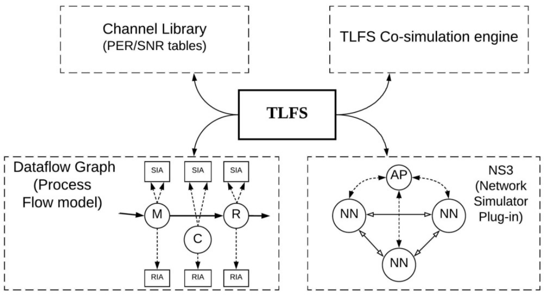

Fig. 5. An illustration of the architecture of a TLFS-based networked process flow simulation together with the new TLFS extension to utilize channel libraries.

CIR of a cluster is simply the CIR that results from averaging all of the CIRs in the cluster. We denote the clusters whose representatives are shown in Fig. 6a–d, respectively, by $\sigma_1, \sigma_2, \sigma_3, \sigma_4$. Cluster σ_1 corresponds to an NLOS channel in the factory, while clusters $\sigma_2, \sigma_3, \sigma_4$ correspond to LOS situations with different delay spreads. Differences in impact on channel performance due to CIRs from different clusters are demonstrated in Section IV-E.

B. *Experimental Setup for Comparing PER/SNR Curves*

In Section IV-C through Section IV-E, we present relevant experimental results and comparisons involving PER/SNR tables that are derived using our proposed linked layer simulation approach. These experiments are performed using the following parameters.

- Duration of simulation. For each SNR point in each generated table, we simulate until there are 10^5 packets transferred through the given channel or until 10^4 packet errors are detected. Whichever condition is detected first triggers the end of the simulation.
- Reduced tap count parameter. The value of this parameter is set to 18 taps, as stated in Section III-C.
- Protocol. All of the packets are generated randomly and transmitted using the 802.11n protocol with 2.4GHz frequency.
- Packet size. A packet size (PSDU length) of 100 bytes is used in all simulations.

C. *Comparison with TGn Channel*

In this subsection, we present a comparison between the channel model produced by our link layer simulator and the TGn model [4], which we choose here as a well-known, representative example of a model that is not specific to industrial environments. The differences between results using these two models help to concretely demonstrate the importance of customizing the channel model for an industrial environment when this type of environment is being studied.

Fig. 7 compares the PER/SNR curves generated from our link layer simulator using the measured automotive plant data with simulation results using the TGn model. To present the results without excessive clutter, we select one representative cluster (σ_3), and three TGn delay profiles (B, D, and E). In our settings for simulation, delay profiles B and D correspond to NLOS scenarios, while E is for LOS. The modulation and coding scheme (MCS) is set to MCS4 for all simulations. For a summary of all of the MCS indices for 802.11n, we refer the reader to [17]. The blue curve shows the PER/SNR characteristic derived by simulating cluster σ_3 in our link layer simulator, while the other three curves show PER/SNR results that we obtained by simulating the selected TGn delay profiles in MATLAB.

From Fig. 7, we can see that there can be significant difference between the performance of a real industrial channel and a TGn channel, and that this difference is captured by our link layer simulator. The disparity illustrated in Fig. 7 helps to quantitatively motivate the need for more accurate integration of channel characteristics into networked process flow simulations and related types of simulations for industrial wireless environments.

D. *Comparison Involving Different MCS Settings*

As mentioned in Section III-E, our link layer simulator can generate a parameterized family of PER/SNR tables based on designer-specified communication parameters. In this section, we demonstrate the utility of this capability by applying the MCS as a parameter for table generation. Fig. 8 shows the generated PER/SNR curves for cluster σ_3 (from the automotive factory) for MCS settings 0 through 6. Here, we use only these 7 MCS settings because the field measurements used in our experiments are based on a SISO antenna. However, our simulation framework of Section III is not restricted to the SISO case. Indeed, it can be applied to MIMO channels. Due to use of field measurements as opposed to mathematical models, the approach in our simulator for handling MIMO channels does not involve traditional MIMO modeling techniques based on correlation matrices (e.g., see [18]).

The results shown in Fig. 8 show that MCS selection can have significant impact on PER. Thus, in the context of WIFS design space exploration, it is useful to have available a parameterized collection of PER/SNR tables where one can easily vary the MCS scheme to assess the overall impact on

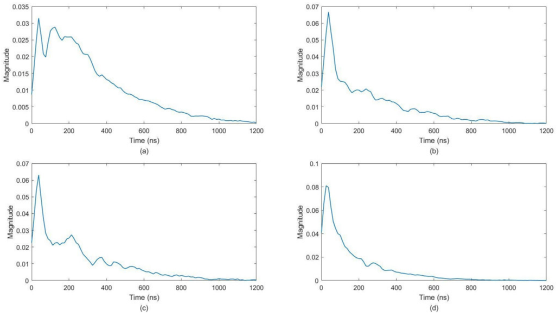

Fig. 6. Representative CIRs derived from the four clusters obtained from the automotive plant measurements. Parts (a)–(d) show the representative CIRs for clusters σ_1 through σ_4, respectively.

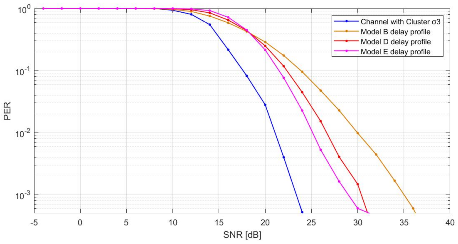

Fig. 7. A comparison between the PER/SNR curves generated from our link layer simulator using the measured automotive plant data with simulation results using the TGn model.

factory system performance in terms of PER and other relevant metrics.

E. Comparison Among Different Clusters

Fig. 9 illustrates the different PER/SNR curves generated by our link layer simulator for the four clusters in the automotive factory dataset. The MCS setting used in this experiment is 4. Cluster σ_1 exhibits poor PER due to its NLOS characteristic and large delay spread. Clusters $\sigma_2, \sigma_3, \sigma_4$, on the other hand, correspond to LOS scenarios. Among these, σ_4 has the lowest PER since signals transmitted in this type of channel have high K-factor, and low delay spread quality. Clusters σ_2 and σ_3 show similar performance characteristics in Fig. 9 with Cluster σ_3 exhibiting slightly better performance.

The results in Fig. 9 illustrate how networked factory simulation results may motivate changes to a factory layout. For example, if better communication reliability is desired than what an NLOS channel can support in a given deployment, then a rearrangement of the layout may be performed to provide a "clean" physical environment for the relevant communication path. This may lead to higher quality PER/SNR curves, which, when plugged into to the networked factory simulator, may provide the desired level of estimated reliability.

F. Integration into Networked Process Flow Simulation

In this section, we present experiments involving the integration into a networked process flow simulator of PER/SNR tables generated by our link layer simulator. As mentioned previously, the networked process flow simulator that we use to demonstrate this integration is TLFS. The experiments presented in this section help to validate the implementation of channel libraries for TLFS based on results of the new link layer simulator, and to demonstrate the kinds of networked process flow simulations and WIFS design space exploration that can be carried out based on field measurements, as enabled through the channel libraries.

The factory process flow model used in these experiments is a pipelined structure with one parts generator, one parts sink, three machines, four rails, and three machine controllers. The parts sink actor represents a subsystem that collects and stores parts after they are processed by the pipeline. For details on the modeling of rails, machines, controllers and other types of factory subsystems in TLFS, see [3].

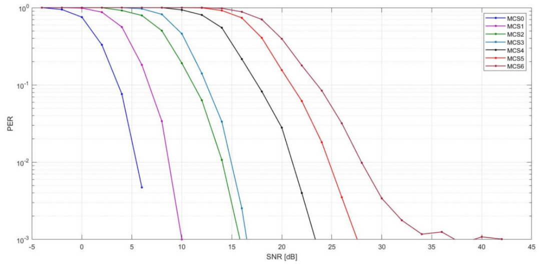

Fig. 8. A comparison across different MCS settings for cluster σ_3.

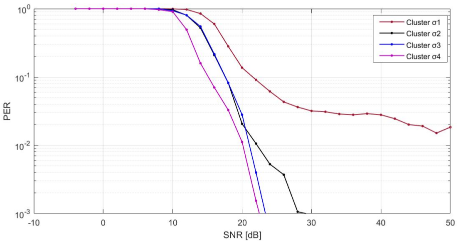

Fig. 9. PER/SNR curves generated by the link layer simulator for the four clusters in the automotive factory dataset.

For simulation, the machine working time (the time for a machine to process a given part) is determined randomly from a uniform distribution within the range $[0.9\mu, 1.1\mu]$, were μ is a model parameter that is set to 40 sec. in our experiments. When initializing the process flow model for each simulation run, the physical spacing between the machines, rails, and machine controller was also determined randomly: the distance between adjacent subsystems was determined from a uniform distribution on $[0.9\delta, 1.1\delta]$, where $\delta = 2 \text{ meters}$. In each simulation run, 10 products were generated by the parts generator actor and processed through the complete pipeline.

Fig. 10 shows networked process flow simulation results for the pipeline model described above using the generated PER/SNR tables associated with different MCS settings. Here we fixed the cluster to be σ_3, and varied MCS indices across the set $\{0, 1, 3, 6\}$. Here, to present the results without too much clutter, we have selected a subset of four representative MCS indices rather than evaluating all of them. For each MCS index, we ran 10 TLFS simulations independently and averaged the results over all the packets. The communication protocol employed in the experiment was the 802.11n protocol.

As shown in Fig. 10, the average communication delay decreases with increasing MCS indices, which is consistent with the increasing data rates associated with higher indices.

Fig. 11 shows networked process flow simulation results using the generated PER/SNR curves for the different clusters $\sigma_1, \sigma_2, \sigma_3, \sigma_4$ under a fixed MCS setting of 4. Here, we have randomly selected 4 as a representative MCS index to show results for a fixed index. In this experiment, we increase the mean spacing parameter to $\delta = 18 \text{ meters}$. At this increased spacing, the SNR falls into a range where there is significant variation among the PER levels across the different clusters. All other parameters are kept the same as in the experiments associated with Fig. 10. The results in Fig. 11 are consistent with those in Fig. 9. We see that The PER/SNR curve for σ_4 leads to the lowest average communication delay and the one with σ_1 gives the highest delay.

V. Conclusions

In this paper, we have developed new methods for integrating realistic models of wireless factory communication network channels into simulation tools and design space exploration processes for wireless-integrated factory systems. Our approach involves systematically incorporating data from field measurements into link layer layer simulation, and generating channel libraries that accurately incorporate channel characteristics into networked process flow simulation. We have demonstrated the proposed methods using a large dataset containing field data collected from an automotive factory. Interesting directions for future work include systematic methods for setting pre-processing parameters based on measurement-process parameters; integration of channel libraries into automated design optimization processes for factory process flows; and application of channel libraries to design space exploration for other types cyber-physical systems.

ABSTRACT

The flow stress of aluminum alloy Al6061-T6 produced by conventional thermomechanical methods has been investigated under the application of strains up to 80 % at a strain rate of the order of 10^3 1/s, and temperatures ranging from ambient to near melting. The high strain and strain rate deformation was imposed using a Kolsky bar apparatus equipped with a fast pulse-heating system to reach the target temperatures at high heating rates. The flow stress was measured to provide a constitutive model under strains, strain rates, temperatures and heating rates that match thermomechanical conditions developed in the primary shear zone for specially-designed comparative machining tests. It is expected that these measurements will enable the formulation of realistic machining models for Al6061-T6. Temperature measurements were obtained using non-contact infrared (IR) full field imaging together with embedded micro-thermocouple (TC) point probing, the latter being used to estimate the emissivity of the aluminum sample via separate, *in situ* calibration tests. Type-K TC measurements were made using the separated junction principle by embedding the TC wires into two micromachined holes in the specimen. The temperature measurement technique is discussed in detail, and temperature uncertainties are estimated. The technique will be used going forward to study the effect of heating time on the dynamic thermal softening behavior of Al6061-T6, which has been shown to be time-sensitive under quasi-static loading when temperatures exceed 200 °C due to Mg-Si precipitate growth.

KEY WORDS: Aluminum, Plastic Behavior, Kolsky Compression, Machining, High Strain, High Strain Rate, High Temperature, High Heating Rate.

INTRODUCTION

Manufacturing processes impose extreme strains, strain rates and temperatures [1]. Because these processes are designed to transform materials, it is important to understand material behavior under such extreme conditions. In particular, for machining, accurate information about the mechanical response of the workpiece material is required to obtain predictive models to optimize performance measures such as surface roughness, energy expenditure and tool wear [2]. One well-known experimental approach that provides accurate information about mechanical response (flow stress) under extreme thermomechanical conditions is the Kolsky bar compression technique. With this technique, dynamic compression (high strain and strain rate) that is similar, in terms of peak strains and strain rates, to deformation imposed by machining may be produced. The Kolsky compression tests may be performed under elevated temperature. However, the heating rates commonly employed in this kind of material testing are quite low compared to those occurring during machining. As a result, the flow stress data obtained may reflect equilibrium material conditions that are quite different than the transient conditions present during machining if the material transforms under heating. For example, in aluminum alloy Al6061, Mg-Si precipitates can grow above 200 °C, causing a significant change in flow stress depending on the time-at-temperature [3].

This work presents results from dynamic compression experiments performed on a model, precipitation treatable alloy (aluminum alloy Al6061-T6), with a special Kolsky bar apparatus equipped with an electric pulse heating element. The compression was performed at high strains and strain rates (up to 80 % and 10^3 1/s, respectively), and at elevated temperatures (up to 500 °C) under rapid heating (of the order of 1000 °C/s). These conditions were selected to match strain, strain rate, temperature and heating rate achievable by special machining tests, where the strains were lowered to less than 100 % by the combined application of highly-positive rake angles and chip pulling [4]. The work is aimed at the generation of material models that include contributions from non-equilibrium, time-sensitive, phase

Paper presented at Society for Experimental Mechanics 2020 Annual Meeting, Orlando, FL, US. June 08, 2020 - June 11, 2020.

transformations that might be more suitable for simulating machining processes compared to models developed from more conventional high temperature Kolsky bar techniques.

EXPERIMENTAL

An extruded 6061-T6 aluminum block purchased commercially was used as the specimen source. The specimens were cut from this block using electrical discharge machining (EDM). Disk-shaped specimens measuring 4 mm in diameter and 2 mm in thickness were dynamically compressed with a Kolsky bar system under both ambient temperature conditions and with rapid pre-heating using a pulse-direct current heating method [5]. Dynamic compression experiments were conducted with a 375 mm striker launched pneumatically at a gage pressure of 205 kPa (30 psi), which produced plastic strains up to 80 % at strain rates of the order of 10^3 1/s. For smoothing the incident pulse, copper pulse shapers, measuring 6.35 mm diameter and 0.0254 mm thick (¼ inch diameter and 0.01 inch thick), were placed in between the striker bar and the incident bar. The strain pulses were measured by metal foil strain gages connected to a battery-powered bridge circuit. The output was sampled at 2 MHz using a digital oscilloscope.

For carrying out the heated Kolsky bar experiments, a single short direct current pulse, produced by a low voltage, high current capacity battery bank (12 V), was passed through the specimen and the bars. Samples were heated using controlled current pulses of 35 A to 90 A with the times ranging from several seconds down to 0.2 s in order to obtain a range of temperatures and heating times prior to impact. With 35 A being the lowest controllable current for the equipment and specimen size used in this study, the minimum achievable steady-state temperature was about 360 °C. Since precipitate growth becomes an issue at temperatures as low as 200 °C, it was of interest to explore lower temperatures, which were achieved by short, ramped current pulses with durations less than 1 second. Because of the very high thermal conductivity of aluminum, the temperature uniformity of the specimens was good even during these very short ramped experiments.

Temperature measurements were obtained using an *in situ* calibrated mid-wave infrared (MWIR) thermal camera, with operating wavelengths between 1.5 µm to 5 µm, a sensor integration time of 150 µs, a frame rate of 870 Hz, and a sensor resolution of 160 pixels by 128 pixels with a magnification yielding 38 µm/pixel. The camera was first calibrated using a blackbody furnace, followed by a second *in situ* calibration that consisted of imaging heated aluminum samples while simultaneously measuring the temperature with a fine-wire (0.127 mm, 0.005 in diameter) type-k thermocouple embedded within the sample. Embedding the thermocouple was necessary because the individual wires were too fine to be reliably spot-welded onto the surface. Embedding the wires involved carefully drilling two small holes into the side wall of the sample using a #80 drill mounted on a linear micrometer stage (Figure 1, left). Each thermocouple wire was press-fit into a hole using a second, small piece of the same thermocouple wire as a wedge. An installed thermocouple can be seen in Figure 1, right. With this distributed-junction thermocouple technique, sample temperature measurements were obtained during the *in situ* thermal camera calibration tests to determine the effective surface emittivity (emissivity plus scattering) for the aluminum samples in the Kolsky bar measurement environment. While it was also determined that the thermocouple holes did not significantly affect the flow stress measurement by comparing identical compression tests on samples with and without holes, it was decided to use the calibrated thermal camera to determine impact temperatures for heated compression tests to avoid having to drill each sample.

The stress-strain curves were analyzed using the usual wave analysis methods [5] with two exceptions. First, because graphite foil was used as a lubricant in the heated tests as well to avoid electrical arcing during heating, the mechanical contribution of the foil was subtracted from the total mechanical response to obtain the specimen response. The complete method of graphite foil correction can be found in the work done by Mates et al. [5]. The other correction implemented was the correction of the elastic indentation of the bars during the dynamic compression, using the method described by Safa and Gary [6]. However, this correction is almost negligible for aluminum.

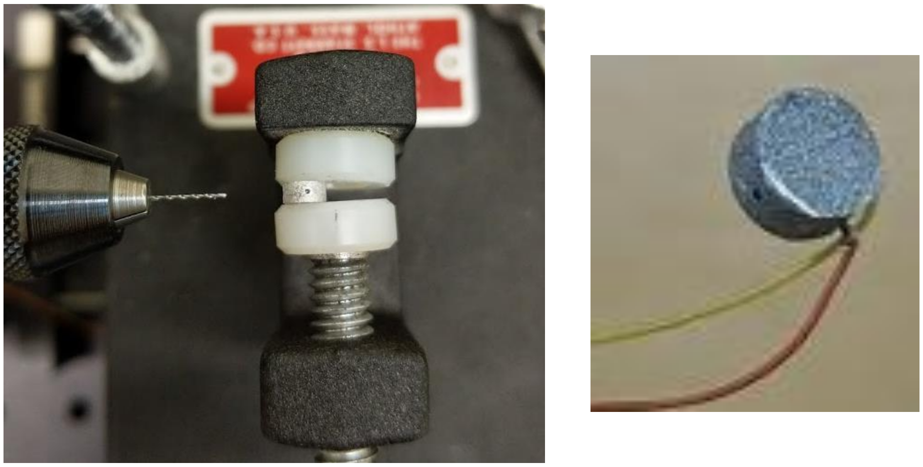

Figure 1. Procedure for drilling holes for the micro-thermocouple point probing installation on a 2 mm thick by 4 mm diameter aluminum sample.

RESULTS

Figure 2 illustrates the flow stress of Al6061-T6 at essentially ambient temperature, without any current going through the sample prior to or during the test. Any temperature rise during this test is only from dissipation of plastic work arising from the compression. Estimates based on temperature measurements using the embedded thermocouple indicate this temperature rise to be no more than 50 °C. In these experiments, grease lubricant was used instead of the foil, and therefore the stress-strain analyses were performed with only the elastic indentation correction applied. The drop-off in the flow stress for strains close to 0.8 is caused by the release-wave, which is produced at the end of the experiment, and does not represent material failure. Also, the upturn in the curve starting from strain about 0.7 may be attributed to friction. The curve shown in the figure represents the mean flow stress of 9 experiments performed under identical impact conditions. The error bars correspond to three times the standard deviation of the flow stress at each strain point. The flow stress observed corresponds well to previous studies of aluminum alloys [7]. The values measured also correspond well with flow stress estimates from special machining tests performed with the intention of matching the strain and strain rate of our Kolsky bar tests performed at ambient temperature [4]. These machining tests were designed to match strains and strain rates in the Kolsky bar tests. The machining tests performed at strain of 0.6, strain rate 10^2 1/s and essentially ambient temperature resulted in flow stress of 383 MPa [4]. This value is within the measurement error in flow stress shown in Figure 2. The agreement between the machining test and the Kolsky bar data is good despite the differences in stress states between the two types of test. The strain rate produced by the machining test was an order of magnitude lower than that produced by the Kolsky bar test. Future machining tests will be performed at faster cutting speeds to improve the strain rate match. However, flow stress estimates are not expected to change significantly, as it is known that the strain rate sensitivity of Al6061-T6 is low at strain rates less than 10^4 1/s [7].

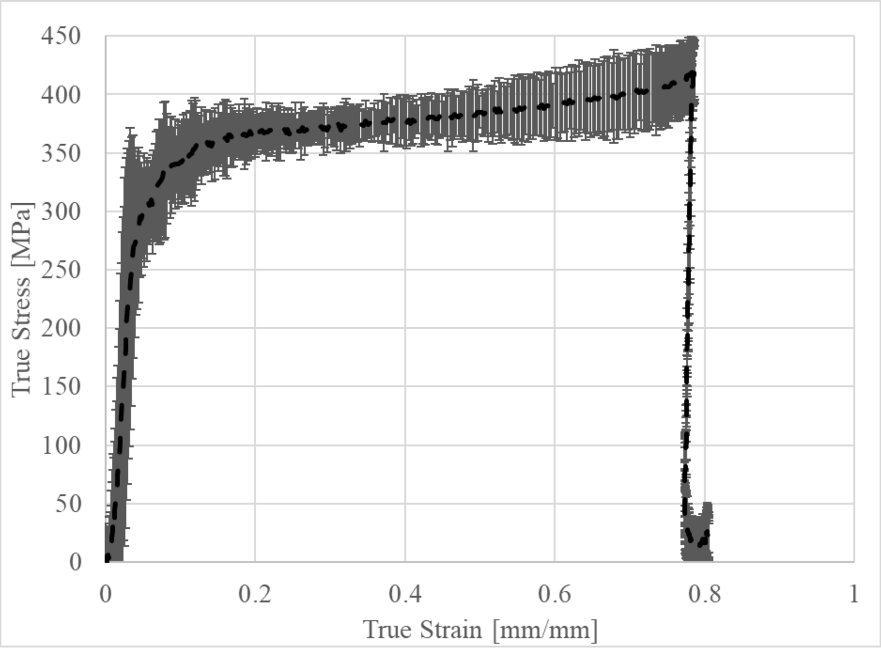

Figure 2. Flow stress as a function of strain. The flow stress is estimated by an average based on 9 repeated experiments. The error bars correspond to ± 3 standard deviations.

Figure 3 shows the plastic flow stress at several temperatures up to about 500 °C at a fixed level of plastic strain (50 %). The heating was performed by applying current pulses of different dwell times (heating times). However, the heating time was always very short – with a maximum of 7.5 s. The higher the temperature and the longer the heating time, the smaller the flow stress (Figure 3). This result is generally reflective of what has been shown at lower strain rates, where time-sensitive thermal softening is likely caused by precipitate growth [3], although grain growth may also play a role as well. In reference [3], a significant reduction in flow stress was reported when a test was performed after subjecting the material to a thermal treatment. The thermal treatment had for target temperature 400 °C. The heating rate was 200 °C/s, and the cooling rate was of the order of 10 °C/s. Therefore, the total time under temperature above 275 °C/s was about 15 s. In Figure 3, points of flow stress and specimen temperature for a given dwell time are assigned a unique color (see the legend in the figure). For the two tests with impact temperatures just below 300 °C and heating times of 3.5 and 7.5 s (one orange point and one red point in Figure 3), the specimens were heated to a steady temperature of about 360 °C and then allowed to cool prior to impact by delaying the striker impact slightly. With a cooling rate of several hundred degrees per second, the striker delay to achieve the final temperature was of the order of 0.1 s. Experiments above 360 °C for heating times longer than 1 s were heated continually until impact, while experiments heated for 0.3 s were obtained with no dwell time or cooling by using a ramped current pulse. For the temperature range from 250 °C to 350 °C, Figure 3 shows a significant difference in the flow stress between sub-second heating times (green and blue points) and the longer heating times (red and orange points). This temperature range matches that over which precipitate growth is promoted by heat energy (see ref. [3]). It is compelling to think that the effects observed herein are due to the dependency of the size and distribution of the Mg-Si precipitates on heating time. This hypothesis needs to be verified by direct observation of the precipitates. In any case, for applications such as machining, where temperature easily rises several hundred degrees Celsius over a fraction of a second, the elevated-temperature Kolsky compression testing developed for this study may provide thermal softening parameters over applicable, high heating rates. Thermal softening parameters derived from slow heating Kolsky compression tests may not be valid for such problems. Further work will focus on developing a more extensive data set from dynamic compression tests obtained under a wider range of thermal histories, and on the characterization of precipitate growth as a function of thermal history using advanced metallography techniques.

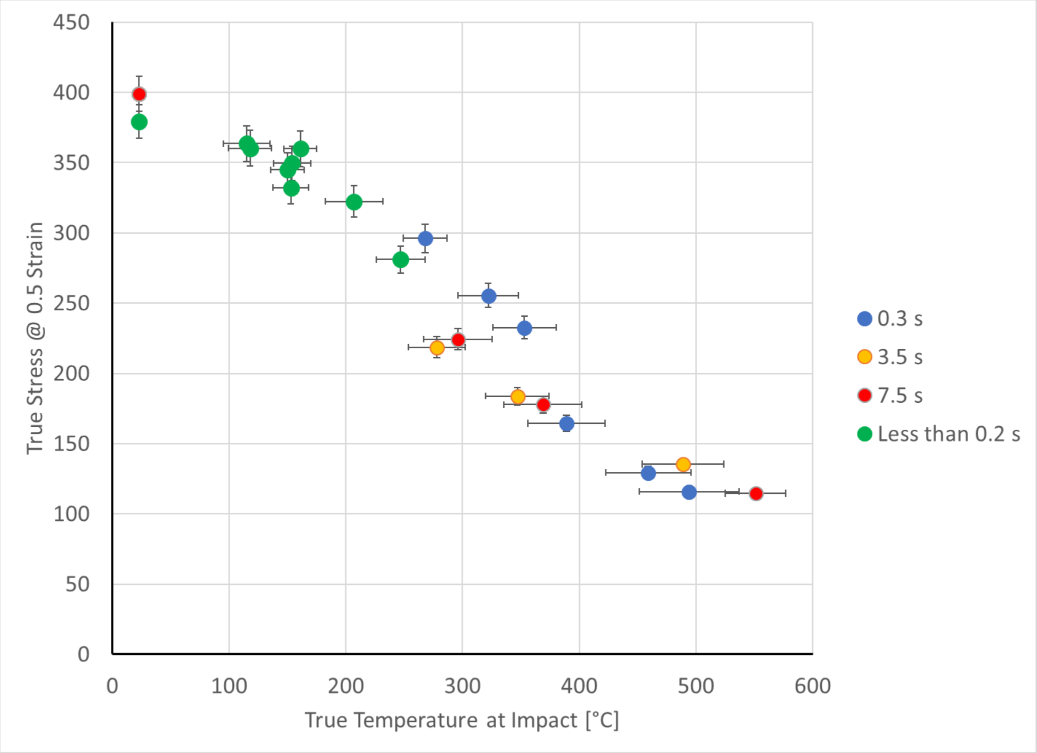

Figure 3. Flow stress of 6061-T6 at several temperatures using the short-pulse-heating method with temperatures determined from the thermal camera. Temperatures are those just prior to impact (within 1.6 ms (=1/614 s)). Error bars on stress are computed from error propagation (95 % confidence interval) and error bars on temperature are computed from thermal gradient measurements obtained during each experiment. The legend shows applied temperature dwell times (heating times).

CONCLUSIONS

At strains of 50 %, strain rates of about 10^3 1/s and near ambient temperature, the flow stress of Al6061-T6 derived from dynamic Kolsky compression tests matches the flow stress derived from machining tests. As the temperature increases, the flow stress decreases. However, differences in thermal softening rates are observed depending on the heating time, owing perhaps to the time-dependent growth of Mg-Si precipitates. The high heating rate, elevated-temperature Kolsky compression test developed for this study offers a unique platform to investigate the effects of time-sensitive material transformations on mechanical response. Future work will expand exploration of time-sensitive material behavior in this model alloy. It will also provide direct observations of the effect of precipitate growth over very short times (of the order of seconds or less) on flow stress, which can be used to develop material models that are better-suited to model machining processes.

***Abstract*—Machine learning (ML) approaches have been extensively exploited to model and to improve wireless communication networks in the past few years. Nonetheless, the estimation of key performance indicators (KPIs) and their uncertainties in Long Term Evolution License Assisted Access (LTE-LAA) based coexistence systems is not adequately addressed. For example, it is not clear if an ML method can accurately predict achievable KPIs (e.g. throughput) and the probability of coexistence (PoC) of LTE-LAA coexistence systems based on partial or no information of MAC and physical layer protocols and parameters. In this paper, we develop a novel ML method by combining a neural network with a logistic regression algorithm to track and estimate KPIs and PoC of coexisting LTE-LAA and wireless local area network (WLAN) links. This ML method can be applied when KPI samples at the base stations (BSs) and access points (APs) are available, without using knowledge of MAC and physical layer parameters. Comparison between the ML and simulation results indicate that the proposed ML method can track the system KPIs and predict the system PoC with good accuracy.**

***Index Terms*—Artificial neural network, LTE-LAA, logistic regression, MAC layer, machine learning, PHY layer, wireless coexistence, WLAN.**

I. Introduction

Wireless communications are tightly integrated in our daily lives. Laptops, tablets, smartphones, and online social networking applications make a level of connectivity to the world available that we have never experienced in the past. This trend continues to dramatically increase wireless network dimensions in terms of subscribers and data throughput [1], especially in the realm of the Internet of Things (IoT). As a consequence, wireless device protocols are beginning to transition from an exclusively-licensed spectrum environment to a shared one, and utilizing the unlicensed spectrum bands seems to be inescapable.

Long Term Evolution (LTE) operating in unlicensed bands, such as license assisted access (LAA), was introduced to improve the spectral efficiency and to help the cellular industry deal with the shortage of the spectrum [2]. However, there are many challenges to overcome in order for multiple networks to constructively share a spectrum. Hence there is a need to accurately evaluate spectrum sharing performance among operators; ensuring the effectiveness of coexistence requires careful consideration.

Recently, artificial intelligence (AI) and machine learning (ML) are having a transformative effect in almost every industry. ML is an important tool for the support of next-generation of wireless device networks. Future 5G and beyond mobile terminals are expected to access the spectral bands using highly developed spectrum learning and inference. However, owing to the involved network topologies, coordination schemes, and the various end-user applications, future networks will be immensely more intricate. Hence, obtaining many optimal key performance indicators (KPIs) might be computationally infeasible or undesirable. Moreover, due to nonlinearity in underlying wireless channels, modeling the end-to-end system's behavior analytically is not easily achieved. It gets even more difficult when it comes to managing networks efficiently in a coexistence scenario where different types of networks need to share a given section of spectrum. ML algorithms can mitigate the underlying unknown non-linearities and can reduce the network complexity so as to be tractable and useful while keeping up ambitious performance goals.

In line with standardization efforts on the evaluation of wireless coexistence [3], [4], in this paper, we develop an ML method to track and estimate the probability of coexistence (PoC) of WLAN and LTE systems in an intelligent and adaptive way. Accurately quantifying the PoC in a given shared spectrum is principal to the evaluation of wireless coexistence, as discussed in the ANSI C63.27 standard [3]. Our proposed method builds up an effective sharing of spectrum, provides an accurate coexistence performance evaluation, and helps to design future radio technologies (e.g., 5G new radio in unlicensed spectrum (5G NR-U) [5]).

The main contribution of this study is to check whether or not ML algorithms can track and provide reliable estimates of KPIs and PoC of coexisting networks. We aim to develop an ML model which provides reliable PoC estimates of various MAC and physical layer parameters, and apply this model to coexistence systems where analytical KPI formulas are not available. These results can support future versions of the ANSI C63.27 standard, and provide insight on developing new ML methods to support KPI uncertainty evaluation in 5G coexistence systems.

We propose a novel PoC estimator to provide an improved assessment of concurrent operation of WLAN and LTE networks in the unlicensed band. Specifically, we take the

Mosleh, Susanna; Ma, Yao; Rezac, Jake; Coder, Jason. "A Novel Machine Learning Approach to Estimating KPI and PoC for LTE-LAA-based Spectrum Sharing." Paper presented at IEEE International Conference on Communications (ICC) Workshop 2020, Dublin, IE. June 07, 2020 - June 11, 2020.

operations of both networks in the MAC and physical layers into account, and employ a novel machine learning algorithm by leveraging neural network with a logistic regression method that utilizes all MAC and physical layers' parameters as inputs (such as contention window size, maximum back-off stage, slot durations, and link signal-to-noise ratio (SNR)) and generates PoC as an output. To do this, we use a neural network to estimate KPIs from input MAC and physical layer parameters. A logistic regression model is then used to estimate PoC from estimated KPIs. The proposed algorithm enables both networks to evaluate wireless coexistence and guarantees a constructive coexistence among operators in an intelligent and a well-planned course of action. It is worth noting that the proposed technique we develop here could be incorporated into many other spectrum sharing systems and we use LTE simply as an example.

The remainder of this paper is organized as follows: Section II describes the system model and assumptions required for our analysis. Section III presents the problem formulation and introduces our proposed intelligent PoC estimator. The impacts of the MAC and physical layer parameters in evaluating a coexistence scenario is also explained in Section III. Simulation results are shown and discussed in Section IV. Finally, in Section V, an overview of the results and some concluding remarks are presented.

II. System Model

Consider a downlink coexistence scenario where two mobile network operators (MNOs) share the same unlicensed bands for operation in an industrial, scientific, and medical (ISM) radio band. Note that we are primarily interested in the operation of cellular base stations in an unlicensed band. However, the LTE base stations may have permission to utilize a licensed band as well. We assume each unlicensed band can be shared between the MNOs in a time sharing fashion. The LAA network consists of L eNodeBs indexed by the set $\mathcal{L} \triangleq \{n_\ell | \ell = 1, 2, \dots, L\}$ while the Wi-Fi network is composed of W APs indexed by the set $\mathcal{W} \triangleq \{n_w | w = 1, 2, \dots, W\}$ APs. Each transmission node $i \in \{\mathcal{L}, \mathcal{W}\}$ serves one single antenna user. The eNodeBs and APs are randomly distributed over a particular area while LAA user equipment (UEs) and Wi-Fi clients are respectively distributed around each eNodeB and AP independently and uniformly. We assume the transmission node i transmits with power p_i and the user association is based on the received power. We also assume (*i*) both Wi-Fi and LAA are in the saturated traffic condition, (*ii*) there is no hidden node problem in the network, *i.e.*, every transmission node i is able to hear one another, (*iii*) a successful transmission happens if only one link transmits at a time, *i.e.*, exclusive channel access (ECA) model is considered, (*iv*) the channel knowledge is ideal (perfect channel sensing among the links), *i.e.*, the only source of packet failure (unsuccessful transmission) is collision, and (*v*) each link is subject to Rayleigh fading and Log-normal shadowing.

Wi-Fi networks utilize a contention-based medium access with a random back-off process, also known as carrier sense multiple access with collision avoidance (CSMA/CA) [6]. In order to discover whether the channel is idle or busy, the station that accesses the medium should sense the channel by performing a clear channel assessment (CCA). The distributed coordination function (DCF) operation progresses if the channel is found out to be idle. Otherwise, the transmitting station refrains from transmitting data until it senses the channel is available. Similarly, LTE uses a listen before talk (LBT) channel access mechanism to maintain fair coexistence with Wi-Fi. Among different LAA-LBT schemes, Category 4 LBT is based on the same Wi-Fi CSMA/CA scheme and is well-suited in a coexistence scenario [2]. Although LTE and Wi-Fi technologies follow the same channel access procedure, they select different carrier sense mechanisms and threshold levels for sensing a channel, and they use different channel contention parameters leading to different unlicensed channel access probabilities which can result in different throughputs.

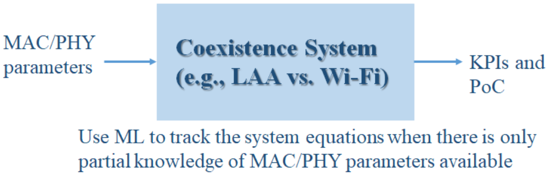
Our aim is to investigate the feasibility of machine learning algorithms to learn and track system measurement equations (when there is only partial knowledge of MAC/PHY parameters available), or even a system model for which the system equations are not available. To be specific, our goal is to develop a method to map PHY and MAC layers' parameters to PoCs, as depicted in Fig. 1. The PoC here is assessed in terms of the normalized network throughput. Here, we will briefly derive the normalized network throughput of both systems, a quantity that will be used in calculating the PoC later. Conforming with the analytical model in [7], the probability of transmitting a packet by a transmitting node i in a randomly-chosen time slot on an unlicensed channel can be written as

$$p_{\mathrm{tr},i}^{(k)} = \frac{2(1-2p_{c,i}^{(k)})}{(1-2p_{c,i}^{(k)})(1+\mathrm{CW}_{\mathrm{min},i}^{(k)})+p_{c,i}^{(k)}\mathrm{CW}_{\mathrm{min},i}^{(k)}(1-(2p_{c,i}^{(k)})^{m_i^{(k)}})}, \quad (1)$$

where $\mathrm{CW}_{\mathrm{min},i}$ and m_i are the minimum contention window size and the maximum back-off stage of the transmitting node i, respectively, and $p_{c,i}$ is the probability of collision experienced by the i-th transmitting node. The probability of collision experienced by the n_w AP and the n_ℓ eNodeB can be expressed as

$$\begin{aligned} p_{c,n_w} &= 1 - \Big(\prod\nolimits_{\acute{w}\neq w}(1 - p_{\mathrm{tr},n_{\acute{w}}})\Big)\prod\nolimits_{\ell}(1 - p_{\mathrm{tr},n_\ell}), \\ p_{c,n_\ell} &= 1 - \Big(\prod\nolimits_{\acute{\ell}\neq \ell}(1 - p_{\mathrm{tr},n_{\acute{\ell}}})\Big)\prod\nolimits_{w}(1 - p_{\mathrm{tr},n_w}), \end{aligned} \quad (2)$$

respectively, where $\acute{w} = 1, \dots, W$ and $\acute{\ell} = 1, \dots, L$ [8]–[10]. The probability of collision can be split into three parts: the



MAC/PHY parameters
Coexistence System (e.g., LAA vs. Wi-Fi)
KPIs and PoC
Use ML to track the system equations when there is only partial knowledge of MAC/PHY parameters available

Fig. 1. System Model

probability of collision due to the collision among the Wi-Fi transmissions, among the LAA transmissions, and between the Wi-Fi and the LAA transmissions, respectively given by

$$p_{c,\mathcal{W}} = (1 - p_{tr,\mathcal{L}})\big[p_{tr,\mathcal{W}} - \sum\nolimits_{w} p_{\text{tr},n_w} \prod\nolimits_{\acute{w}\neq w}(1 - p_{\text{tr},n_{\acute{w}}})\big],$$
$$p_{c,\mathcal{L}} = (1 - p_{tr,\mathcal{W}})\big[p_{tr,\mathcal{L}} - \sum\nolimits_{\ell} p_{\text{tr},n_\ell} \prod\nolimits_{\acute{\ell}\neq \ell}(1 - p_{\text{tr},n_{\acute{\ell}}})\big],$$

and $p_{c,\mathcal{W},\mathcal{L}} = p_{tr,\mathcal{L}} \cdot p_{tr,\mathcal{W}}$. Here $p_{tr,\mathcal{L}} = 1-\prod_{\ell}(1-p_{\text{tr},n_\ell})$ and $p_{tr,\mathcal{W}} = 1 - \prod_{w=1}^{W}(1 - p_{\text{tr},n_w})$ denote the LAA's and Wi-Fi's probability of transmission [8], [9], respectively. Moreover, the probability of a successful transmission by the n_w AP and the n_ℓ eNodeB can be respectively written as [8]–[10]

$$p_{s,n_w} = p_{\text{tr},n_w}\big(\prod\nolimits_{\acute{w}\neq w}(1 - p_{\text{tr},n_{\acute{w}}})\big)\prod\nolimits_{\ell}(1 - p_{\text{tr},n_\ell}),$$
$$p_{s,n_\ell} = p_{\text{tr},n_\ell}\big(\prod\nolimits_{\acute{\ell}\neq \ell}(1 - p_{\text{tr},n_{\acute{\ell}}})\big)\prod\nolimits_{w}(1 - p_{\text{tr},n_w}). \quad (3)$$

Hence, the average length of a time slot can be calculated as

$$T_{\text{avg}} = (1 - p_{tr})\mathbb{E}\{T_{\text{idle}}\} + p_{s,\mathcal{W}}\mathbb{E}\{T_{s,\mathcal{W}}\} + p_{s,\mathcal{L}}\mathbb{E}\{T_{s,\mathcal{L}}\}$$
$$+ p_{c,\mathcal{W}}\mathbb{E}\{T_{c,\mathcal{W}}\} + p_{c,\mathcal{L}}\mathbb{E}\{T_{c,\mathcal{L}}\} + p_{c,\mathcal{W},\mathcal{L}}\mathbb{E}\{T_{c,\mathcal{W},\mathcal{L}}\}$$

where p_{tr} is the probability of occupation of the unlicensed channel, and $p_{s,\mathcal{W}}$ and $p_{s,\mathcal{L}}$ denote the successful transmission probability of the entire Wi-Fi and LAA network, respectively. Moreover, $T_{s,\mathcal{L}}$, $T_{s,\mathcal{W}}$, $T_{c,\mathcal{W}}$, $T_{c,\mathcal{L}}$, and $T_{c,\mathcal{W},\mathcal{L}}$ indicate the time that the channel is being occupied by an LAA successful transmission, a Wi-Fi successful transmission, a collision among the Wi-Fi transmissions, a collision among the LAA transmissions, and a collision between the Wi-Fi and the LAA transmissions, respectively [10]. The network throughput of LAA and Wi-Fi systems as a function of both MAC and physical layers' parameters can be expressed as

$$S_{\mathcal{L}} = p_{s,\mathcal{L}} T_{P,\mathcal{L}} R_{\mathcal{L}} / T_{\text{avg},\mathcal{L}},$$
$$S_{\mathcal{W}} = p_{s,\mathcal{W}} T_{P,\mathcal{W}} R_{\mathcal{W}} / T_{\text{avg},\mathcal{W}}, \quad (4)$$

where $T_{\text{avg},\mathcal{W}}$ ($T_{\text{avg},\mathcal{L}}$) denotes the average time duration to assist a successful transmission in the Wi-Fi (LAA) network, $T_{P,\mathcal{W}}$ ($T_{P,\mathcal{L}}$) indicates the Wi-Fi (LAA) payload duration, and $R_{\mathcal{W}}$ ($R_{\mathcal{L}}$) refers to the Wi-Fi's (LAA's) physical data rate.

Here, we modify the PoC metric described in [11] and define coexistence in terms of the ability to maintain throughput above a certain threshold. Based on the throughput of both LAA and WLAN systems, the PoC metrics that quantify the coexistence performance of these two systems can be calculated as follows

$$\text{PoC}(\eta_{\text{LAA}}, \eta_{\text{WiFi}}) = \mathbb{P}(\text{S}_{\mathcal{L}} > \eta_{\text{LAA}}, \text{S}_{\mathcal{W}} > \eta_{\text{WiFi}}) \quad (5)$$

where equation (5) shows how the joint throughput of Wi-Fi and LAA networks can be mapped to the PoC.

III. Predicting PoC using ML approaches

As mentioned above, an evaluation of the wireless coexistence performance can be determined by the probability of coexistence metric, defined in [11]. This metric will identify the ability of both wireless networks to successfully perform their desired functionality in a given shared spectrum band.

As we discussed earlier, if the physical and MAC layers' parameters are appropriately selected, the throughput of both systems, given by (4), increases, leading to a higher PoC. To be specific, if transmitter i selects the unlicensed spectrum when it is not utilized by the other transmission nodes, then the probability of successful transmission by the i-th node increases, according to (3), leading to a higher throughput. Moreover, if each unlicensed band is selected such that interference is avoided (or at least minimized) among the transmission nodes then there will be a higher SNR, leading to a higher physical data rate (*i.e.,* $R_{\mathcal{L}}$ and $R_{\mathcal{W}}$) and thus higher throughput.

In order to estimate the PoC of Wi-Fi and LAA networks in the unlicensed band, we now develop a machine learning algorithm by leveraging a neural network with a logistic regression method, as depicted in Fig. 2. The proposed model aims to track and estimate KPIs of coexisting LTE-LAA and WLAN links, and evaluate the PoC of these networks. To be specific, the neural network maps the physical and MAC layers input parameters to the KPIs, such as throughput, and the low-cost training logistic regression algorithm conducts a regression analysis to map KPIs to PoC.

A neural network can be thought of as a tracking system used to predict a quantity. It approximates a mapping function from input variables to output variables. In this context, we will use it to track (approximate) the mapping function, i.e., Eq. (4), and determine the LAA and Wi-Fi KPIs based on MAC layer parameters (e.g., contention window size, maximum back-off stages, slot duration) and physical layer characteristics (such as link SNR, link distances, fading parameters). We aim to develop a model which provides reliable approximation of this mapping function of various MAC and physical layer parameters, so we can apply this model to more complex coexistence systems where analytical KPI formulas are not available. The neural network consists of processing nodes organized into three layers, input layer, hidden layer(s), and output layer. These nodes are densely interconnected. In the model that we consider in this paper, known as feed-forward, data moves through the layers in one direction. Each node in a hidden/output layer is connected to several nodes and receives data from them. Moreover, each node in a hidden layer is connected to several nodes and sends data to them. Each connection between nodes is assigned a number named a coefficient or weight. At the training phase, training data is fed to the input layer, it passes through the hidden layer(s), and arrives at the output layer. The data get multiplied by the weights, added together, and go through the activation function of each node. During the training phase, the weights are adjusted until a predefined goal is achieved, such as the mean squared error (MSE) of the training data falling below a pre-set threshold. After this goal is achieved, the trained neural network is applied to test (unseen) data.

Logistic regression can be thought of as a classification algorithm used to assign observations to a discrete set of classes. In this context, we will use it to determine the probability that both LAA and WiFi KPIs are above a user-provided threshold, based on the outputs of the neural network. Logistic regression, when given a set of features, attempts to estimate the probability of success for some function of those features. We use it to estimate the probability of successful coexistence given LAA and Wi-Fi KPIs. In order to solve this prediction problem, we use the gradient descent optimization technique. Let us assume $\mathbf{x}_k$ is the n-dimensional feature vector (the above-mentioned physical and MAC layers' parameters) and y_k is the outcome (PoC of LAA and WLAN networks) of a given test-run $k \in \{1, \ldots, m\}$, where m denotes the total number of observations in the dataset. The feature matrix $\mathbf{X}$ and the outcome vector $\mathbf{y}$ can be written as

$$\mathbf{X}_{n\times m} = \begin{pmatrix} x_{1,1} & x_{1,2} & \cdots & x_{1,m} \\ x_{2,1} & x_{2,2} & \cdots & x_{2,m} \\ \vdots & \vdots & \ddots & \vdots \\ x_{n,1} & x_{n,2} & \cdots & x_{n,m} \end{pmatrix},$$

and $\mathbf{y}_{1\times m} = \begin{pmatrix} y_1 & y_2 & \cdots & y_m \end{pmatrix}$. The primary assumption leading to logistic regression is that outcome y_k is Bernoulli-distributed with the success probability π_k. Logistic regression proceeds by estimating the probability of a constructive/destructive coexistence (indicated by the variable $\gamma = 1$ or $\gamma = 0$, respectively) given the training set $\mathbf{x}_k$, *i.e.,* $\hat{y}_k = \mathbb{P}(y_k = \gamma|\mathbf{x}_k) = \pi_k^{\gamma}(1-\pi_k)^{1-\gamma}$.

In order to estimate this probability using the logistic regression method, we need to find a hypothesis $h_{\boldsymbol{\theta}_k}(\mathbf{x}_k) = \hat{y}_k$. The goal is to learn the optimum value of the regression coefficients $\boldsymbol{\theta}_k$ in the sense that $\hat{y}_k$ is approximately equal to the test target y_k. $\boldsymbol{\theta}_k$ is the set of weights corresponding to n features and the bias. In order to learn these weights, we need to define a cost function. A cost function is an estimator of how well our model predicts the known output. This cost function will be used to train the logistic regression model (prediction function) that could predict the PoC in unlicensed band. The logistic regression model can be given as

$$\hat{\mathbf{y}} = \mathrm{S}(\mathrm{diag}(\boldsymbol{\Theta}^{\mathrm{T}}\mathbf{X})), \tag{6}$$

where $\hat{\mathbf{y}}_{1\times m} \triangleq \begin{pmatrix} \hat{y}_1 & \cdots & \hat{y}_m \end{pmatrix}$, $diag(\mathbf{A})$ returns a vector of the main diagonal elements of $\mathbf{A}$, $\boldsymbol{\Theta}_{n\times m}$ is the weight matrix, subscript T is the transpose operator, and $S(z) = \exp(z)/(1+\exp(z))$ is the so-called sigmoid (logistic) function. The sigmoid function $S(z)$ introduces non-linearity to the model and maps predicted values to probabilities. Then, the hypothesis of logistic regression for the training pair $(\mathbf{x}_k, y_k)$ can be written as

$$\hat{y}_k(\mathbf{x}_k) = h_{\boldsymbol{\theta}_k}(\mathbf{x}_k) = \frac{1}{1+e^{-\boldsymbol{\theta}_k^T\mathbf{x}_k}}. \tag{7}$$

In order to calculate the weight matrix $\boldsymbol{\Theta}$, a cost function is needed for optimization. Cost functions are usually defined as MSE functions. However, it is known that when using this cost function, the optimization problem turns out to be non-convex and has many local minimums [12, Chapter 3]. Hence, in this paper we use a cost function called "cross-entropy", also known as log loss function, for each pair of training samples, *i.e.,* $(\mathbf{x}_k, y_k)$, as follows [13, Chapter 5]

$$\mathcal{L}(y_k, \hat{y}_k) = -y_k \log(h_{\boldsymbol{\theta_k}}(\mathbf{x}_k)) - (1-y_k)\log(1-h_{\boldsymbol{\theta_k}}(\mathbf{x}_k)),$$

which plays the same role as the MSE function, but now the optimization problem becomes convex in $\boldsymbol{\theta}$. This cost function turns the optimization problem into a convex one which is much easier to solve using standard computational techniques. $\mathcal{L}(y_k, \hat{y}_k)$ shows how well the prediction is in a single training example. The cost function of all training samples used in the logistic regression algorithm can be expressed as

$$\begin{aligned}\mathcal{J}(\boldsymbol{\Theta}) &= \frac{1}{m}\sum_{k=1}^{m}\mathcal{L}(y_k, \hat{y}_k) \\ &= \frac{1}{m}(-\mathbf{y}^T \log\hat{\mathbf{y}} - (1-\mathbf{y})^T\log(1-\hat{\mathbf{y}})).\end{aligned} \tag{8}$$

By minimizing this cost function with respect to $\boldsymbol{\theta_k}$, the optimum value of the weight matrix $\boldsymbol{\Theta}$ can be found using following optimization

$$\min_{\boldsymbol{\Theta}} \quad \mathcal{J}(\boldsymbol{\Theta}). \tag{9}$$

In order to minimize the cost function $\mathcal{J}(\boldsymbol{\Theta})$ we apply the gradient descent method, which is the most popular approach to iteratively minimize the cost function. The update equation for the k-th observation in the data set can be written as

$$\begin{aligned}\boldsymbol{\theta}_k &= \boldsymbol{\theta}_k - \alpha\nabla_{\boldsymbol{\theta}_k}\mathcal{J}(\boldsymbol{\Theta}) \\ &= \boldsymbol{\theta}_k + \alpha(y_k - h_{\boldsymbol{\theta}_k}(\mathbf{x}_k))\mathbf{x}_k,\end{aligned} \tag{10}$$

where $\nabla\mathcal{J}$ denotes the gradient of the function $\mathcal{J}$, and $0 \leq \alpha \leq 1$ is the step size, also known as the learning rate, and determines how fast the learning happens. As is typically the case in learning algorithms, selecting α requires some care. A small value of α results in a long learning process (which could be detrimental in practice), while a large value of α could cause bouncing around the optimum point.

After calculating the optimal weight matrix $\boldsymbol{\Theta}$, the new label of an unseen sample can be estimated by using (7). To map the estimated label to a discrete class (constructive/destructive coexistence), the predefined threshold value η_{PoC} is selected above which we will classify values as constructive coexistence (high PoC) and below which we classify values as destructive coexistence (low PoC).

IV. Simulation Results and Discussions

We evaluate the performance of the proposed algorithm in a coexistence scenario. We simulate a scenario in which 6 eNodeBs compete for an unlicensed channel with 6 APs. All transmitters are randomly distributed over an area of size 120×80 m^2 with a minimum distance of 20 meters, as shown in Fig. 3. All UEs and Wi-Fi clients are independently and uniformly distributed around each eNodeB and AP, respectively. We consider one UE (Wi-Fi client) per eNodeB (AP). Each UE (Wi-Fi client) is assigned to the eNodeB (AP) that provides it with the highest received power. The antenna height of the transmission nodes and users are 6 meters and 1.5 meters, respectively. The carrier frequency is 5 GHz and the bandwidth of each channel is 20 MHz. The path-loss and shadowing between transmission nodes and users are generated following [14] for the indoor scenario. The transmit power at each transmission node is fixed to 23 dBm while the noise figure and the thermal noise level at each user is set to 9 dB and -174 dBm/Hz, respectively [14]. Moreover, we assume the omni-directional antenna pattern with a 0 dBi antenna gain.

According to this geometry and propagation model, we compute the SNR of each link. Given the MAC layer parameters in Table I, we select a sample set of input parameters, and train the neural network to generate output KPIs of both LAA and WLAN networks. The data used for this simulation consists of 1000 feature vectors. Only 30% of the data are used for training and the rest are considered for test. Here, we consider a feedforward neural network consisting of one input layer with 16 nodes (Wi-Fi and LAA contention window sizes, Wi-Fi and LAA backoff stages, and 12 link SNRs), one hidden layer with 16 neurons, and one output layer with two nodes (LAA's and Wi-Fi's throughput). The network is trained and converges quickly, as shown in Fig. 4. After training the network, we applied the trained neural network on unseen (test) data. In order to evaluate the trained network, we calculated the MSE as an average of the squared error $(\mathbf{y}-\hat{\mathbf{y}})^2$, where $\mathbf{y}$ is the KPI values calculated using equation (4) and $\hat{\mathbf{y}}$ is the output of the trained neural network. Comparing the neural network's outputs with the analytical results, the MSE of the test data is equal to 0.0043. The small value of MSE on test data indicates that the neural network tracks the mapping function (system equations) well. We also plot the normalized MSE of both Wi-Fi and LAA KPIs in Fig. 5.

Having the LAA and WLAN throughput pairs as the outputs of neural network, now we map the KPI pair to PoC using the trained logistic regression model and then compare the results with the theoretical one found by Eq. (5). In order to train the logistic regression model, given the predefined thresholds η_{LAA} and η_{WiFi}, we first plot the probability of satisfactory quality of service (QoS) of LAA and Wi-Fi networks, *i.e.*, $\mathbb{P}(S_{\mathcal{L}} > \eta_{\text{LAA}})$ and $\mathbb{P}(S_{\mathcal{W}} > \eta_{\text{WiFi}})$, in Fig. 6 and Fig. 7, respectively. It is observed that the analytical and neural network results follow the same trend. As expected, by increasing the thresholds, the probability of satisfactory QoS of each system decreases. Moreover, the probability of coexistence versus the Wi-Fi's and LAA's throughput threshold is plotted in Fig. 8. The goal is to train the logistic regression model to accurately estimate PoC from estimated throughput and enable both networks to evaluate the wireless coexistence. We pass the test data to the trained logistic regression network.

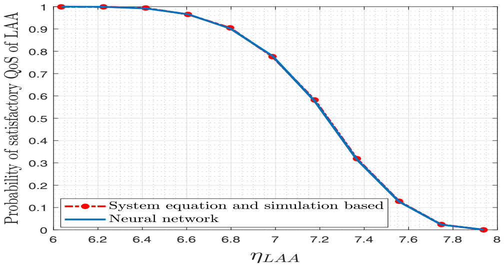

Fig. 6. Probability of satisfactory QoS of LAA versus different thresholds

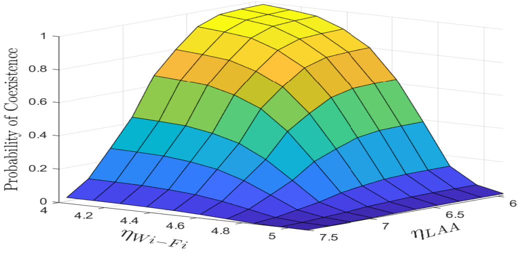

Fig. 8. PoC versus different Wi-Fi's and LAA's throughput threshold

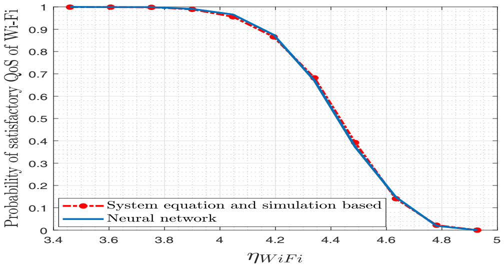

Fig. 7. Probability of satisfactory QoS of Wi-Fi versus different thresholds

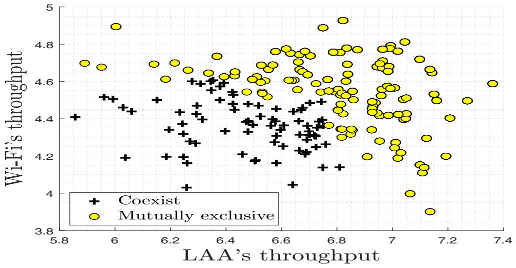

Fig. 9. Labeling Wi-Fi's and LAA's throughput pair using the trained LR

The logistic regression network labeled the unseen data as they can/cannot coexist with each other. Fig. 9 shows that by knowing the throughput of two networks we are able to decide whether or not these two networks can coexist with each other. Moreover, we compare the PoC calculated by equation (5) with the PoC output of the trained logistic regression network and compute the MSE. The MSE on the unseen test data is 0.0658. Furthermore, the logistic regression accuracy, which is defined as percentage of correct predictions, on the training and test data is calculated and given as 84.466% and 84.046%, respectively. In future work we develop further enhanced classification schemes to improve the accuracy.

V. Conclusion

In this paper, we have proposed a machine learning method to accurately track and estimate coexistence performance and its uncertainty between LTE-LAA and WLAN networks in unlicensed bands. The proposed method can work without knowledge of MAC and physical layer protocols and parameters of the system (except the KPI samples). We have also developed a system equation and simulation-based scheme to train and validate the performance of our method. Comparison of the proposed ML method and simulation results has demonstrated that our method can achieve a perfect KPI (i.e., throughput) tracking and a good PoC estimation performance. The proposed method can be extended to the cases where analytical results are not available. In future work, we will develop further enhanced ML methods for KPI and an uncertainty estimation, and generalize our proposed approach to more challenging coexistence scenarios.

Contributions to Acoustic Loss in Langasite, Langatate, and Catangasite Resonators at High Temperatures

Ward L. Johnson
Applied Chemicals and Materials Division, National Institute of Standards and Technology, 325 Broadway St., MS 647, Boulder, CO 80305, USA
wjohnson@boulder.nist.gov

Summary:

Piezoelectric crystals in the langasite family can serve as a basis for resonant acoustic sensors that operate at temperatures exceeding the range of conventional piezoelectric resonators, but their performance is limited by acoustic loss at elevated temperatures. This paper presents an overview of what is currently known and not known about physical contributions to temperature-dependent acoustic loss in langasite, langatate, and catangasite [1].

Keywords: acoustic loss, attenuation, high temperature, langasite, langatate, catangasite, piezoelectric resonators

Background

Applications of resonant piezoelectric sensors have traditionally been limited to temperatures below several hundred degrees Celsius, because phase transitions and/or material degradation occur at higher temperatures in common commercially available piezoelectric materials [2]. However, over the past four decades, substantial research has focused on growing, characterizing, and optimizing innovative piezoelectric crystals that can be used in resonant sensors at temperatures exceeding 1000 K [3]. These piezoelectrics include crystals with the structure of langasite ($La_3Ga_5SiO_{14}$, LGS).

A critical factor in the performance of resonators is the quality factor Q and corresponding acoustic loss Q^{-1}. This paper is focused on contributions to Q^{-1} in LGS and two piezoelectrics with similar crystal structure, langatate ($La_3Ga_{5.5}Ta_{0.5}O_{14}$, LGT) and catangasite ($Ca_3TaGa_3Si_2O_{14}$, CTGS).

LGS

Figure 1 shows measurements of Q^{-1} acquired at the National Institute of Standards and Technology (NIST, U.S.A.) and Clausthal University of Technology (TUC, Germany) on two Y-cut crystals grown by different manufacturers [2,4]. The combined data in this figure extend over an exceptionally broad temperature range and thereby provide a unique illustration of typical contributions to the temperature-dependent loss in LGS and other crystals in the langasite family. The NIST measurements were performed with noncontacting electrodes in vacuum, and the TUC measurements were performed with Pt surface electrodes in air.

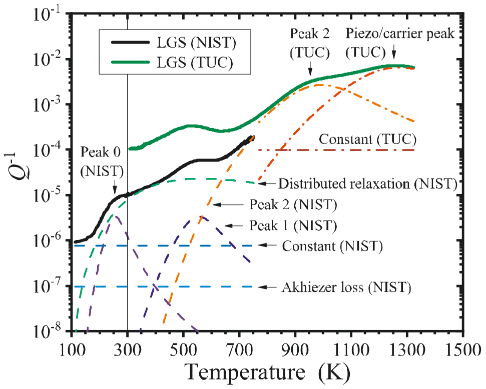

Fig. 1. Acoustic loss Q^{-1} of two LGS crystals measured at NIST and TUC. Resonant frequencies were 6.05 MHz (NIST) and 5.0 MHz (TUC) at ambient temperature. Dashed and dashed-dotted lines are contributions to Q^{-1} of the NIST and TUC crystals, respectively, determined from least-squares fits.

The three peaks below 1100 K in Fig. 1 are consistent with anelastic point-defect relaxations with a characteristic Debye dependence on temperature T and angular frequency ω [5]:

$$Q^{-1} = (\Delta/T)\omega\tau/(1+\omega^2\tau^2) , \qquad (1)$$

where the relaxation strength Δ is proportional to defect concentration. The relaxation time τ has an Arrhenius dependence on T,

$$\tau = \gamma\exp(U/kT) , \qquad (2)$$

where U is an activation energy on the order of an electron volt and k is Boltzman's constant.

Another peak appears in the TUC data near 1260 K, and this is associated with piezoelectric/carrier relaxation, involving the motion of charge carriers in acoustically generated piezoelectric fields [2,4]. In LGS, this peak is expected to have Debye form, but without T in the pre-factor [4]. An additional contribution in all crystals is intrinsic loss from phonon-phonon interactions (Akhiezer loss) [6], which is expected to be proportional to ω and weakly dependent on T above 100 K [4].

The data from NIST in Fig. 1 (112 K to 752 K) were fit to a function that includes three point-defect relaxations, Akhiezer loss approximated as independent of T, a constant background, and a broad relaxation consisting of a continuous set of Debye functions with a log-normal distribution of activation energies. The last term was found necessary to accurately fit the data [4]. Piezoelectric/carrier loss was not included, because initial analysis indicated it to be a minor contribution at all measured temperatures. The results of this fit at 6 MHz, simultaneously performed on data from two additional harmonics, are shown in the figure.

A fit of the TUC data (Fig. 1) accurately matches the data without including a distributed relaxation term. To simplify the figure, contributions to this fit are only plotted above the range of the NIST data and Peak 1 is not included. The piezoelectric peak position is consistent with predictions based on the measured temperature-dependent conductivity and dielectric constant [7]. The constant term in the fit is $1.0\text{x}10^{-4}$, two orders of magnitude greater than the constant in the fit of the NIST data. This difference may be due to greater mechanical contact and/or anelasticity in the Pt electrodes.

LGT and CTGS

Similar point-defect and piezoelectric/carrier contributions have been reported in LGT and CTGS at resonant frequencies in the low megahertz range [4,7,8]. Two point-defect peaks are typically observed between 300 K and 1000 K. Lower conductivity and corresponding τ_c of CTGS, relative to LGS, lead to lower piezoelectric carrier loss over the measured ranges of temperature, since the peak maximum is shifted to higher temperatures [7].

In an LGT crystal measured at NIST, no broad temperature-dependent contribution similar to that observed in LGS (NIST, Fig. 1) was detected [4]. The fact that dislocation density was much lower in this LGT crystal supports the hypothesis that the physical mechanism responsible for this contribution in LGS involves anelastic motion of kinks in dislocations [4].

Suhak *et al*. [7] found evidence for a broadly temperature-dependent background loss in Y-cut CTGS and employed a simpler Arrhenius form to fit this background. They also found the constant term in the fitting function to be much greater for a CTGS crystal with Pt electrodes than for a different CTGS crystal without electrodes.

Conclusions

LGS, LGT, and CTGS display similar features in the temperature dependence of acoustic loss, although the magnitudes and peak positions of loss contributions vary. The general form of the piezoelectric/carrier contribution and its dependence on electrical conductivity is well understood. However, specific defects responsible for point-defect peaks have not been identified. Such identification may be less than straightforward because correlations of peaks with impurity concentrations can be indirect. In particular, defect symmetries and associated relaxations can depend on charge states that change with dopant levels. The physical mechanisms responsible for observed contributions with broad temperature dependence are also not established. The combination of results from multiple crystals suggests that these mechanisms include effects that are both internal and external to the piezoelectric material.

***Abstract* — A system for the calibration of electrometers that measure currents from ionization chambers is described. The calibration system uses a 1 GΩ standard resistor in series with a stable voltage source to generate calibration currents from 1 pA to 20 nA, traceable to quantum voltage and resistance standards through an 8-1/2 digit digital voltmeter and the standard resistor. Expanded uncertainties (k = 2) of 100 × 10^{-6} or better for the calibration of the electrometer is needed for the ionization chamber measurements. The electrometer calibration was verified by current measurements following the decay of the short-lived radionuclide ^{18}F in a re-entrant ionization chamber.**

***Index Terms* — Electrometer, ionization chamber, quantum electrical standards, standard resistor, small current measurement.**

I. Introduction

For decades, radionuclide metrology has relied on re-entrant ionization chambers for comparing and maintaining secondary measurement standards and measuring half-lives in support of nuclear medicine, nuclear power, and other fields [1]-[2]. The output of the ionization chambers is a small current in the range of 10^{-13} A to 10^{-8} A, depending upon the radionuclide and activity. The ionization chamber is sealed vessel containing pressurized gas, typically nitrogen at 1 MPa. When a radionuclide source is placed in the well in the center of the ionization chamber, the gas is ionized by gamma rays from the decaying radionuclide and the freed charge is collected by applying high voltage (typically 500 V) across the chamber. The output current is proportional to the activity of the sample.

Linearity and stability over the 5 decades of currents generated by ionization chambers is a major uncertainty component and has been addressed for many years by using long-lived sealed radioactive sources to generate reference currents as standards to measure other sources. Highly active reference sources, such as ^{226}Ra, have been relied upon in the past. But reduced availability of the reference radioactive sources in the future, the aging of electronics used for the ionization current measurements, and improvements in electrical metrology for low current measurements have made the linking of ionization chamber measurements to the quantum SI through electrical units an attractive alternative [3].

One approach, described here, is to use a calibrated high value standard resistor, a stable voltage source, and an 8-1/2 digit digital voltmeter (DVM) to generate currents which are traceable to quantum resistance and voltage standards. This measurement system provides a cost-effective method to routinely calibrate the ionization chamber electrometer in the laboratory with an expanded uncertainty (k = 2) of 100 × 10^{-6} or better for the 20 pA to 20 nA ranges.

II. Measurement System

The main components of the measurement system are the standard resistor, the 8-1/2 digit DVM, the stable voltage source, and a switch. These instruments, along with a temperature monitor, cables, interfaces, and optical isolators have been packaged in a small portable instrument rack; allowing the system to be easily moved.

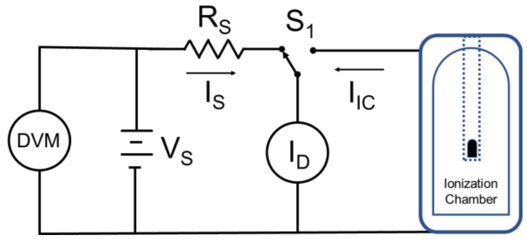

Fig. 1. Circuit diagram for calibration of electrometer used with an ionization chamber. Switch S_1 connects the electrometer I_D (measuring currents I_S and I_{IC}) to the ionization chamber or the voltage source V_S, DVM, and standard resistor R_S.

The currents are generated with a standard resistor and a voltage source in series, where Ohm's Law defines the calibration current. Four ranges were identified (20 pA, 200 pA, 2 nA and 20 nA) with a goal of 100 × 10^{-6} or better expanded relative uncertainty (k = 2). The standard resistor was calibrated with traceability to the quantum Hall resistance (QHR); a DVM, to measure the voltage source, was calibrated with traceability to the Josephson voltage standard (JVS). A 1 GΩ standard resistor was chosen with a voltage source of 0.02 V to 20 V to generate the required currents to calibrate the electrometer at full scale for each range. The relative standard uncertainty for calibration of the 1 GΩ standard resistor was 5 × 10^{-6} and the relative standard uncertainty for calibration of the DVM was 10 × 10^{-6}. Figure 1 shows the ionization chamber and the electrical calibration system.

The standard resistor has been fabricated and calibrated in the NIST resistance laboratory [4]. The resistance element has been

Jarrett, Dean G.; Payagala, Shamith; Fitzgerald, Ryan P.; Bergeron, Denis E.; Cessna, Jeffrey T.; Waduwarage Perera, Charles; Zimmerman, Neil M. "Ohms Law Low-current Calibration System for Ionization Chambers." Paper presented at 2020 Conference on Precision Electromagnetic Measurements(CPEM 2020), Denver, CO, US. August 24, 2020 - August 28, 2020.

heat treated and hermetically sealed for long-term stability and characterized for temperature and voltage dependence. The drift rate has also been determined to be less than 1 x 10^{-5}/year so the calibration interval for the resistor can be greater than one year. For this application, the standard resistor was rack mounted in an insulated enclosure at the bottom of the rack to minimize heating from the other instruments. A thermistor was permanently mounted on the sealed resistor canister (inside the insulated enclosure) so the resistance value can be corrected for temperature.

The voltage burden of the electrometer pushes uncertainty estimates above the target uncertainty at the lower current ranges of 20 pA and 200 pA [5]-[6]. The voltage burden has been found to be stable and has a Gaussian distribution during short-term intervals of 5 minutes with a relative standard deviation of 2.9 x 10^{-4}, indicating that the electrometer voltage burden is stable for a calibrate – measure – calibrate procedure. A switch is used to connect the electrometer to either the ion chamber or the electrical calibration system.

III. Ionization Chamber Measurements

The calibration of two electrometers verified that the instruments were within the manufacturer specification and showed similar results. Figure 2 shows the difference between the measured current and the calculated calibration current across five decades of current from 2 pA to 20 nA for an electrometer used with the ionization chamber. The solid lines show the manufacturer's specification for the electrometer. Data points are the difference between the measured net current and the calibration current based on the standard resistor and the voltage source.

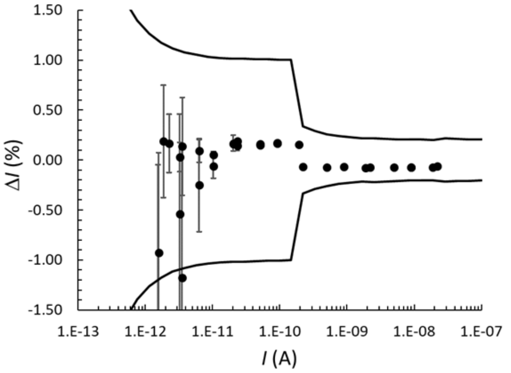

Fig. 2. Electrometer calibration within the manufacturer specification. Error bars are the standard deviation of the repeated measurements.

A test of the calibration system was made using the short-lived radioactive source ^{18}F over four decades of current as shown in Fig. 3. After calibration, the residuals from fits to the exponential decay of the current were reduced both in magnitude and in range-change artifacts.

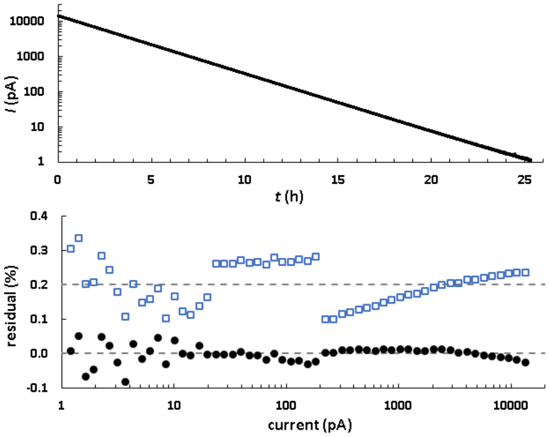

Fig. 3. Upper panel shows decay of ^{18}F from 10 nA to 1 pA. Lower panel shows fit residuals before (□) and after (●) calibration correction. For clarity, the before residual has been offset by + 0.2 %.

IV. Conclusion

A calibration system to provide ionization chamber measurements traceable to electrical units in the quantum SI is described. The calibration currents are sourced from a 1 GΩ standard resistor and a voltage source, with a digital voltmeter measuring the sourced voltage. Calibration of the ionization camber electrometer with relative uncertainty better than 0.1 % over the range 10^{-12} A to 10^{-8} A has been demonstrated, improving the measurement uncertainties and reducing reliance on high activity radioactive sources in the regular calibration workflow. Testing with the short-lived radionuclide ^{18}F was done to verify the calibration over a four-decade range.

Abstract— **As we power through to the future, in-vehicle communications' reliance on speed is becoming a challenging predicament. This is mainly due to the ever-increasing number of electronic control units (ECUs), which will continue to drain network capacity, hence further increasing bandwidth demand. For a wired network, a tradeoff between bandwidth requirement, reliability, and cost-effectiveness has been our main motivation in developing a high-speed network architecture that is based on the integration of two time-triggered protocols namely; Time Triggered Ethernet (TT-E) and Time Triggered Controller Area Network (TT-CAN). Therefore, as a visible example of an Internet of Vehicles technology, we present a time triggered communication-based network architecture. The new architecture can provide scalable integration of advanced functionalities, while maintaining safety and high reliability. To comply with the bandwidth requirement, we consider high-speed TT-Ethernet as the main bus (i.e., backbone network) where sub-networks can use more cost-effective and lower bandwidth TT-CAN to communicate with other entities in the network via a gateway. The main challenge in the proposed network architecture has been to resolve interoperability between two entirely different time-triggered protocols, especially in terms of timing and synchronization. With that in mind, we explore the main key drivers of the proposed architecture, which are bandwidth, reliability, and timeliness.**

Keywords—Internet of Vehicles (IoV), Time Triggered Ethernet (TT-E), Time Triggered Controller Area Network (TT-CAN), Electronic Control Units (ECUs), Intra Vehicle Communications

I. INTRODUCTION

A rapid growth in electric vehicles and Advanced Driver Assistant Systems (ADAS) is transforming future cars into large mobile data centers. The most important example of such a transformation is the self-driving car technology, which requires a large number of smart devices and sensors that can guarantee much better safety than manual driving. This, together with the increasing scale and scope of data generated from a vehicle with multiple ECUs, represents a tremendous challenge for future intelligent transportation under the auspices of the Internet of Vehicle (IoV).

Currently, vehicle electronics consist of several "sub-systems" or "domains" where each has its own control units, such as mechanical, electrical, or computer controls. The data generated by these sub-systems can vary with respect to bandwidth, reliability, and latency requirements. There are several advanced intra-vehicle communications standards, such as TT-CAN [1] and FlexRay [2, 3]. In particular, TT-CAN, which is an extended version of CAN [4], has been one of the most cost-effective communications deployed in today's vehicles [4]. While TT-CAN can fulfill the short term need for time-critical in-vehicle communications, its limited bandwidth is insufficient to respond to the ever increasing demand for more bandwidth. Such a demand has been further intensified in recent years by the introduction of more bandwidth hungry services, such as infotainment, camera-based Advanced Driver Assistance Systems (ADAS), advanced Laser detection and ranging (LADAR) scanners for crash detection and prevention [5], as well as future advanced 3-dimensional range video [6].

As a long-term solution, Ethernet technology, which is capable of providing a much higher bandwidth, embraces a logical transition towards IoV [7-9]. Currently, there are a few Ethernet-based protocol standards for in-vehicle communications [10]. While these protocols have undergone massive advancements, the reliability of the network to respond to emergency situations in a timely manner has been the main requirement.

Therefore, to keep up with the increasing integration of multiple sub-networks and cope with the staggering amount of video streaming for both safety and entertainment, in-vehicle communication would require not only faster, but highly reliable Ethernet-based networks, such as Time-triggered Ethernet (TT-E) [11]. On the other hand, transitioning from non-Ethernet-based TT-CAN to TT-E is a huge undertaking in terms of cost as most existing in-vehicle components are generally developed for CAN. Therefore, as a comprise between cost and capacity, in this paper we present a new network architecture, which is based on two time-triggered protocols. The main objective of integrating the two protocols is to expand the bandwidth and yet reduce the overall cost as much as possible. The main challenge, however, has been to achieve interoperability between the two time-triggered protocols. The proposed architecture provides a scalable integration of both protocols with advanced functionalities, while ensuring safety and reliability.

After a brief overview of the existing protocols, we provide greater details of the time protocols that have been used in our architecture. Section II presents a brief review of some of the most popular in-vehicle protocols. We discuss the potential of Ethernet based systems, especially the TT-E standard, for advanced in-vehicle communications. In Section III, we present our proposed network architecture, which includes our novel gateway design for achieving interworking and synchronization between the two time-triggered protocols, namely TT-CAN and

Gharavi, Hamid. "Deterministic Intra-Vehicle Communications: Timing and Synchronization." Paper presented at IEEE International Conference on Communications (IEEE ICC), Dublin, IE. June 07, 2020 - June 11, 2020.

TT-E. Finally, Section IV presents the simulation results of the integrated time protocols followed by the conclusion.

II. Time Triggered Intra-Vehicle Communications

Currently there are a number of intra-vehicle communication protocols such as Controller Area Network (CAN) [4], LIN (Local Interconnect Network) [12], FlexRay [2, 3], Media Oriented Systems Transport (MOST) [13] that have been used in today's vehicle. CAN however, is the most widely utilized technology. It is available in different forms, such as low and high-speed CAN, with Flexible Data Rate. Low-speed CAN has a data rate of 40 Kbps to 125 Kbps while the high -speed CAN offers bandwidth from 40 Kbps to 1 Mbps (depending on the length of the cable). In addition, the high-speed Time-triggered CAN (TT-CAN) offers bandwidth from 40 Kbps to 1 Mbps (depending on the length of the cable) [1]. The none-IP compliant TT-CAN has been extensively deployed in today's automobile. Bear in mind that time triggered protocols aim to provide reliable distributed computing and networking for in-vehicle communication systems. In a time-triggered system, the activities are initiated periodically to ensure a high level of determinism. However, the increasing number of ECUs, smart sensors, and other data-generating devices in modern vehicles, would require a much greater bandwidth that the TT-CAN cannot provide.

To meet the demand for greater bandwidth, FlexRay was introduced, which can support data rates of up to 10 Mbps. Some of the key characteristics of the FlexRay protocol are; synchronous and asynchronous frame transfer, guaranteed frame jitter and latency during synchronous transfer, single as well as multi-master clock synchronization, prioritization of frames during asynchronous transfer, error detection and signaling, time synchronization across multiple networks, and scalable fault tolerance [2].

TT-Ethernet (TT-E) is another standard, which is designed to expand traditional Ethernet with services to fulfill the requirements of deterministic, time-critical, and safety-related applications. TT-E is based on the AS6802 standard [11], which has been developed for integrated systems and safety-related applications primarily in aerospace, industrial controls, and automotive applications. It is a Layer 2 Quality-of-Service (QoS) enhancement, which is designed to expand traditional Ethernet-based networks with services to fulfill the requirements of deterministic and time-critical traffic, as well as other types of non-critical traffic. This is achieved by providing different traffic classes in parallel, namely Time-Triggered (TT), Rate-Constrained (RC), and Best Effort (BE). For instance, a time-triggered message, which has the highest priority transmission, is scheduled over the network at pre-configured time instances. The generation (triggered!!) time, delay, and precision of time-triggered messages are pre-set and guaranteed. The rate-constrained messages have less strict determinism and real-time requirements. Rate-constrained messages have a predefined bandwidth with temporal deviations of well-defined bounds. The best-effort messages are similar to traditional ethernet traffic where no delay is guaranteed. These messages use the residual bandwidth of the network and have the lowest priority. TT-E, due to its important features such as low latency, reliability, and higher bandwidth, has been selected as the backbone network in our proposed architecture.

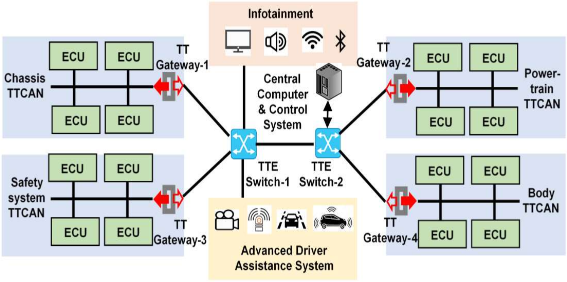

Fig. 1. A simplified in-vehicle time triggered communication system.

III. Proposed Network Architecture

Today's vehicles are becoming more complex than ever mainly due to more advanced requirements for safety regulations, luxury conveniences, computer-based diagnostics, and a vast array of power accessories supported by each car. These requirements have raised a need for more Electronic Control Units (ECUs) in cars. These ECUs not only make monitoring easier, but also report back to the driver if something is wrong. An ECU is a computer module that communicates with the sensors deployed in a car and controls various electrical functions. There are several ECUs in modern cars that control different operations ranging from monitoring engine performance to controlling electronic accessories. Some common ECUs include powertrain control module, chassis control module, advanced driver assistance system, safety system, infotainment module, and comfort module. These ECUs exchange information with each other using various in-vehicle networking technologies. Amongst the most critical in-vehicle components are the advanced driver assistance system and its extension to all aspects of the drive towards "self-driving" cars. The advanced driver-assistance systems (ADAS) mainly focus on enhancing the driving experience by offering technologies to avoid accidents and collisions. These technologies help in detecting potential problems and alerting the driver. The ADAS relies on various types of cameras (e.g., right, left, front, and rear cameras), LADAR, and lane departure warning (LDW)/traffic signal recognition (TSR) systems. The cameras allow the driver to easily detect approaching pedestrians, vehicles, or cyclists with the help of a screen. For instance, the LDW/ TSR mechanisms are used to alert the driver when a vehicle begins to move out of its lane without any prior signal indication. These mechanisms aim at minimizing accidents by relying heavily on the ADAS to guarantee safety of vehicles and passengers and to perform corrective actions such as returning the vehicle to its lane or emergency braking, especially in the case of Self-Driving Automation.

With the growing number of ECUs and further expansion of ADAS for self-driving, the major challenge is how to provide enough bandwidth, as well as ensuring reliability of the in-vehicle communication network. TT-E not only can provide a huge bandwidth, but also offers deterministic communications for safety related sensors and ECUs. The main drawback of the TT-E is the deployment cost (e.g., switches and end-system) compared with the bus-based TT-CAN technology.

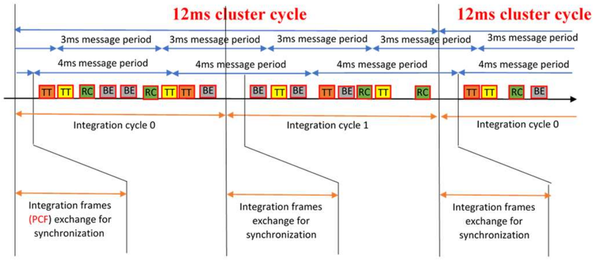

Fig. 2. An example of message periods, cluster cycle and integration cycles.

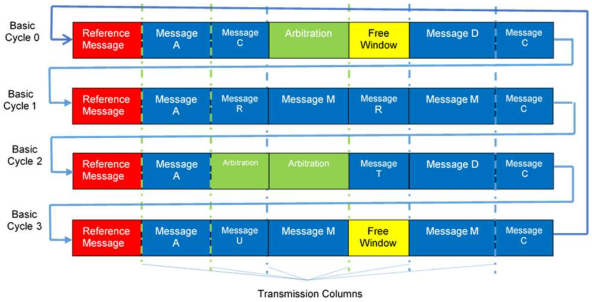
Furthermore, many traditional ECUs have already been designed for deployments in the TT-CAN environments. Therefore, as a comprise solution between cost and capacity, in this paper we a present a network architecture, which uses TT-E as the backbone network with multiple TT-CANs as sub-networks. Fig. 1 shows a simple example of the proposed architecture showing interworking between the two time-triggered protocols: TT-E and TT-CAN, via the design of a suitable gateway that can achieve interoperability between two entirely different time-triggered protocols.

A. *TT-Gateway Design*

The main functionality of the gateway is to allow interworking between two distinctly different time triggered protocols. This would require developing strategies to solve incompatibilities in terms of physical infrastructure, timing, and synchronization. To explore this further, we first provide more detailed information about the timing protocols of TT-E and TT-CAN.

For TT-E synchronization, the AS6802 protocol uses dedicated messages called protocol control frames (PCF) to establish and maintain system-wide clock synchronization amongst all the nodes at regular intervals (e.g., 1 millisecond), which is called integration cycles. The Synchronization entities consist of Compression Master (CM) and Synchronization Master (SM) or synchronization clients (SC), which are selected based on the system architecture. Generally, switches are configured as CM and end-systems as SM. Switches and end-systems that are not configured as synchronization master or compression master will be configured as the synchronization client.

The synchronization is achieved in two steps during normal operation mode (as shown in Fig. 11 of [11]). In the first step the synchronization masters send a PCF message (i.e., a short Ethernet frame: 64 bytes) to the compression masters (CM). The CMs then compute the average value using the relative received times of these PCFs. In the second step, the CMs then send out a new PCF to the SMs and SCs. More specifically, a TT-E switch, as the Compression Master (CM), generates a global time based on the PCF frames received from the Synchronization Masters (SMs) and distributes it to all Synchronization Masters and Synchronization Clients (SCs). In the two-step synchronization, the PCF frame (i.e., exchanges between SM and CM) is known as the integration frame, whereas the synchronization procedure for dispatching these integration frames (sending and compressing) within a configurable period is defined as the integration cycle. Fig. 2 shows the relationship between the integration cycle and the cluster cycle, where the overall cluster cycle in TT-Ethernet consists of multiple integration cycles, ranging from 0 to max_integration_cycle-1 [11]. On the other hand, the cluster cycle comprises the least common multiple of message periods, as depicted in Fig. 2.



Basic Cycle 0	Reference Message	Message A	Message C	Arbitration	Free Window	Message D	Message C
Basic Cycle 1	Reference Message	Message A	Message R	Message M	Message R	Message M	Message C
Basic Cycle 2	Reference Message	Message A	Arbitration	Arbitration	Message T	Message D	Message C
Basic Cycle 3	Reference Message	Message A	Message U	Message M	Free Window	Message M	Message C

Fig. 3. TTCAN system matrix.

Unlike TT-E, TT-CAN is a serial bus network and its messages are broadcast on the bus (instead of using sender and receiver's addresses) where they can be picked up by interested receivers according to the message's unique identifier. As a TDMA based scheme, TT-CAN divides the timeline between two consecutive reference messages, called the basic cycle, into time slots (windows). As shown in Fig. 3, a system matrix can be constructed by grouping a number of basic cycles. A basic cycle comprises several time windows of different sizes where a time master can send a reference message to every node to achieve synchronization. A time window may be an exclusive window, an arbitration window, or a free window. Exclusive windows are mainly considered for periodic messages without having to compete for network access (i.e., deterministic). An arbitrating window is for event triggered messages and a free time window is reserved for future extensions. A TT-CAN node, however, does not need to know the whole system matrix (only the information in each message) and based on the reference message, nodes can update their local time slots for transmission and reception of their data messages.

There are two possible timing levels in TT-CAN. In the first level (level-1) a time-triggered operation is carried out based on the reference message from a time master while an independent clock runs in each node. On the other hand, level-2, with the support of global time and a continuous drift correction in each node, provides higher synchronization quality. In our model, level 2 timing is considered where the TT-CAN section of the gateway operates as the time master in the TT-CAN network. Under level-2 timing, each node uses a cyclically incrementing counter as its Local-Time, which is decided by the Network Time Unit (NTU). The local time contains at least 19 bits where the three least significant bits represent a fraction of the NTU and is incremented in the unit of $NTU/2^n$. The length of the NTU is configurable and generated locally based on the local Time Unit Ratio (TUR) where $NTU = TUR \cdot t_{sys}$ and t_{sys} is the local clock period. It should be noted that TUR is a non-integer value and can be adjusted accordingly for continuous drift correction [1]. More specifically, TUR can be adjusted based on the difference between local time and the time transmitted by the gateway (i.e., time master).

As shown in Fig. 3, at the beginning of each basic cycle a time master, which is the gateway in our proposed architecture, sends a reference message to every node within its sub-network and start its Cycle_Time (CT). Based on this message, nodes can update their local time slots for the transmission and reception of their messages. When the CT reaches a predefined value: T_{cycle} (the length of the basic cycle), the time master resets its CT, starts a new basic cycle by sending a new reference message to the TT-CAN sub-network. On the other side, when receiving a reference message every node starts its new basic cycle and resets its CT. The value of the local time is saved as the Sync_Mark at the sample point of the Start-Of-Frame (SOF) bit of each message. The Sync_Mark of a reference message is defined as the Ref_Mark.

Fig. 4 shows the level-2 timing process for obtaining the cycle time and global time. As shown, the difference between a node's local time and Ref_Mark is the Cycle_Time, which is reset at the beginning of each basic cycle as soon as Ref_Mark is captured [14]. It should be noted that Global_Time is employed only in level-2 as the reference for the synchronization and calibration of all the local times to the time master's clock, hence providing more fine-grained synchronization. This is generated by the time master and transmitted in the reference message as Master_Ref_Mark to all nodes. The TT-CAN nodes derive their Global_Time by summing their Local_Time and their Local Offset (see Fig. 4). Local_Offset is the difference between the Ref_Mark in Local_Time and the Master_Ref_Mark in Global_Time, caused by the difference between local nodes' NTU and the time master's NTU. In the time master, the Local_Offset is zero. By comparing the differences between two consecutive Master_Ref_Marks (measured in time master's global NTUs and received in reference messages) and two consecutive Ref_Marks (measured in local NTUs), local nodes can derive the clock speed difference and compensate the drift by updating their TURs as follows: $TUR = df \cdot TUR_{previous}$, where drift factor $df = \frac{Ref\_Marks - Ref\_Marks_{previous}}{Master\_Ref\_Marks - Master\_Ref\_Marks_{previous}}$. Local nodes will then update local NTUs after this drift compensation (see Fig. 4) and calibrate local time base to the time master's time base.

B. *Integrated TT-E and TT-CAN*

Figure 5 shows an example of the interworking between TT-E and TT-CAN protocols via a TT-gateway. The function of the gateway is to perform timing and synchronization between the two protocols. Specifically, the TT-E synchronization master in the TT-gateway synchronizes with the TT-E switch (compression master) periodically. Meanwhile the TT-CAN time master in the TT-gateway updates its clock to the local TT-E clock at the beginning of each basic cycle to achieve synchronization with the compression master (as seen in Fig. 5). Under these conditions, a TT-E switch, as the Compression Master (CM), generates a global time that is based on the PCF frames received from SMs, which is then distributed to all SMs and SCs. The synchronization process within the integration cycle operates inside a configurable period where TT-E clocks in TT-gateways can be updated. On the other hand, before sending the Reference (REF) message to the local TT-CAN network, the TT-CAN time master in the TT-gateway updates its clock to the local TT-E clock at the beginning of every basic cycle. The period in which the TT-CAN can be updated depends on the total amount of aggregated TT-CAN data that can be generated by multiple ECUs in the TT-CAN subnetwork. Therefore, due to the much larger bandwidth of the TT-E backbone network, such a time interval should be much larger than the TT-E integration cycle. As an example, in our simulation, the TT-CAN is updated every 0.024576 seconds (configurable) with respect to the TT-E integration cycle of 0.003.

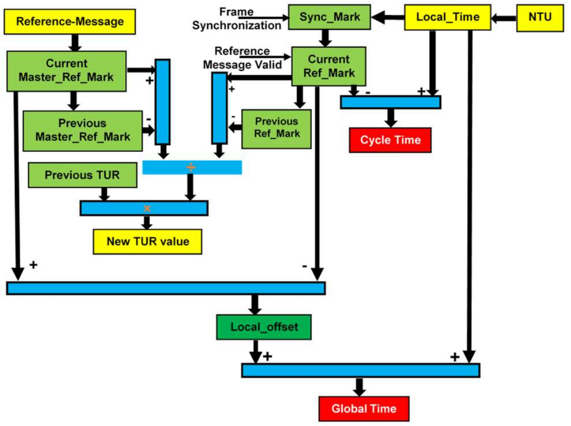


Fig. 4. Level-2 timing process: Cycle_Time, Global_Time, Local_offset and New TUR.

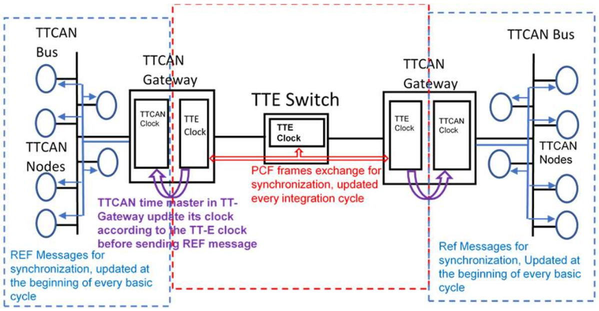

Fig. 5. An example of interworking between TT-E and TT-CAN protocols via a TT-Gateway.

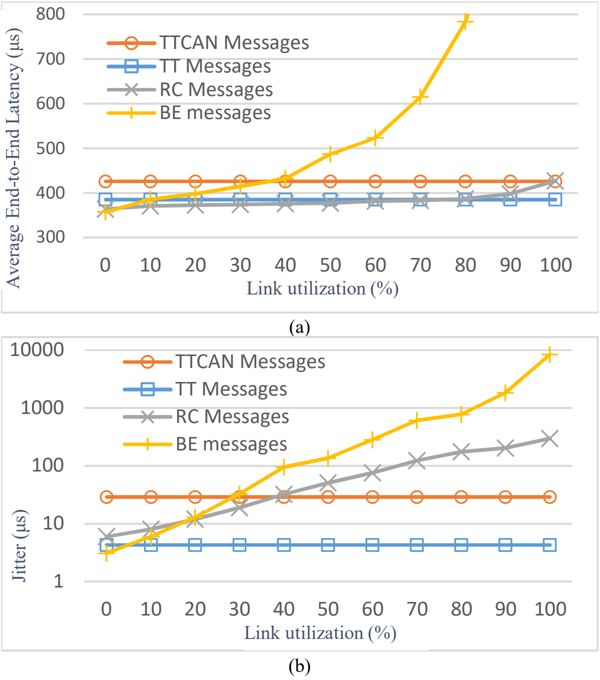
Without an external clock, the TT-CAN time master can keep its TUR and NTU constant. However, in our system, the time master (the TT-CAN clock in the TTCAN gateway) will update itself with the TT-E clock in order to achieve full synchronization in the proposed integrated TT-E and TT-CAN network. At the end of the basic cycle, the TT-CAN clock in the TT-gateway first updates its Local_Time by incorporating the difference between itself and the TT-E clock; T_{gap}, where

$$\text{Local\_Time} = \text{Local\_Time}_{previous} + T_{gap}.$$

The new Local_Time is saved as the Master_Ref_Mark. It then updates its

$$df = \frac{Local\_Time_{previous} - Master\_Ref\_Marks_{previous}}{Maste\ \ \_Ref\_Marks - Maste\ \ \_Ref\_Marks_{previous}},$$
$$TUR = df \cdot TUR_{previous}$$

Gharavi, Hamid. "Deterministic Intra-Vehicle Communications: Timing and Synchronization." Paper presented at IEEE International Conference on Communications (IEEE ICC), Dublin, IE. June 07, 2020 - June 11, 2020.



(a)

(b)

Fig. 6. The influence of link utilization on (a): average end-to-end latency performance and (b): the jitter performance of all traffic.

and NTU, calibrating their time base to that of the TT-E backbone network. Furthermore, it sends a new reference message to TT-CAN sub-network and resets its Cycle_Time to T_{gap} (not zero as before). This means that the TT-CAN clock in TT-gateway will be re-synchronized with the TT-E clock after $T_{cycle} - T_{gap}$ seconds.

When receiving reference messages, the local node in the TT-CAN sub-network will first update its df as

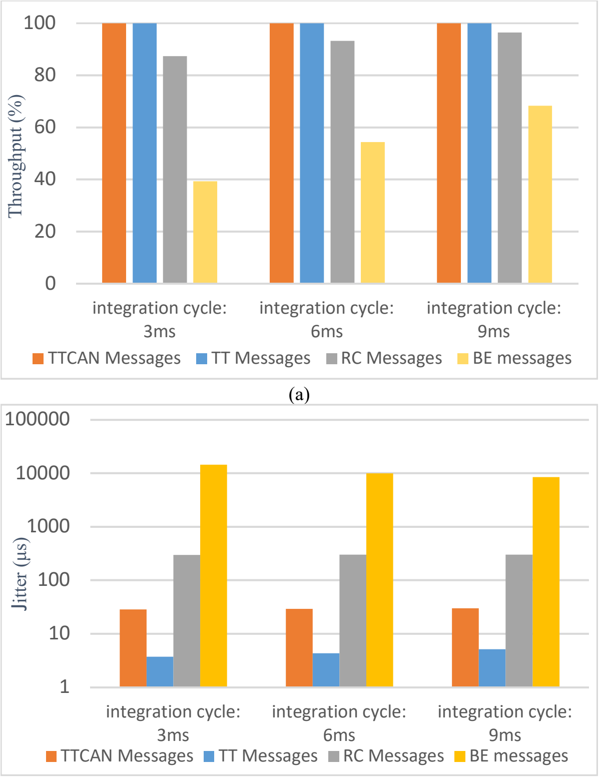
$$df = \frac{Local\_Time - Ref\_Marks_{previous}}{Master\_Ref\_Mar \qquad gap - Master\_Ref\_Marks_{previous}}.$$

It then updates TUR and NTU. Note that the time master has updated its Local_Time and Master_Ref_Marks by incorporating the T_{gap} between the TT-CAN sub-network and the TT-E backbone network. The local node then updates its Local time to Master_Ref_Marks + τ (τ is the transmission delay between the local node and the time master) and saves it as Ref_Mark, to achieve synchronization with the time master.

IV. Simulation

In this section, we evaluate integrated time triggered communication in the system topology of a simplified in-vehicle communication network shown as in Fig. 1, where video, audio, control, and inter-gateway traffic are categorized as BE traffic, RC traffic and TT traffic for investigation.

As shown in Fig. 1, the integrated in-vehicle communication network consists of two TT-E switches and 4 TT-Gateways producing a TT-E backbone network. Each TT-Gateway interconnects a TT-CAN sub-network with the TT-E backbone network. High-speed devices, such as ADAS and infotainment modules, are directly connected to one of the TT-E switches, sending TT traffic, RC traffic, and BE traffic to the control system through TT-E links. All TT-E links are bidirectional 100 Mbps links. On the other hand, low-speed devices, such as ECUs are connected to TT-CAN sub-networks with a 1 Mbps bandwidth. In our simulation, TT-CAN messages between ECUs are first sent to the local TT-Gateway and converted to TT messages, which will be sent to destination TT-Gateways via TT-E switches. A destination TT-Gateway first converts them back to TT-CAN messages before forwarding them to the destination ECUs or the central control unit.



(a)

(b)

Fig. 7. The impact of the integration cycle on (a): throughput performance and (b): jitter performance.

For simplicity, the payload of the TTCAN traffic is set at 8 bytes, the payload of the TT traffic is 50 bytes, the payload of the RC traffic is 100 bytes, while the payload of the BE traffic is 500 bytes. The drifts of TT-E clocks and TT-CAN clocks are configured as 200 parts per million (ppm). The propagation delay of the TT-E backbone network is 100 ns per link, while the propagation delay of the TTCAN bus is set to 100 ns (5 ns per meter propagation delay and a maximum cable length of 40 meters on the CAN bus with 1 Mbps bandwidth [4]).

In a TT-E network, virtual links are used as logical connections to route traffic from a sender to one or more receivers and are pre-configured during the scheduling process. TT-E switches use pre-defined forwarding tables to concatenate virtual links and create tree structures with one sender as root and multiple receivers as leaf nodes [15]. Fig. 6 depict the average end-to-end latency and jitter performance of the in-vehicle time triggered communication network under the influence of different link utilizations caused by varying amounts of traffic. The TTCAN traffic, as a special and small part of TT Traffic in the TT-E backbone network, is measured with TT traffic but listed separately. Due to synchronization protocols and the link reservation mechanism in both TT-E backbone networks and TT-CAN sub-networks, TTCAN traffic and TT traffic are able to achieve a constant average end-to-end latency with very low jitter, despite the increasing link utilization. Their low jitters are mainly due to the clocks' drift.

Since TTCAN traffic experiences extra links with a lower timing resolution in TT-CAN sub-networks, it has a higher jitter (28.97 μs) and latency (426 μs) compared with TT traffic (i.e., jitter of 4.3 μs and latency of 385 μs). The jitter caused by the TT-CAN clocks' drift is higher than the jitter caused by the TT-E clocks' drift. The basic cycle (e.g. 0.024576 s) in TT-CAN is much longer than the integration cycle (e.g. 0.024576 s) in TT-E, resulting in more drift in TT-CAN clocks than in TT-E clocks before clock correction. The latency and jitter performance of the RC traffic degrades because of increasing link utilization. However, it is limited to an ensured bounded latency. For BE traffic, its latency and jitter performance degrade significantly (with increasing traffic) when the link overload is increased. The fully utilized link results in high collision possibility and unstable communication.

Our investigation in Fig. 7 is based on worst-case scenarios. In these experiments, we allocate 1.6Mbps, 18 Mb/s, and 30 Mb/s bandwidth to handle TTCAN, TT, and RC traffic, respectively. In Fig. 7, we evaluate the influence of the integration cycle on the performance of all traffic in a worst-case scenario. When reducing the period of the integration cycle, more overhead will be generated because of the PCF frames exchanged between the compression master and synchronization masters. On the other hand, a clock's drift is decreased with a shorter integration cycle and therefore improves the timing precision in the TT-E backbone network. It can be seen from Fig. 7(a) that TTCAN and TT traffic is not affected by the varying integration cycle because they are protected by link reservation. The throughput performance of RC and BE traffic is degraded due to the increased overhead. Fig. 7(b) demonstrates the jitter performance under the influence of the integration cycle. TTCAN, TT and RC traffic achieves a slight improvement in the jitter performance due to increased time precision when reducing the integration period. In contrast, BE traffic shows a worse jitter performance due to the dominant factor of increased overhead and packet loss rate.

V. Conclusion

In this article, we present a time triggered communication network architecture that integrates two time-triggered protocols: namely TT-Ethernet and TT-CAN. Specifically, high speed TT-E is employed as the backbone network to comply with the high bandwidth requirement, while lower bandwidth TT-CAN is used as sub-networks for low speed ECUs with consideration of cost-effectiveness. Thanks to the synchronization and link reservation mechanism in both TT-E and TT-CAN, they are capable of supporting constant and low latency traffic with very low jitter. This guarantees reliability in-vehicle communication. Our investigation into fully overloaded links and worst-case scenarios further demonstrates the reliability and robustness of the integrated time-triggered communication network architecture.

ABSTRACT

Industrial Control Systems (ICS) collect information from a variety of sensors throughout the process, and then use that information to control some physical components. Control engineers usually have to pick which measurements they are going to use and then they purchase sensors to take these measurements; however, in most cases they only need a small subset of all possible measurements that can be used. Economic and efficiency reasons motivate engineers to use only a small number of sensors for controlling a system; however, as attacks against industrial systems continue to increase, we need to study a systematic way to add sensors to the system to identify potentially malicious attacks. We propose the addition of **hidden sensor measurements** to a system to improve its security. Hidden sensor measurements are by our definition measurements that were not considered in the original design of the system, and are not used for any operational reason. We only add them to improve the security of the system and using them in anomaly detection and mitigation. We show the addition of these new, independent, but correlated measurements to the system makes it harder for adversaries to launch false-data injection stealthy attacks and even if they do, it is possible to limit the impact caused by those attacks. When an attack is detected we replace the compromised sensor measurements with estimated ones from the new sensors improving the risky open-loop simulations proposed by previous work.

1 INTRODUCTION

Attacks against the integrity of cyber-physical systems are a growing concern. An attacker that falsifies the data that sensors are reporting or falsifies the actions that actuators are supposed to execute, can drive the system to unsafe states, causing potential operational, economic, and safety problems. An attacker can compromise a subset of sensors and send false information to the control system. The attacks do not even have to be because of software vulnerabilities; new *transduction attacks* [10] allow the attacker to change sensor signals without compromising any device. Sensors are transducers that translate a physical signal into an electrical one, but these sensors sometimes have couplings between the property they want to measure and the analog signal that can be manipulated by the attacker. For example, sound waves can affect accelerometers and make them report incorrect movement values [20], and radio waves can trick pacemakers into disabling pacing shocks [16].

To detect these attacks we can use our understanding of the physical evolution of the system, to see if the measurements from sensors match our predictions. There is an active community working on this type of Physics-Based Attack Detection systems (PBAD) [11]. PBAD has been explored in water control systems [1, 13], state estimation in the power grid [9, 17], chemical processes [2, 4], autonomous vehicles [6], and a variety of other cyber-physical systems [11].

All these models assume that the sensors we use for attack-detection are the same that are already present for the control algorithm. Furthermore, attack-mitigation proposals like Cardenas et al. [4] remove the sensor under attack and estimate the missing quantity with the remaining sensor measurements (they try to operate the system with less information, given the removal of this measurement). However, they do not take into account that we can gather new measurements, usually from different stages of a cyber-physical system which are correlated with each other.

We call these new measurements **hidden sensor measurements** because they are hidden from the operation of the system under normal conditions. Furthermore, because hidden measurements are not used in regular operations, an attacker that performs reconnaissance of the industrial network will not see them (hidden sensors may remain silent and will only start reporting values based

Giraldo, Jairo; Tang, CheeYee; Urbina, David; Cardenas, Alvaro. "The More the Merrier: Adding Hidden Measurements for Anomaly Detection and Mitigation in Industrial Control Systems." Paper presented at Hot Topics in the Science of Security (HotSoS) 2020, Lawrence, KS, US. April 07, 2020 - April 08, 2020.

on a request by the intrusion mitigation algorithm or by the intrusion detection system based on some indicators of compromise).

For example, in the classical Tennessee-Eastman (TE) chemical process benchmark [19] (which has been used extensively in cyber-security [2, 4, 8]), the "separator cooling water outlet temperature" is not measured nor used for any purpose; however we found that this variable is highly correlated with the "product separator temperature," a measurement that is critical for safe control of the system. If an attacker falsifies or takes down the "product separator temperature," we can use the "separator cooling water outlet temperature" (with an appropriate estimation algorithm) to derive a good estimate of the attacked-sensor. Similarly the "pressure in the stripper" is a measurement that is not used at all in any control loop; however this measurement is highly correlated with the "pressure in the reactor," and therefore we can use the pressure in the stripper for security purposes.

Our contributions include:

- We introduce the concept of **Hidden Measurements**; i.e., new measurements that are not used during the normal operation of the system, but only for security purposes.
- Using new hidden sensors, we propose an anomaly detection architecture that uses the correlations between *operational* sensor measurements and *hidden* sensor measurements. Our formulation is generic and can be applied in a wide number of cyber-physical systems.
- We introduce a mitigation strategy that uses hidden sensors to respond to an attack. In particular, when an attack is detected, we generate approximate sensor signals based on redundant sensors using autoregression models. For instance, in the TE benchmark, if the reactor pressure value is compromised, we can use our added stripper pressure sensor or added separator pressure sensor (which are not used in any control loop [19]) to estimate the reactor pressure value.
- We implement our attacks and defenses in a Hardware-in-the-Loop testbed that uses a TE process simulation and is controlled with an industrial Programmable Logic Controller (PLC). In particular, we show how to launch man-in-the-middle attacks against an Open Platform Communications (OPC) server to coordinate the communication between the central controller and the field devices. The attack is able to intercept Ethernet/IP packets and falsify sensor/actuator information.

2 PROBLEM FORMULATION

In this section, we present a general mathematical model of an industrial control system (ICS) with an anomaly detection scheme. The dynamics of an ICS can be modeled using differential equations as

$$\begin{aligned}\dot{\boldsymbol{x}}(t) &= F(\boldsymbol{x}(t), \boldsymbol{u}(t)),\\ \boldsymbol{y}(t) &= H(\boldsymbol{x}(t), \boldsymbol{u}(t))\end{aligned} \tag{1}$$

where $\boldsymbol{x}(t) \in \mathbb{R}^n$ corresponds to the vector with the states of the process (e.g., temperature, pressure, and water level in a chemical reaction), $\boldsymbol{u}(t) \in \mathbb{R}^m$ describes the control commands, and $\boldsymbol{y}(t) \in \mathbb{R}^p$ are the sensor readings. $F(\cdot)$ and $H(\cdot)$ are nonlinear functions that describe the system behavior.

Due to the complexity of some industrial processes, decentralized control has proven to be a practical control option in industrial plants. Decentralized control has many benefits, including easy implementation, maintenance, tuning, and robust behavior. For this reason, we assume that there are m decentralized control loops, and each one has been designed and tuned to guarantee specific performance conditions, as depicted in Figure 1; this architecture is usually implemented with Programmable Logic Controllers (PLCs), each of them controlling a subset of a larger infrastructure. In addition, we assume that there has been an adequate control configuration or input-output pairing, such that for each input u_i there is a suitable output y_i [15, 18]. We then define the controller as follows

$$u_i(t) = \mathcal{K}_i(y_i(t)), \tag{2}$$

where $\mathcal{K}_i(\cdot)$ is the function that takes sensor readings and generates control commands.

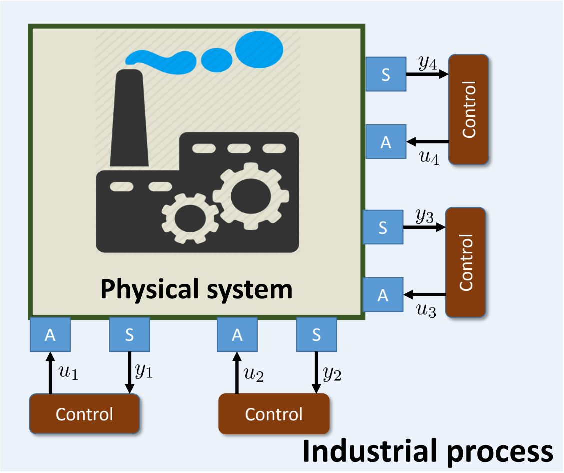

Figure 1: Decentralized control loops in an industrial control system.

Let us assume that the sensor readings and control commands can be sampled each τ seconds such that we have $y_i(k)$ and $u_i(k)$, for $k \in \mathbb{Z}_+$ the k^{th} sampling instant. Using the historical data of the sensors and control actions, we can define an estimation function of the form

$$\begin{aligned}\hat{\boldsymbol{x}}(k+1) &= \hat{F}(\boldsymbol{y}(k), \boldsymbol{y}(k-1), \ldots, \boldsymbol{y}(k-T), \boldsymbol{u}(k), \boldsymbol{u}(k-1), \ldots, \boldsymbol{u}(k-q))\\ \hat{\boldsymbol{y}}(k) &= \hat{H}(\hat{\boldsymbol{x}}(k), \boldsymbol{u}(k))\end{aligned} \tag{3}$$

where T and q are the number of historical values we consider for the sensors and the actuators (respectively). Notice that Kalman filters, ARMA models, and neural networks can be described using Equation (3).

2.1 Detection Mechanism

Physics-based anomaly detection strategies compare current sensor readings with an estimation or prediction of the behavior of the system to detect cyber-attacks [11]. This prediction can be computed using approximated models as described in equation (3). Thus, for each sensor measurement we define the residual $r_i(k) = y_i(k) - \hat{y}_i(k)$ as the difference between the sensor reading and its corresponding prediction. An anomaly detection metric $\mathcal{D}(r(k))$ quantifies how different the historical behavior the sensor reading is from the predicted one. For instance, the χ^2-detection computes the normalized summation of all the residuals, $\mathcal{D}(r(k)) = r(k)^\top \Sigma r(k)$, for Σ the inverse of the covariance matrix. More sophisticated mechanisms accumulate the residuals in order to keep historical track of possible persistent attacks such as the CUSUM algorithm [4]. In this work, we focus our attention on the distributed bad-data detection (DBDD) mechanism defined by $\mathcal{D}_i(r_i(k)) = |r_i(k)|$. DBDD provides a detection metric for each sensor, which is useful in the context of decentralized ICS.

2.2 Attacker Model

We consider a powerful adversary that gains access to a subset of sensors and/or actuators. The adversary knows the detection architecture, the prediction algorithms we use, and is able to generate accurate sensor predictions.

3 ADDING HIDDEN SENSORS

ICS use sensor readings in order to generate control actions; however, most systems possesses physical quantities in the system that are not used, and are not necessarily needed for the safe operation of a system (without considering attacks).

However, if we have a physical model of the system, we can identify variables that although not needed, might be useful for security purposes. Suppose that in our model of the system we have the following observable variables (variables for which a physical sensor can be bought and installed to measure): $\mathcal{I}^y = \{1, \ldots, p\}$. Let $\mathcal{I}^{CL} \subset \mathcal{I}^y$ be the indexes of the variables that are currently being measured and that belong to a control loop and are paired with a control input. Similarly let $\mathcal{I}^{rd} \subset \mathcal{I}^y$ be the indexes of variables that can be physically measured, but that we are not currently measuring in our physical system. Notice that $\mathcal{I}^y = \mathcal{I}^{CL} \cup \mathcal{I}^{rd}$.

According to equation (2), the control command $u_i(k)$ depends on $y_i(k)$, for all $i \in \mathcal{I}^{CL}$. As a consequence, attacks in $y_i(k)$ will affect the control command causing the system to deviate from its operation point. In order to leverage our new hidden sensors we need to find potential sensor signals that are also affected by u_i.

There are several techniques that help to quantify the input-output relationship, such as Relative Gain Array (RGA) and its variations for linear and nonlinear systems [15]; however, they depend on having a very accurate dynamic model of the system, which is difficult for nonlinear industrial control systems. We propose a simple approach that uses historical data of sensor readings and consists on calculating correlation coefficients between each pair (y_i, y_j) for $i \in \mathcal{I}^{CL}$ and $j \in \mathcal{I}^{rd}$. The correlation coefficient determines the degree at which two variables' movements are associated. As a consequence and because of the feedback relationship between y_i, u_i, if the pair (y_i, y_j) is highly correlated, this implies that the control action u_i affects not only y_i but also our potential hidden sensor measurement y_j.

Let $s_i \in \mathbb{R}^T$ be the signal that consists on T readings of sensor i under normal operation. The correlation coefficient is then calculated as follows

$$corr(s_i, s_j) = \frac{cov(s_i, s_j)}{\sqrt{cov(s_i, s_i)cov(s_j, s_j)}}$$

where $cov(s_i, s_j)$ denotes the covariance between s_i and s_j and correlation ranges between $-1 \leq cor(s_i, s_j) \leq 1$.

Next, we will introduce how we can use the correlation coefficient to build multi-variable anomaly detection algorithms that take advantage of hidden sensors.

3.1 Multi-Variable Anomaly Detection

Typically, centralized anomaly-detection mechanisms gather all sensor readings to construct a single prediction model in order to compute residuals and calculate a detection metric (e.g., χ^2); however, for systems with a large amount of sensors and several interconnected processes, these kind of models can be computationally expensive. Taking advantage of the decentralized nature of multiple control loops and redundant sensors, it is possible to decrease the complexity of the prediction models by constructing individual models for each control loop. Each model can be implemented locally at each control loop, and it does not only help to reduce the computational cost but also removes the single point of failure. The estimation of sensor i can be obtained according to

$$\hat{y}_i(k) = \hat{h}_i(y_i(k-1), y_i(k-2), \ldots, y_i(k-T), u_i(k-1), \ldots, u_i(k-q)).$$

The main limitation of this approach lies in the fact that an intelligent adversary can easily design stealthy attacks by only affecting a single sensor. The main idea behind multi-variable detection lies in combining some properties of both approaches, centralized and decentralized by using hidden sensors in order to limit the impact of cyber-attacks.

Our proposed Multi-Variable Detection (MVD) architecture is depicted in Figure 2 and consists on building a single prediction of sensor i based on the history of the control commands, y_i readings, and redundant sensors measurements (to ease notation we refer to redundant sensors as y_j^{rd}). The main difference with a centralized strategy is that the prediction model only depends on highly correlated sensors, instead of all sensors. As a consequence, the complexity of the model is much lower and still guarantees good accuracy.

If an adversary attacks $y_i(k)$, the controller u_i will be affected, which in turn will also affect the redundant sensors. As a consequence, the effects of the attack in y_i and in all y_j^{red} will add up causing an error in the prediction.

Paper presented at Hot Topics in the Science of Security (HoTSoS) 2020, Lawrence, KS, US. April 07, 2020 - April 08, 2020.

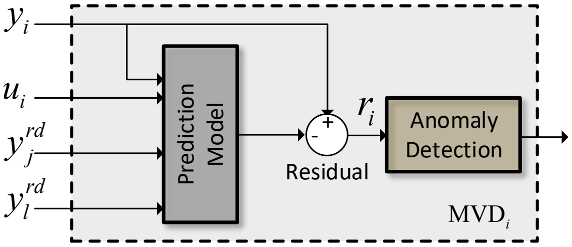

Figure 2: General architecture of the Multi-variable detection block.

3.2 System Reconfiguration for Attack Mitigation

When an attack is successfully detected, it is necessary to remove the compromised sensor readings while maintaining the system operation as close as possible to the nominal operation. In one of our earlier papers [4], we proposed to replace compromised sensor readings with estimated ones obtained from the remaining sensors. In this work, we propose a different approach that makes use of new hidden sensors. Let y_i denote sensor i and y_j^i denote one of the hidden and correlated sensors to i. Therefore, it is possible to find a mapping of $y_j^i \rightarrow \widetilde{y}_i$, where $\widetilde{y}_i$ is an approximation of the sensor reading y_i. This mapping can be computed using historical data and autoregressive models or by knowing the physical relationship between the two sensors (e.g., it is possible to compute pressure from temperature in a gas using the Gay-Lussac's Law.)

Then, when an attack associated to sensor i is detected, we replace the compromised sensor reading $y_i(k)$ with its approximation $\widetilde{y}_i(k)$ to ensure the operation of the system. The higher the correlation, the better the approximation. This is illustrated in Figure 3.

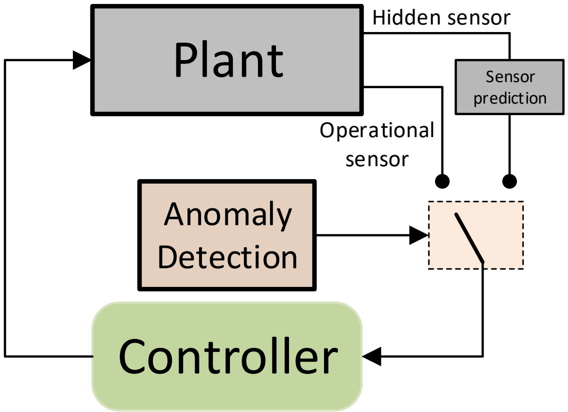

Figure 3: The system is reconfigured to use hidden sensors.

4 TESTBED

4.1 Description

The Tennessee-Eastman (TE) process was first proposed by Down and Vogel [7] and has been extensively used for the evaluation of novel control techniques, due to its complexity and large number of sensors. We were one of the first groups to use this process to study the security of industrial control systems [4, 14].

The process has five major unit operations: the reactor, the product condenser, a vapor-liquid separator, a recycle compressor, and a product stripper. The process produces two products, G and H, from four reactants A, C, D, and E. It has 41 measurements and 12 manipulated variables. The TE is open-loop unstable, which makes it very sensitive to cyber-attacks that affect the control actions.

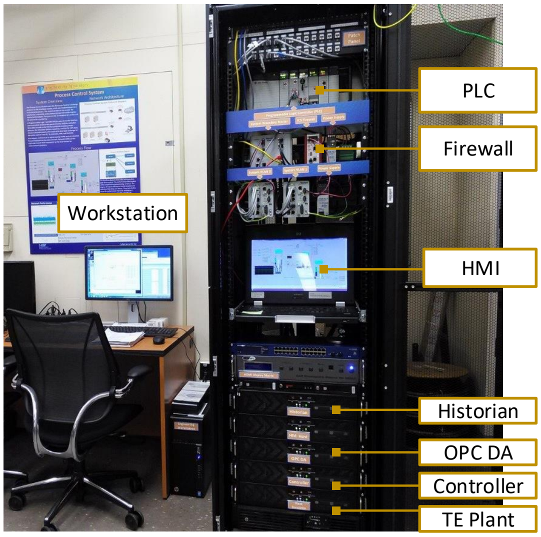

Figure 4: Tennessee-Eastman HIL Testbed.

The NIST Hardware-In-the-Loop (HIL) testbed for the TE process consists of 5 modules running in Microsoft Windows machines:

- simulated plant in C++,
- OLE for Process Technology (OPC) Server,
- distributed proportional-integral-derivative (PID) controller proposed in [19] where 12 control loops keep the states of the plant within operational limits while desired set-points are followed.
- Historian,
- Human-Machine Interface (HMI).

The network architecture of the testbed is illustrated in Figure 5.

The testbed also has an Allan Bradley Programmable Logic Controller (PLC). The C++ plant simulation interacts with the PLC through a Common Industrial Protocol (CIP) communication link. The PLC interacts with the OPC Server through an OPC communication link. The OPC Server communicates with the controller, the

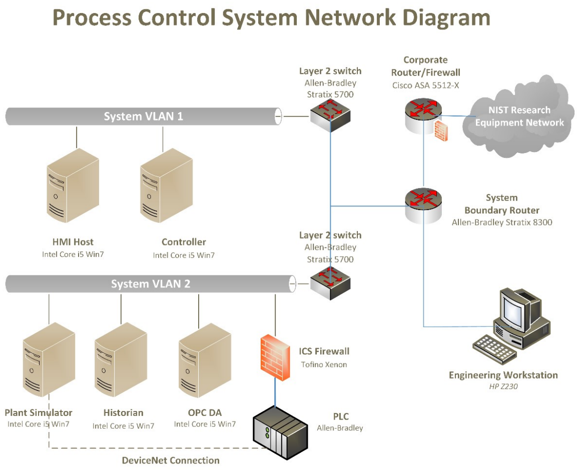

Figure 5: Network architecture of the TE testbed.

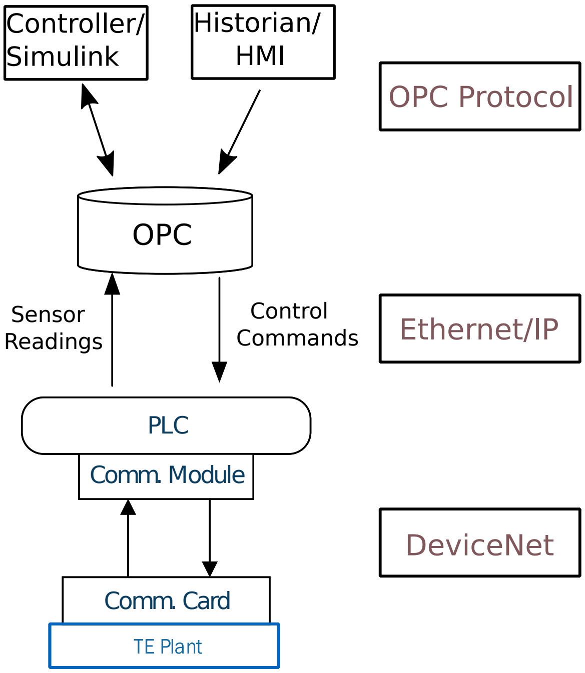

Figure 6: Logical architecture of the TE testbed.

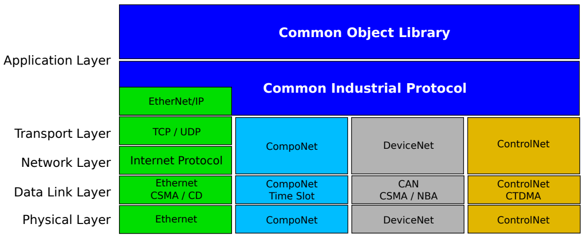
Historian, and the HMI through the TCP/IP network. This logical interaction of components is illustrated in Figure 6.

We believe this testbed represents highly relevant aspects of an ICS. Field communications (Layer 0) are captured by the DeviceNet protocol; industrial network protocols used to connect PLCs and workstations (Layer 1) is represented by the Ethernet/IP industrial protocol, and the widely available OPC server is used to translate among different standards and technologies. The OPC protocol is under particular interest for study as it is one of the industrial protocols that was targeted by the Industroyer malware that attacked Ukraine's power grid in 2016 [5]. OPC was also targeted by the Havex industrial espionage malware [23].

4.2 Common Industrial Protocol



Application Layer	Common Object Library			
	Common Industrial Protocol			
	EtherNet/IP			
Transport Layer	TCP / UDP	CompoNet	DeviceNet	ControlNet
Network Layer	Internet Protocol			
Data Link Layer	Ethernet CSMA / CD	CompoNet Time Slot	CAN CSMA / NBA	ControlNet CTDMA
Physical Layer	Ethernet	CompoNet	DeviceNet	ControlNet

Figure 7: CIP stack and its different physical layers.

The Common Industrial Protocol (CIP) network specification library [3] was originally developed by Rockwell Automation and subsequently standardized and maintained by Open Device Vendors Association (ODVA) and ControlNet International. It aims to fulfill the main three needs of ICS systems: control, configuration, and collection of data. It defines the CIP application layer protocol as a encapsulated object-oriented protocol for transmission of connected (I/O implicit) messages between a data producer and one or more data consumer devices, and unconnected (explicit) messages between two devices in the control network. Transmissions associated with a particular connection are assigned a unique *connection ID*. While being an application layer protocol, CIP is independent of the underlying layers, and requires an encapsulation protocol which allows abstraction from different data link and physical layers. It also includes a Common Object library defining commonly used objects, some of which are specific for a particular encapsulation protocol, and allows for extension and definition of vendor specific objects. The CIP specification library includes the definition of 4 different CIP stacks depending of the physical layer in use (see Figure 7): Ethernet/IP(over IEEE 802.3 Ethernet), CompoNet, DeviceNet, and ControlNet.

4.2.1 Ethernet/IP. The CIP stack introduces the Ethernet/IP protocol [3] for both, SCADA network and fieldbus communications alike. Its specification defines the Common Packet Format (CPF) for the encapsulation of message oriented protocols, such as CIP, Modbus, and vendor proprietary messages. Ethernet/IP CPF can be stacked over UDP or TCP, in both multipoint and point-to-point connection modes. When stacking over UDP, it requires devices to select a maximum of 32 consecutive addresses from the range 239.192.1.0 to 239.192.128.255 (which belongs to the *Organizational Local Scope* [12]).

4.3 False-data Injection in CIP packets

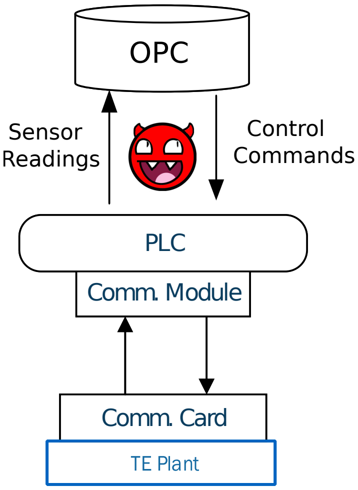


Figure 8: Man-in-the-Middle attack in the TE testbed at NIST.

We established a Man-in-the-Middle attack (MitM) between the C++ plant simulator and the Allan Bradley PLC (Figure 8), by creating a bridge that allows us to capture all the packets coming from the sensors and the controller, modify them and send them back. This communication uses the Common Industrial Protocol (CIP) as industrial communication protocol. Although the CIP specification provides a very comprehensive library of common objects, this communication link implements a vendor-dependent extension over the protocol in order to transfer the 42 sensor measurements constantly by the plant. On the other hand, the 12 actuation commands sent from the PLC to the plant are transmitted with separate and standard CIP write-object messages containing the actuator ID number and the command value.

The CIP communication link implements a client/server mode of communication. Therefore, for the MitM to be successful sniffing sensor measurements simulated controller (PLC and OPC server also) must be online. In other words, the controller must request the sensor measurements for our MitM to be able to sniff the response from the plant.

We leveraged the Allan Bradley visualization tool (Logix5000 Fig. 9) installed in the workstation to program the PLC to understand at a high level the structure of the CIP extension with the 42 measurements. At first glance, it follows an array structure with every sensor measurement encoded using the Floating-Point Arithmetic Standard IEEE 754.

After developing a Scapy parser for the CIP extension, we performed initial false-data injection attacks. From the results of these attacks, we realized that some sensor measurements (such as the temperature) were being replicated in the CIP extension, and only injecting one of the instances was not enough to successfully achieve the attack, as the controller would freeze the sensor measurement to the last value before the attack started.

To identify the replicated sensor measurements in the CIP extension, we performed a packet diffing similar to the process proposed by Urbina et. al. [21]:

1. Using the Allan Bradley visualization tool we forced 5 different sensor values while sniffing a tuple (2 packets per value change) of CIP generated packets (5 tuples).
2. We then performed diffing of packets to calculate a change-coefficient matrix representation: Any byte-change introduced by the first packet of every tuple increments its cell coefficient, while any change introduced by the second packet of the tuple decrements it.
3. When the 5 tuples were diffed we obtained a matrix with each cell containing the coefficient of change for the corresponding byte in the CIP extension.
4. We used the change-coefficient matrix to visualize the heatmap: the higher the coefficient the higher the heat of the cell (byte), and vice versa.

After understanding the replication on the CIP extension, we improved our parser and were able to launch false-data injection attacks on the sensor measurements.

5 EXPERIMENTAL RESULTS

Due to the correlation of the different distributed control loops, attacks that may be stealthy to one control loop might be visible (easily detectable) in other loops. Under these conditions, adversaries would need to attack all distributed loops simultaneously to remain stealthy, or decrease the impact of such attacks in a way that it does not trigger alarms in other parts of the plant.

The TE benchmark has a large amount of variables where hidden sensors can be deployed. For instance, there are 11 control loops, but 42 measurements. Recall that we define two types of measurements: i) operational sensors i.e., measurements used to generate control

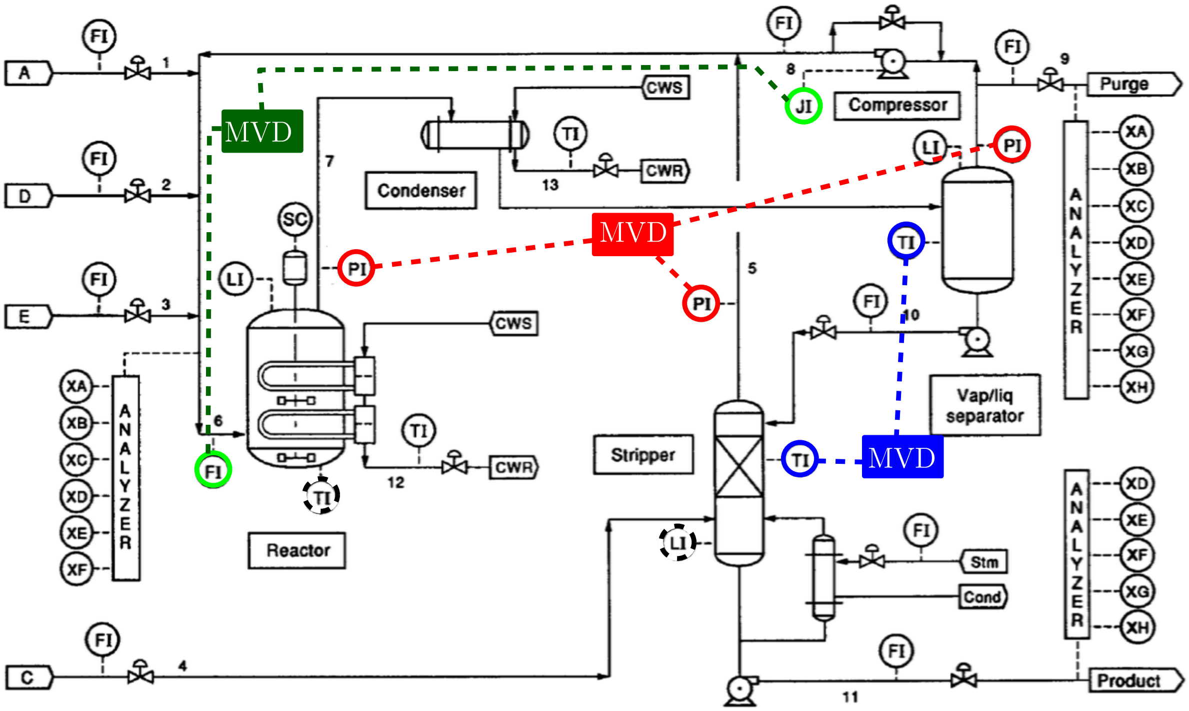

Figure 10: Tennessee Eastman Process with some Multi-variable detection (MVD). Similar colors indicate a high correlation coefficient (i.e., > 0.95). Dashed circles indicate low correlation coefficient (i.e., < 0.01). Each CD receives sensor information and the actuator signal corresponding to at least one of the sensors.

signals, and ii) hidden measurements—that is, measurements that provide information about the system but are not used by the controllers. The correlation among operational and hidden sensors can be exploited to increase the difficulty on deploying stealthy attacks.

Fig. 10 depicts the general architecture of the TE process. Using the correlation coefficient, we are able to identify the hidden sensors with the highest correlation to operational sensors.

As an example, colored circles in Fig. 10 indicate correlation and black dashed circles represent sensors without correlation. Our Multi-Variable Detection (MVD) can be located in such a way it receives information from different PLCs. The information is used to obtain detection statistics for the measurements that are not used. If an attacker wants to remain stealthy, she will have to attack several sensors simultaneously from different PLCs.

Using the identification tool IDENT from Matlab, we are able to obtain individual Hammerstein-Weiner models for several control loops that estimate the input/output relationship. These models combine linear and nonlinear blocks that approximate the sensor measurement behavior for a given control input. Therefore, we are able to generate detection statistics, such as the residuals, by comparing the estimated model with the real system behavior.

As an example, let us consider the reactor pressure (called xmeas 7 in the simulation code), which is a critical parameter of the TE process and is used to control the purge rate, i.e., a valve. We construct a prediction model based on historical data from $xmeas7$ and $xmv6$ using nonlinear ARX models. Figure 11 depicts how a simple bias attack is easily detected by the DBDD strategy. However, an attacker with enough knowledge about the system and the detection strategy is able to design optimal stealthy attacks, as it was proposed in [22], where the adversary replaces the sensor reading by $y_i^a(k) = \hat{y}_i(k) - y_i(k) + \tau_i$, for τ_i the detection threshold. Notice that the residuals under attack become $r_i(k) = |\tau_i|$, such that the detection static is never above the threshold. Now, suppose the adversary forges an attack that remains stealthy for the detector D_7. Figure 12 shows how the attack causes a shut down because the pressure reaches unsafe levels but it is never detected.

Analyzing the correlation coefficients of reactor pressure with measurements that were not being used, we found out that the reactor pressure is highly correlated with the product separator pressure (xmeas 13). Therefore, we constructed prediction model for the separator pressure using $xmv6$ and $xmeas13$ as inputs and we define a multi-variable block. Figure 12 illustrates how an stealthy attack in the reactor pressure is rapidly detected by D_{7-13} due to

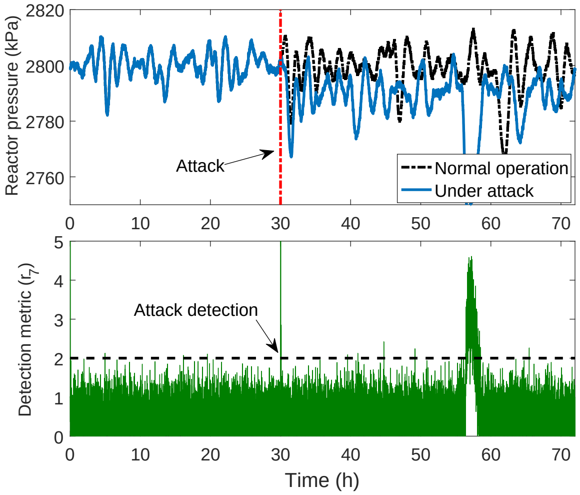

Figure 11: Reactor pressure and detection metric when an bias attack of the form $y_7^a = y_7 + 10$ is launched after 30 h. Notice that the sudden changes make the detection metric to grow rapidly and detect the attack.

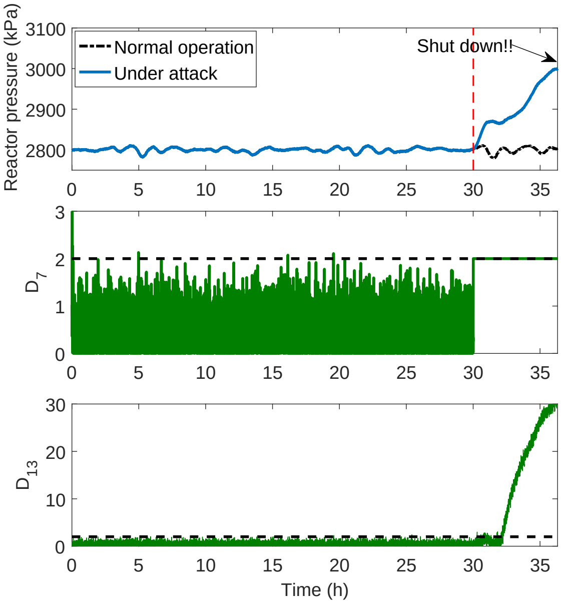

Figure 12: MVD when an optimal stealthy attack is launched only in sensor xmeas 7 (y_7). The attack remains stealthy for the detection D_7 even though the reactor pressure grows until it reaches unsafe states. However, due to the high correlation between y_7 and y_{13} (i.e., $corr(s_7, s_{13}) = 0.96$), D_{7-13} is able to detect the attack.

the high correlation between the signals. Similarly, other blocks can be constructed by using the stripper pressure sensor and other correlated measurements. As a consequence, an adversary will have to compromise all the correlated sensors in order to remain completely stealthy. Even if an attacker gains access to both sensors, the stealthy attack will not have a damaging impact in the system as depicted in Figure 13. Clearly, adding sensors is able to limit the impact of powerful attackers.

As an additional measure of security, we implemented the proposed mitigation strategy such that if an attack is detected, the compromised sensor reading is replaced by an estimation obtained from one of its correlated sensors. In our case study, the reactor pressure is highly correlated with the stripper pressure. Therefore, using an autoregressive model we can estimate the reactor pressure from the stripper pressure. Figure 14 illustrates how our proposed mitigation strategy is able to ensure the stable operation of the system even in the presence of an attack.

5.1 Comparing Detection Architectures

In order to compare how different detection mechanisms perform depending on the amount of redundant sensors included and on the type of architecture, we use the **evaluation metric for the effectiveness of physics-based anomaly detection** introduced in [22]. This metric takes into account the usability and security factors by analyzing the trade-off between the impact of the worst attack the adversary can launch while remaining undetected (y-axis) and the average time between false alarms (x-axis).

Y-axis (Security). The adversary wants to drive the system to the worst possible condition it can without being detected, where ‘'worst” refers to *the maximum deviation of a signal from its true value that the attacker can obtain* (without raising an alarm, and given a fixed-period of time, otherwise given infinite time, the attacker might be able to grow this deviation without bound).

X-axis (Usability). Typically, the false alarm rate is used to measure the usability of a detection mechanism. However, it has been shown that using the expected time between false alarms $E[T_{fa}]$ offers several advantages. The usability metric can be computed by counting the number of false alarms nF_A for an experiment with a duration T_E under normal operation (without attack) for several τ. Then, for each τ we calculate the estimated time for a false alarm by $E[Tfa] = T_E/nF_A$.
As a consequence, small τ will cause small $E[Tfa]$, but it will limit the impact that an adversary can cause in order to remain stealthy.

We launched stealthy attacks for different detection strategies that involve single and multiple sensors. Figure 15 depicts the reactor pressure increase for each stealthy attack. Without attack, the reactor pressure is 2800 kPa. If it reaches 3000 kPa, the plant is shut down. Using only one sensor allows the adversary to drive the reactor pressure to dangerous values; however, using MVD with highly correlated sensors limit significantly what the attacker can

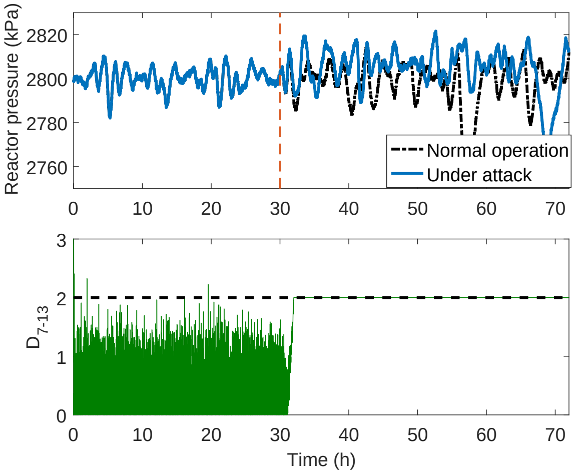

Figure 13: MVD when an optimal stealthy attack is launched in sensor y_7 with the detection D_{7-13}. Even though the attack is stealthy it causes a small deviation from the nominal operation. The attack might only be detected if we consider the correlation with other control loops.

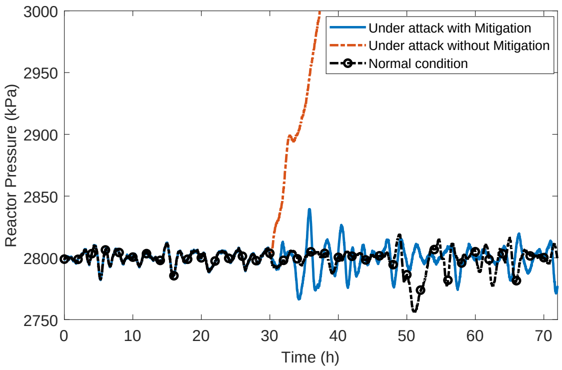

Figure 14: Reactor pressure for 3 different cases. Notice that with the proposed mitigation strategy, the system continues operating close to nominal conditions.

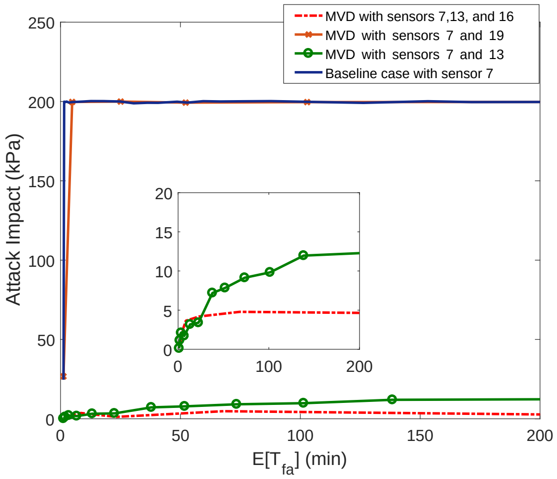

Figure 15: Comparison between different detection strategies. Sensors 13 and 16 are highly correlated with sensor 7, but sensor 19 is not. Notice that including correlated sensors in the prediction models significantly decreases the impact of stealthy attacks. On the other hand, a stealthy attack for the baseline case and by including sensor 19 is able to drive the system to dangerous pressure levels causing the plant to shut down.

do. On the other hand, when a MVD is constructed with a non-correlated sensor (sensor 19), it cannot prevent the shut down of the plant.

6 CONCLUSIONS

In this paper we have introduced the concept of hidden sensors: the idea of deploying new sensors to measure variables that are not being used by the process, in order to use them to improve the security of cyber-physical systems. We showed how these new measurements can be identified (correlation analysis) and then deployed for better attack-detection (MVD) in Figure 3 and better attack mitigation (by replacing the attacked-sensor with the new hidden sensor estimates).

We implemented our attacks and defenses in a realistic Industrial Control testbed controlling the TE process with classical industrial technologies and industrial network protocols representative of protocols that have been attacked in the real-world [5, 23].

Our results show that attacks that are not detected by previous proposals can be detected by our new hidden variables, as shown at the bottom of Figure 12. In addition we show that if the attacker becomes aware of our hidden variables, and tries to launch an attack that bypasses our hidden-variable anomaly detection algorithm, then it will not succeed in driving the plant to an unsafe state, as illustrated in Figure 13. Finally, our attack-mitigation strategy (replacing the compromised sensor value with an estimate given by the hidden sensor) is also able to keep the system safe under attack, as illustrated in Figure 14.

Abstract

Although it is clear that a building must be capable of carrying gravity loads while developing large inelastic deformations and associated lateral displacements during a large earthquake, achieving this performance objective in day-to-day practice still represents a major challenge. Current code-based consideration of seismic P-Delta effects is generally based on simplistic elastic models, and despite major advances in seismic systems and analysis techniques, no simple and reliable design methods for seismic stability are available.

Specific to steel buildings and the design framework in the United States, the current fundamental approach for stability design was developed and calibrated for non-seismic scenarios where the structure has modest overstrength and the ultimate strength (stability point) of the structure occurs prior to significant inelastic deformation. However, in a ductile steel seismic lateral force-resisting system (LFRS), the design-level forces and resulting nominally-elastic deformations are not consistent with the ultimate strength state of the system, which corresponds to significant overstrength and inelastic deformation.

Despite the vastly different behaviors expected in wind-dominated design vs. seismic-dominated design, the same stability design approach is employed. This stability design approach is nominally based on second-order elastic analysis (i.e., in the structural analysis model, equilibrium is formulated on the elastic deformed position and inelastic response is not considered). However, in seismic design it is not rational to consider P-Delta effects at elastic deformation levels.

The results described in this paper are part of a comprehensive study that is seeking to identify the most critical LFRS parameters that affect seismic stability and to develop a rigorous yet simple methodology whereby these parameters can be considered in design. This paper focuses on a set of steel special moment frames that is designed with or without consideration of stiffness reduction due to inelasticity, elastic P-Delta effects and drift limits. The moment frame designs are interrogated using nonlinear static and dynamic analyses to assess their collapse potential and to identify the most important parameters for design. The results from this paper will be combined with similar assessments for other types of steel seismic LFRS to propose design provisions that will enhance safety and economy for future design.

Keywords: Steel Structures; Seismic Stability; Design Provisions

Fahnestock, Larry; Shi, Shitao; Speicher, Matthew. "Seismic Stability Assessment of Steel Moment Frames and Implications for Design." Paper presented at 17th World Conference on Earthquake Engineering, Sendai, JP. September 13, 2020 - September 18, 2020.

1. Introduction

Seismic stability design has been studied for many years [1-3], and although modern performance-based seismic design does employ advanced analysis to rigorously consider stability effects, there has been relatively little advancement in how seismic stability is considered in pragmatic code-based procedures. In the United States, most buildings are designed for seismic loads using reduced forces based on the R factor prescribed in *Minimum Design Loads and Associated Criteria for Buildings and Other Structures* (ASCE/SEI 7-16) [4] with second-order elastic analysis – namely, the strength of the lateral force-resisting system (LFRS) is determined considering elastic P-Delta effects. However, research indicates that parameters related to inelastic response – such as post-yield stiffness and overstrength – are more important for seismic stability than initial elastic strength (i.e., the system yield strength).

Focusing on steel buildings and the *Specification for Structural Steel Buildings* (ANSI/AISC 360-16) [5], stability design is conducted with the direct analysis method (DM), which was developed and calibrated for non-seismic scenarios where the structure has modest overstrength and the ultimate strength (stability point) of the structure occurs prior to significant inelastic deformation. In a ductile steel seismic LFRS, such as a special moment frame (SMF), the design-level forces and resulting nominally-elastic deformations are not consistent with the ultimate strength state of the system, which corresponds to significant overstrength and inelastic deformation. Although the *Seismic Provisions for Structural Steel Buildings* (ANSI/AISC 341-16) [6] contain rigorous requirements related to capacity-based proportioning and ductile detailing, global seismic stability is not directly considered. The code-based seismic drift limit per ASCE 7 [4] is the primary means by which seismic stability is indirectly considered in the design process. In describing the seismic design landscape two decades ago, Gupta and Krawinkler [3] wrote, “At this time, no simple procedure can be recommended that will permit a definite assessment of collapse hazard due to P-Delta effects.” Current code-based consideration of seismic stability has advanced little since that time, and a more fundamental approach is needed.

Several studies have provided preliminary insight into the effectiveness of current seismic design and assessment approaches. Buckling-restrained braced frame (BRBF) and BRBF-SMF dual systems were examined, and the study indicated that ignoring stiffness reduction, imperfections and (elastic) P-Delta effects in design while considering post-yield stiffness can provide acceptable seismic performance [7]. Furthermore, an earlier study examined SMFs and the effects of residual stresses and imperfections were shown to be unimportant for seismic response [8]. In a study that was focused on consistency between ASCE 7 and ASCE 41 [9] for BRBF, SMF, special concentrically-braced frame (SCBF) and eccentrically-braced frame (EBF) systems, nonlinear models were used to assess the performance of code-compliant buildings [10-14]. In general, the results indicate that the ASCE 41 assessment procedure is overly conservative and that collapse performance evaluated with the *Quantification of Building Seismic Performance Factors* FEMA P695 methodology [15] is generally acceptable for buildings designed per ASCE 7.

This paper summarizes the initial portion of a study that is comprehensively evaluating seismic stability design of steel frames. A series of code-compliant and non-code-compliant SMFs were designed and evaluated with nonlinear static (pushover) and nonlinear dynamic (response history) analyses. Differences in observed response are discussed and implications for future work are presented.

2. Building Designs and Numerical Models

2.1 Prototype Building Designs

The 8-story and 16-story office buildings referenced in NIST Technical Note 1863-1 [16] were the basis of the prototype buildings designed for this research. As shown in Fig. 1 for the 8-story building, the rectangular plan of the prototype buildings contains two perimeter 3-bay SMFs in the East-West direction and four perimeter SCBFs in the North-South direction. The research reported here focuses on the SMFs only, and the designs are based on ASCE 7-16, which leads to small variations compared to the original

NIST designs that were based on ASCE 7-05. All other parameters for the prototype building are consistent with NIST Technical Note 1863-1 [16]. Along with ASCE 7-16, AISC 341-16 and AISC 360-16 were used to design the prototype buildings. Stability was considered in accordance with the Direct Analysis Method (DM) in Ch. C of AISC 360-16 [5], which includes elastic P-Delta effects and stiffness reduction. There are two basic approaches for seismic lateral force analysis in ASCE 7-16: the equivalent lateral force procedure (ELF) and modal response spectrum analysis (RSA). ELF approximates a first-mode force profile, whereas RSA includes contributions from multiple modes. In both approaches, the analyses are elastic (no material nonlinearity) but do included geometric nonlinearity (P-Delta effects).

North
East

Fig. 1 – 8-story Prototype Building

The frame design matrix is based on code-compliant designs that use second-order elastic analysis. From this baseline design, variations are made to study the effect of analysis type (first-order elastic) and the effect of a seismic drift limit. Table 1 shows the design matrix, where FO represents a non-code-compliant design ignoring stiffness reduction and P-Delta effects, and SO represents a code-compliant design. An asterisk indicates a design that ignores the drift limit. Table 1 indicates that the controlling requirement of all 16-story SMFs was strength (and drift was satisfied automatically). A summary of frame member sections is provided in Tables 2 and 3, and seismic design parameters are presented in Table 4. The dead load calculation considered self-weight for each design, so seismic weights (D + 0.2L) are slightly different within each building scenario. V_{design} is the base shear for strength design and V_{drift} is the base shear for the drift check. For reference, the story drift profiles under drift check lateral forces are shown in Fig. 2.

2.2 Numerical Models

The OpenSees framework [17] was used to carry out the nonlinear static (pushover) analyses and nonlinear dynamic (response history) analyses of the SMF models. Given that the lateral force-resisting frames are located at the perimeter and the building is symmetric, the numerical models were 2D. Modal damping of 3% was used and an additional 0.3% stiffness-proportional damping was applied to damp out higher modes. Nonlinear rotational springs were placed at the ends of the SMF columns (half the column depth from the face of the beam) and at the center of each reduced beam section (RBS) connection. The nonlinear springs use the modified Ibarra Medina Krawinkler (IMK) deterioration model, which simulates in-cycle and cyclic degradation [18]. The force-deformation parameters for the RBS connections followed the recommendations made by Lignos and Krawinkler [19], which were derived using multivariate regression analysis of a database of experimental results. The force-deformation parameters for the column hinges followed the recommendations produced by NIST [20] using a monotonic backbone. The panel zones were modeled using the approach outlined by Krawinkler [21]. Additionally, although the column splice was designed at 1.2 m (4 ft) above the beam-to-column joint, this was ignored in the model and section size changes were made at the floor levels.

To approximately capture the behavior of the gravity framing system, a leaning column was used. The leaning column was assigned a moment of inertia equal to the sum of the moments of inertia of the tributary gravity frame columns and SCBF columns. The leaning column was attached to each floor of the SMF using equal degree of freedom constraints in the horizontal direction. Additionally, elastic-plastic hinges were placed at the top and bottom of each story and assigned a strength equal to the sum of the plastic moments of the non-SMF columns.

3. Numerical Simulations

3.1 Nonlinear Static Analyses

Nonlinear static analyses were performed to evaluate and compare behavior of the prototype designs. Based on the nonlinear analysis procedures described in FEMA P695 [15], the gravity loading applied in the numerical models was 1.05D + 0.25L, and the lateral load distribution was in proportion to the fundamental mode shape. Pushover curves (base shear vs. roof drift ratio) are shown in Fig. 3, with the following three important points marked: a) end of the linear range, b) peak base shear (V_{max}), and c) $0.8V_{max}$. These curves demonstrate that all frames exhibit significant softening around 1% roof drift ratio and reach V_{max} between 1% and 2% roof drift ratio. Beyond V_{max}, significant negative stiffness develops due to the global P-Delta effects. Response quantities from the pushover analyses provide useful comparisons between the prototype designs. Ultimate displacement (δ_u) is defined as the roof displacement at $0.8V_{max}$, and the effective yield displacement ($\delta_{y,eff}$) is calculated per FEMA P695 [15] and used as a reference for defining ductility as $\mu = \delta_u / \delta_{y,eff}$. System overstrength is defined as $\Omega = V_{max} / V_{design}$. A summary of these response quantities is provided in Table 5.

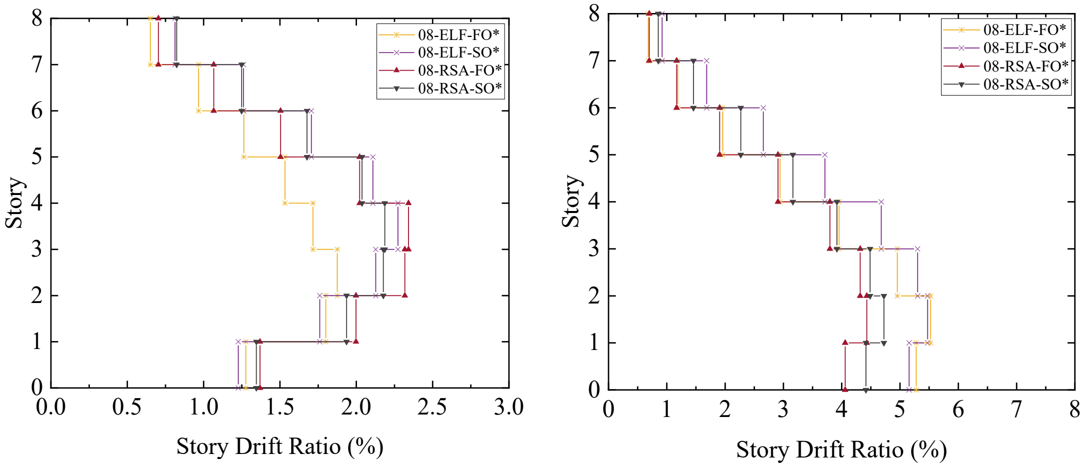
Fahnestock, Larry; Shi, Shitao; Speicher, Matthew. "Seismic Stability Assessment of Steel Moment Frames and Implications for Design." Paper presented at 17th World Conference on Earthquake Engineering, Sendai, JP. September 13, 2020 - September 18, 2020.

Table 5 – Summary of Response Quantities of One Perimeter Frame from Pushover Analyses

Case	V_{design} (kips)	V_{drift} (kips)	V_{max} (kips)	$\delta_{y,eff}$ / h (%)	δ_u / h (%)	Ω	μ	K_1 (k/in)
08-ELF-FO	256	167	653	0.98	3.61	2.54	3.67	47.6
08-ELF-SO	257	169	735	0.95	3.85	2.86	4.04	55.4
08-ELF-FO*	256	–	512	1.01	3.38	2.00	3.34	36.3
08-ELF-SO*	256	–	591	1.04	3.75	2.31	3.60	40.7
08-RSA-FO	254	120	322	1.06	3.05	1.27	2.88	21.8
08-RSA-SO	255	115	373	1.08	3.40	1.46	3.14	24.7
08-RSA-FO*	254	–	315	1.07	2.95	1.24	2.76	21.1
08-RSA-SO*	254	–	363	1.08	3.20	1.43	2.96	24.1
16-ELF-FO	479	221	915	0.86	3.12	1.91	3.63	38.9
16-ELF-SO	481	224	1068	0.88	3.20	2.22	3.64	44.4
16-RSA-FO	476	186	633	0.90	2.89	1.33	3.21	25.6
16-RSA-SO	476	179	717	0.93	3.21	1.50	3.46	28.2

As shown in Table 5, V_{design} is essentially equal for designs of the same building using ELF and RSA, but Ω is significantly reduced for RSA designs compared to ELF designs. For the two code-compliant ELF designs, Ω is greater than 2, whereas for the two code-compliant RSA designs, Ω is around 1.5. For the code-compliant designs, the 8-story ELF design has approximately 30% greater μ than the RSA design, whereas the 16-story ELF design has only 5% greater μ than the RSA design. The impact of these differences in overstrength and ductility, in conjunction with other parameters, requires further investigation through dynamic analysis.

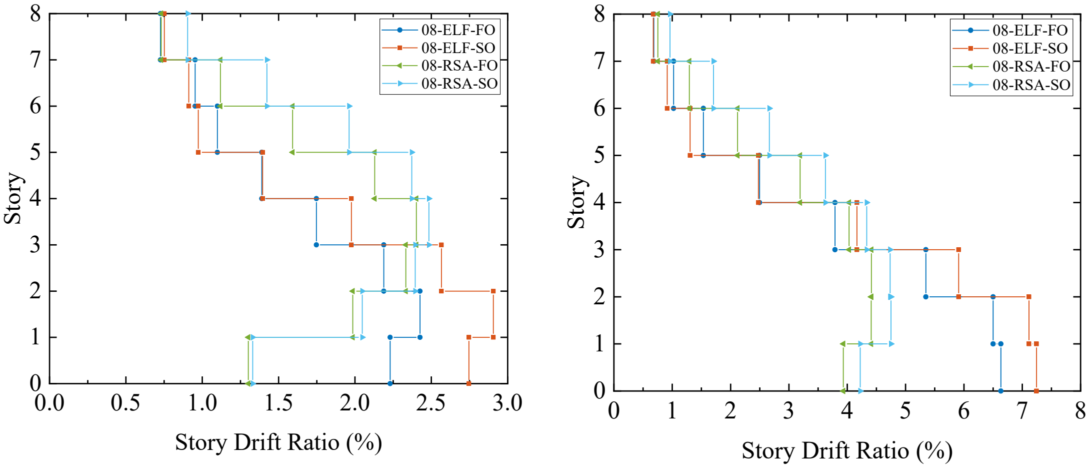


(a) At Maximum Base Shear Capacity (V_{max})

(b) At Ultimate Displacement (δ_u)

Fig. 4 – Effect of Analysis Type on Story Drift Profile of 8-story SMFs without Drift Limit

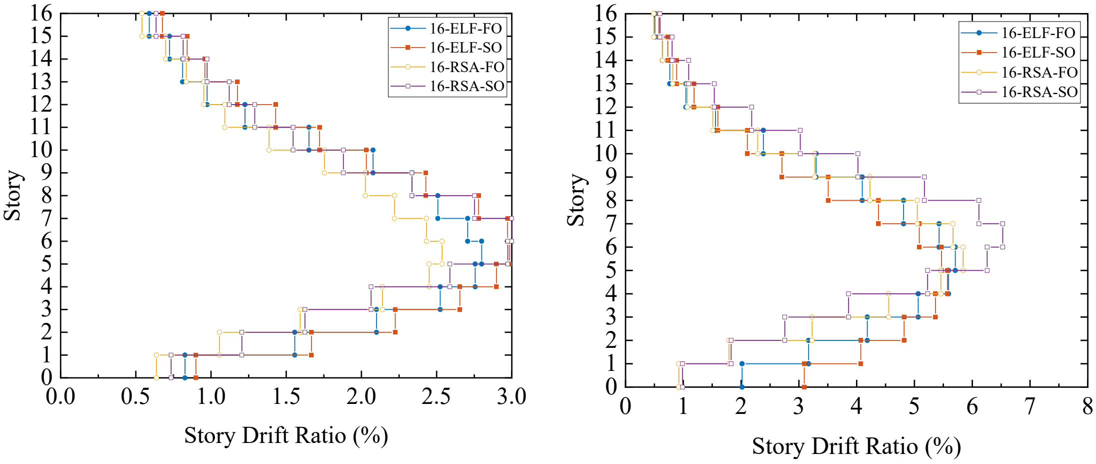
The influences of analysis type on the distributions of inelasticity in the pushover analyses are presented in the story drift profiles taken at the points of V_{max} and δ_u, as shown in Fig. 4, Fig. 5 and Fig. 6. These figures demonstrate that story drift was generally concentrated in the middle stories at the points of maximum base shear, and then drift became more pronounced in the lower stories in the region of global negative stiffness. The shape of the story drift profiles of SMFs designed considering elastic P-Delta effects are similar to the cases designed without elastic P-Delta effects. Comparison of the 8-story ELF designs with and without drift limits indicates that stiffening of the frame in the middle stories to meet drift limits leads to greater concentration of inelastic demands in the lower stories. However, this is not observed in the 8-story RSA designs, which consider higher modes of response.



(a) At Maximum Base Shear Capacity (V_{max})

(b) At Ultimate Displacement (δ_u)

Fig. 5 – Effect of Analysis Type on Story Drift Profile of 8-story SMFs from Pushover Analyses



(a) At Maximum Base Shear Capacity (V_{max})

(b) At Ultimate Displacement (δ_u)

Fig. 6 – Effect of Analysis Type on Story Drift Profile of 16-story SMFs from Pushover Analyses

The effects of drift limit and analysis type on response quantities are summarized in Table 6 and Table 7, respectively, by calculating the ratios of response quantities. Comparing cases with and without drift limit for the 8-story designs, removing the drift limit is seen to reduce the weight of steel in the special moment frame (W_{SMF}) by 11% in the code-compliant ELF design, but only 1% in the code-compliant RSA design. Correspondingly, V_{max} was reduced by 20% in the ELF design and only 3% in the RSA design. The drift limit has a significant impact on initial stiffness for the ELF design (over 30%), but minimal impact for the RSA design (less than 5%).

Considering the impact of P-Delta effects (second-order analysis), which also includes stiffness reduction per the Direct Analysis Method (DM), Table 7 shows an increase of W_{SMF} roughly in the range of 5-10%. This increased steel weight translates into increases in strength of roughly 10-15% and increases in ductility of roughly 5-10%. The pushover curves in Fig. 3 illustrate these increases graphically, and the increases in elastic stiffness are also evident. Elastic stiffness increases are approximately on the same order as the strength increases (10-15%).

Table 6 – Effect of Drift Limit on Response Quantities from Pushover Analyses

Case	$\frac{(W_{SMF})^*}{(W_{SMF})}$	$\frac{(V_{max})^*}{(V_{max})}$	$\frac{(\Omega)^*}{(\Omega)}$	$\frac{(\mu)^*}{(\mu)}$	$\frac{(K_1)^*}{(K_1)}$
08-ELF-FO*/08-ELF-FO	0.91	0.78	0.79	0.91	0.76
08-ELF-SO*/08-ELF-SO	0.89	0.80	0.81	0.89	0.73

08-RSA-FO/08-RSA-SO	0.96	0.86	0.86	0.92	0.88
08-RSA-FO*/08-RSA-SO*	0.92	0.87	0.87	0.93	0.88
16-ELF-FO/16-ELF-SO	0.92	0.86	0.86	1.00	0.88
16-RSA-FO/16-RSA-SO	0.95	0.88	0.88	0.93	0.91

3.2 Nonlinear Response History Analyses

To further evaluate the influence of LFRS design parameters on seismic performance, the 8-story ELF designs were subjected to the far-field record set (44 individual horizontal ground motions) from FEMA P695. The ground motions were normalized per FEMA P695 then the median spectral ordinate of these 44 ground motions scaled to match the acceleration of the risk-targeted MCE response spectrum at the target fundamental period for the building (C_uT_a, tabulated in Table 4).

Table 8 – Median Response Quantities under MCE Ground Motions

Case	**Peak Story Shear (kips)**	**Peak Roof Drift Ratio (%)**	**Peak Story Drift Ratio (%)**
08-ELF-FO	873	1.87	3.14
08-ELF-SO	945	1.77	3.21
08-ELF-FO*	763	2.00	3.35
08-ELF-SO*	859	1.93	3.42

Median response quantities for the set of nonlinear dynamic analyses are summarized in Table 8. For the code-compliant design (08-ELF-SO), the median peak roof drift ratio is 1.77% and the median peak story drift ratio is 3.21%. Considering that the design basis earthquake (DBE) is approximately 2/3 of the MCE, the MCE response indicates a median DBE response around the design target of 2%. Comparing 08-ELF-FO to 08-ELF-SO, the design including P-Delta is seen to have a slightly smaller median peak roof drift ratio, but a slightly larger median peak story drift ratio. This somewhat unusual result arises due to the larger section sizes that are used in the SO design, which lead to redistribution of inelastic response.

The designs without drift limit clearly experience greater inelastic drifts than their counterpart designs with drift limits. In the scenario considered here, the drift limit appears to be more influential than consideration of P-Delta effects. The design by first-order analysis that considers the drift limit (08-ELF-FO) performs better than the design by second-order analysis that ignores the drift limit (08-ELF-SO*). Fig. 7 shows that 08-ELF-FO has the most uniform distribution of drift of the four cases considered. Referring back to Fig. 4 and Fig. 5, the story drift profiles from pushover analyses, which use an elastic first mode force profile, have greater variation. The drift limit, which led to larger section sizes in the middle stories, reduced story drift ratios in this region, but also increased story drift ratios above and below.

4. Summary

The ongoing research project described in this paper aims to identify the most critical LFRS parameters that affect seismic stability and to develop a rigorous yet simple methodology whereby these parameters can be considered in design. This paper focuses on a set of steel special moment frames (SMF) that is designed with or without consideration of stiffness reduction due to inelasticity, elastic P-Delta effects and drift limits. Office buildings with two heights (8-story and 16-story) were based on prior work conducted at NIST and designed using current code provisions in the United States. The buildings have regular plan configurations with perimeter lateral force-resisting frames. Equivalent lateral force (ELF) and modal response spectrum analysis (RSA) procedures were used in the design process. The moment frame designs are interrogated using nonlinear static and dynamic analyses to assess their collapse potential and to identify the most important parameters for design. Several observations from the present study are:

- For the 8-story case, removing the drift limit reduces the weight of steel in the SMF by 11% in the code-compliant ELF design, but only 1% in the code-compliant RSA design. From pushover analyses, the peak base shear was reduced by 20% in the ELF design and 3% in the RSA design.
- For the 8-story cases, the drift limit has a significant impact on initial stiffness for the ELF design (over 30%), but minimal impact for the RSA design (less than 5%). For the 16-story cases, the drift limit was not influential since it was satisfied based only on strength requirements.
- Enforcing the drift limit for the 8-story cases led to larger member sizes in the middle stories. This increase in stiffness and strength reduced inelastic dynamic response in stories 4-7, but increased the response above and below.
- Considering the impact of P-Delta effects (second-order analysis), which also includes stiffness reduction per the Direct Analysis Method (DM), the weight of steel in the SMF increased by approximately 5-10% compared to the designs by first-order analysis. This increased steel weight translates into increases in strength of approximately 10-15% and increases in ductility of approximately 5-10%. Elastic stiffness increases are approximately on the same order as the strength increases (10-15%).
- Based on the limited results from this study, the drift limit appears to be more influential than consideration of P-Delta effects.

Further study of seismic stability for steel special moment frames will include comprehensive collapse assessments per FEMA P695. The results from this paper will also be combined with similar assessments for other types of steel seismic lateral force-resisting systems to develop design provisions that will aim to enhance safety and economy for future design.

Abstract

With the gaining popularity of performance-based engineering, it is essential to have reliable estimates of component (e.g., steel beam or column) performance under actual earthquake loading demands. Physical laboratory tests are traditionally used to determine component inelastic behaviors. A loading protocol refers to the sequence of quasi-static displacements applied to a test specimen to simulate the demands imposed by an earthquake. The vast majority of *standard* tests use loading protocols consisting of fully-reversed cyclic loading with progressively increasing amplitudes. Standard tests are in many cases, unlike the demands posed by earthquakes, and using realistic earthquake loading patterns can lead to different conclusions on component performance. Unfortunately, there are relatively few tests using realistic earthquake loading patterns. Likewise, there are relatively few tests using monotonic loading that may best represent the demands at incipient collapse caused by large near-field type shaking.

In the United States, a component *backbone* curve representing the inelastic force-deformation behavior is typically taken as the envelope of laboratory test hysteresis data. A shortcoming is that the backbone curve is dependent on the loading protocol used in the tests, and customary standard tests can lead to overly pessimistic estimates of component behavior. This can cause rejection of buildings that would otherwise be considered acceptable should component behaviors be based on tests using realistic earthquake loading patterns. It is therefore recommended that future tests consider realistic earthquake loading protocols so that the results are best suited for performance-based engineering.

Alternatively, a Japanese *skeleton* curve concept using decomposition of standard test data may be a way to leverage the current wealth of available standard test data thereby providing a better description of component seismic performance than simply taking an envelope of standard test data. The skeleton curve consists of horizontally stacked hysteretic loops that resemble a monotonic curve. To demonstrate this concept, a simple *adaptive* component model incorporating skeleton curves is presented. The model accounts for both in-cycle and cyclic strength degradation. It is shown to mimic observed monotonic and cyclic behaviors depending on the displacement loading history. The model is simple and can be easily incorporated into structural analysis computer programs used for building evaluation. Ongoing work includes more validation of the adaptive model as well as possible extension to other materials such as reinforced concrete and wood components.

Keywords: loading protocols; performance-based engineering; backbone curves; experimental tests, steel components

Maison, Bruce; Kasai, Kazuhiko; Speicher, Matthew. "Loading Protocols and Backbone Curves: U.S. and Japan Perspectives." Paper presented at 17th World Conference on Earthquake Engineering, Sendai, JP. September 13, 2020 - September 18, 2020.

1. Introduction

Performance-based engineering, in which a structure is proportioned to meet certain predictable performance requirements, necessitates good estimates of component (e.g., steel beam) inelastic behavior during earthquakes. In the United States, a so-called *backbone* curve is the customary way of describing component behaviors over a range of deformations. It is formulated as an envelope of hysteresis loops from component experimental tests and is a critical factor in component modeling and acceptance criteria [1].

To determine backbone curves, the vast majority of steel component tests use *standard* displacement loading patterns (protocols) that do not necessarily simulate realistic earthquake demands. Results from standard tests can lead to overly conservative component backbone curves (i.e., indicating premature failure), especially for components meeting current ductility requirements in steel construction standards. This can cause rejection of buildings that would otherwise be considered acceptable should component behaviors be based on tests using loading patterns that simulate actual earthquake demands [2, 3].

This paper underscores the influence loading protocols have on backbone curves and demonstrates how a Japanese *skeleton* curve concept can be used in a simple *adaptive* model for steel components. Strength degradation caused by local buckling is separated into in-cycle and cyclic parts. The model incorporates the skeleton curve to mimic observed monotonic and cyclic behaviors depending on the displacement loading history. It better describes inelastic behaviors as opposed to a conventional approach using an envelope of the standard test hysteretic loops. The model can be easily implemented into structural analysis computer programs for the seismic evaluation of structures.

2. Loading Protocols

Figure 1 contrasts a standard protocol to that of a simulated earthquake response from a building undergoing inelastic actions. It consists of a series of fully-reversed displacement cycles having progressively increasing amplitudes. In contrast, the earthquake response has relatively few cycles with a one-direction bias.

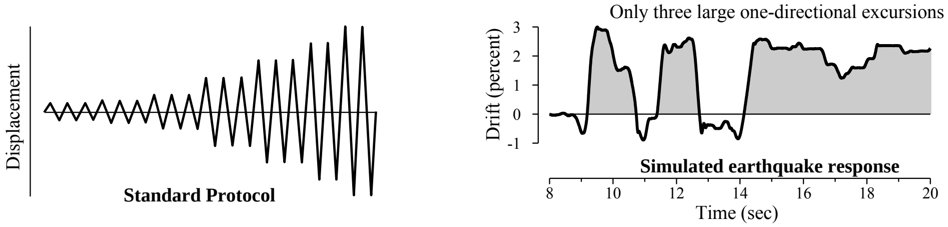

Fig. 1 – Typical standard protocol [4] compared to simulated building inter-story drift earthquake response.

With the advancement and increasing use of nonlinear structural analysis, a better understanding of actual seismic response has led researchers to propose different protocols better reflecting building inelastic seismic response (Figure 2). Such protocols are termed here as *realistic*. Realistic protocols differ from standard protocols, and their use can lead to different conclusions about component performance. Unfortunately, relatively few tests have been conducted using realistic protocols as compared to the plethora of tests using standard protocols. Likewise, relatively few tests have been conducted using monotonic loading that provide insights about component performance at near-collapse displacements [5].

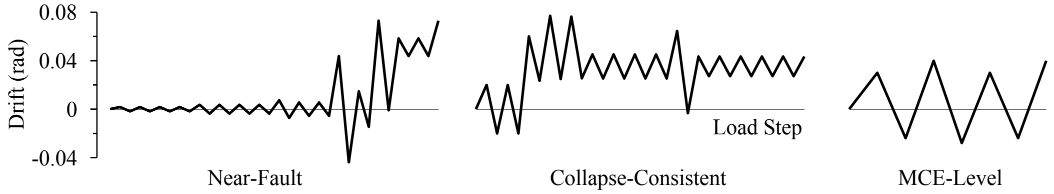

Fig. 2 – Realistic protocols simulating building inelastic drift response during earthquakes: Near-Fault [6], Collapse-Consistent [7], and MCE-Level [8].

3. United States Backbone Curves

Figure 3 shows backbone (envelope) curves from component tests of steel reduced beam section (RBS) connections using standard and realistic loading protocols [9]. The displacement reversal points control where there is an abrupt decline in force giving the impression that the component has a 5 % ultimate drift capacity in the standard test, whereas it has 8 % ultimate drift capacity in the realistic test (1.6-times larger). In reality, the component can have greater capacity than that from either test since the ultimate drifts are an artifact of the protocol reversal points, and not an intrinsic property. This is of particular importance for ductile components such as those designed and constructed in accordance with current steel construction standards such as AISC 341-16 [10]. Nevertheless, realistic tests are most likely better representations of earthquake performance since the loadings mimic actual earthquake demands. Additional shortcomings of standard tests are discussed in reference [8]. Given the abundance of tests conducted using standard loading protocols, it may be advantageous to decompose existing standard test results to gain insights about component performance during earthquakes, as proposed in the next section.

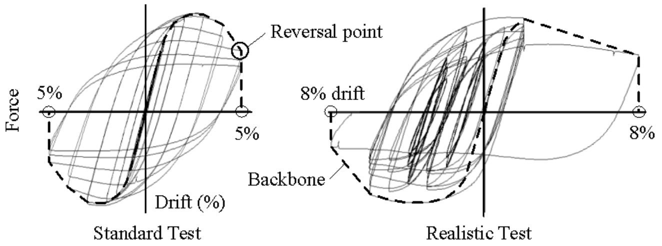

Fig. 3 – Backbone curves from RBS connection tests using standard and realistic loading protocols.

4. Japanese Skeleton Curves

Yamada et al. [11, 12] studied the hysteretic behavior of steel beam-columns having rectangular hollow shaped (RHS) sections. It was found that the cyclic degradation of the moment-rotation relationship caused by local buckling can be represented by a so-called *skeleton* curve. A novel way to decompose the results from a standard test to create a skeleton curve was developed. The process takes the individual hysteretic loops from a standard test and expands them to resemble a monotonic curve. The skeleton curve was then incorporated into an analytical model that reasonably captured RHS inelastic moment-rotation behaviors under random earthquake loadings.

Used here is a modified version of the Yamada skeleton approach as presented by Kimura et al. [13, 14, 15] for steel sections having H-shapes. Figure 4 illustrates the decomposition of the positive-side hysteretic loops to construct a skeleton. The skeleton strength deterioration is based on segments of the hysteretic loops that have declining strength. The segments are shifted horizontally so they connect at the respective unloading rotation in the previous loading cycle. Another skeleton curve can be constructed in a similar manner using the negative-side data.

For the case in Figure 4, the skeleton suggests ductile behavior out to about 0.2 rad that is well beyond the limits of the standard test (0.04 rad). The skeleton curve can serve as an improved (less conservative) backbone curve compared to the conventional approach of taking an envelope of the standard test hysteretic loops. The skeleton curve lacks an abrupt decline in strength like that in conventional backbones (Figure 3) signaling the ultimate rotation. Thus for component acceptance criteria, it may be appropriate to set the ultimate rotation as when the skeleton moment drops below some value (e.g., below 50 % of peak value). However, for computer modeling in building analysis/evaluation, it seems more correct for the component to follow the skeleton even at relatively large rotations.

It should be noted that if a monotonic curve is available, then it can be referenced directly without construction of a skeleton curve. However, there is relatively scant monotonic test data so using decomposition of the plentiful standard test data is an attractive alternative.

(b) Positive-Side Skeleton Construction

(c) Skeleton Curve

Fig. 4 – Skeleton curve derived using positive-side hysteretic loops from standard test.

5. Case Study Using Skeleton Curves

To further explain the concept of skeleton curves and how they can be used in an adaptive model, a set of experimental test data by Kimura et al. [13] for steel H-shaped sections is studied. The test arrangement and hysteretic responses from two tests are shown in Figures 5 and 6, respectively. Case A had no axial force, and Case B had an applied constant compressive axial force of 30 % of the yield force. Conventional backbone (envelope) curves are denoted by red dashed lines in Figure 6.

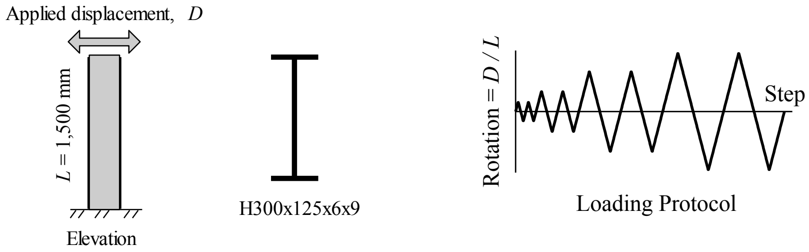

Fig. 5 – Experimental arrangement of standard test.

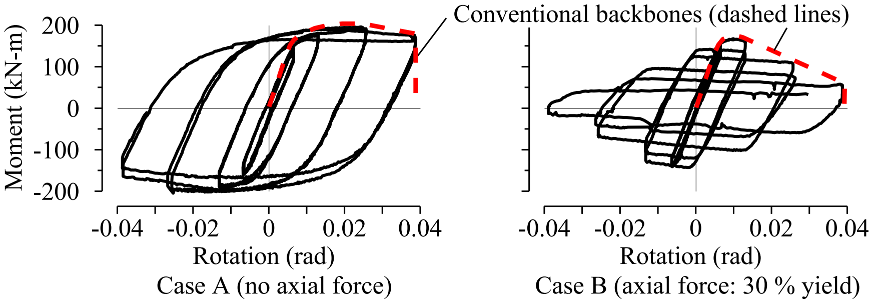

Fig. 6 – Hysteretic response from standard tests.

Figure 7 shows the skeleton curves using the hysteretic loop decomposition technique explained in section 4. The skeleton curves are in reasonable agreement with the monotonic curves for both cases. Case B exhibits earlier strength degradation that is more rapid than that for Case A due to the compressive axial force in Case B promoting local buckling. Conventional backbone curves (red dashed lines), taken as envelopes of the hysteretic loops in Figure 6 indicates ultimate rotation of 0.04 rad defining failure simply due to the fact this was the maximum rotation used in the tests. Both Case A and B would have ultimate rotations well beyond 0.06 rad based on the skeleton curves (Figure 7). Hence, using the skeleton as the backbone curve could have an ultimate rotation for use in acceptance criteria at least 50% greater than the conventional backbones.

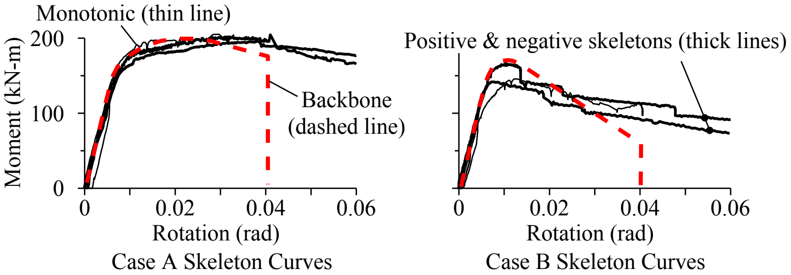

Fig. 7 – Skeleton curves derived from decomposition of standard test hysteretic loops.

Figure 8 shows piecewise linear representations of the skeleton curves from Figure 7. These will be used in a simple adaptive model described in the next section.

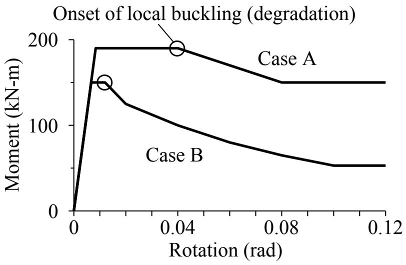

Fig. 8 – Piecewise linear skeleton curves from standard tests.

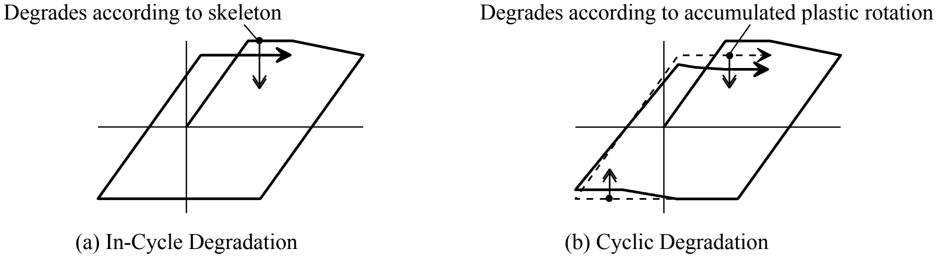
6. Adaptive Model

A simplified version of the Yamada et al. approach for the moment-rotation behavior is presented here. It is based entirely on observations of standard test hysteretic behaviors through use of skeleton curves to account for strength degradation. It should be noted that if a monotonic curve is available, then it can be referenced directly without construction of a skeleton curve. The model is termed *adaptive* because it can reflect monotonic as well as hysteretic strength degradation depending on the deformation loading history.

Strength degradation can be considered as having two parts [16]: in-cycle and cyclic. In-cycle is characterized by loss of strength occurring within a single cycle (e.g., during a monotonic push). Cyclic is delineated by loss of strength occurring in subsequent cycles (e.g., after cycles having the same peak-to-peak displacements).

6.1 In-Cycle Degradation

The skeleton curve serves as the boundary limit for the peak moment. In-cycle degradation is controlled by the skeleton curve as indicated in Figure 9a. The behavior is elasto-plastic and as the rotation increases, the ultimate moment progressively decreases according to the skeleton curve boundary.



Degrades according to skeleton
Degrades according to accumulated plastic rotation

(a) In-Cycle Degradation

(b) Cyclic Degradation

Fig. 9 – Adaptive mode strength degradation controlled by skeleton curve.

6.2 Cyclic Degradation

Cyclic degradation is modeled by a shrinking of the backbone curve according to cyclic actions (Figure 9b). The backbone curve is progressively scaled smaller as a function of the cumulative positive (*APR+*) and negative plastic rotations (*APR-*). The *smaller* of *APR+* or the absolute value of *APR-* is taken as a measure of the cyclic action. A scale factor is computed as the ratio of moments from the skeleton curve (Figure 10). The scaling occurs continuously as the plastic rotations accumulate during the loading history.

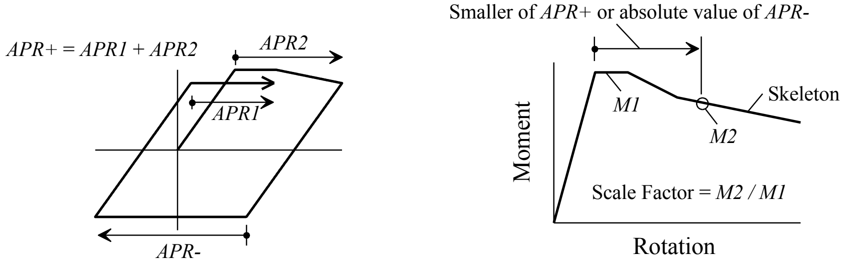


Fig. 10 – Adaptive model cyclic strength degradation feature.

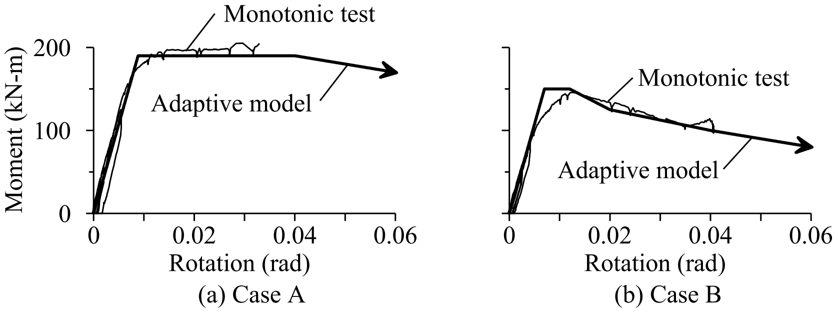
6.3 Comparison to Test Results

The adaptive model was implemented into a computer program and numerical simulations performed. The program has rotation as input and computes the moment according to the adaptive model algorithm described above. A future step is to implement the model into a structural analysis program for building seismic analysis.

Figure 11 compares the results from the adaptive models to monotonic test results. The models produce close fits to the tests. This is expected since there is no cyclic action and therefore no cyclic degradation occurs in the model.

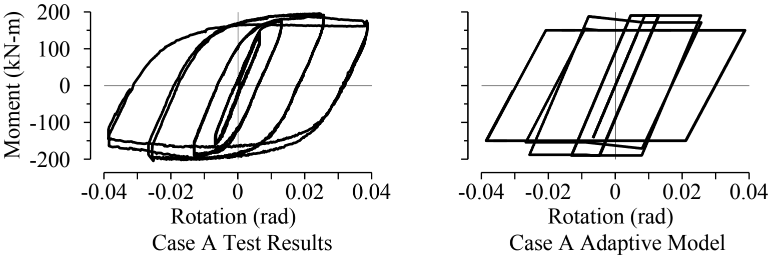


(a) Case A

(b) Case B

Fig. 11 – Comparison of monotonic results.

The Case A adaptive model hysteresis is compared to the standard test in Figure 12. The model exhibits reasonable agreement with the test, albeit the strength degradation is modest.



Case A Test Results

Case A Adaptive Model

Fig. 12 – Comparison of Case A hysteretic response (no axial force).

Figure 13 shows the Case A moment versus cumulative absolute rotation. This can be thought of as a pseudo-time history of moment response. The model reasonably captures the degradation of peak moments in the test and has an excellent fit out to about 0.3 rad cumulative rotation.

Maison, Bruce; Kasai, Kazuhiko; Speicher, Matthew. "Loading Protocols and Backbone Curves: U.S. and Japan Perspectives." Paper presented at 17th World Conference on Earthquake Engineering, Sendai, JP. September 13, 2020 - September 18, 2020.

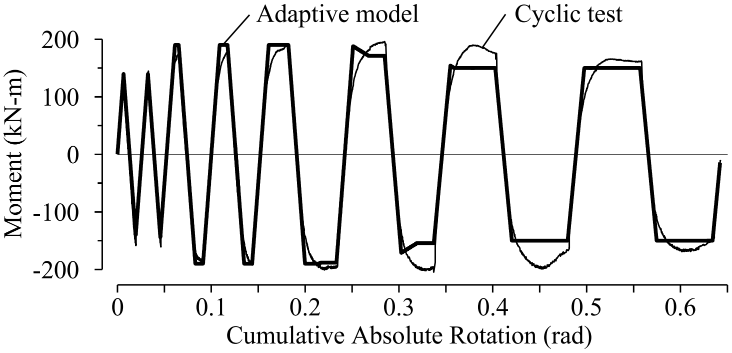


Fig. 13 – Case A (no axial force) moment versus cumulative rotation (pseudo-time history).

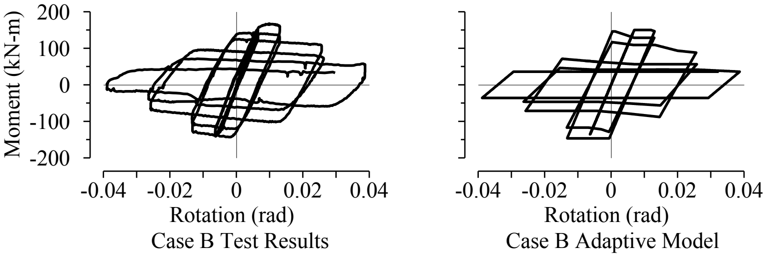
The Case B adaptive model hysteresis is compared to the standard test in Figure 14. There is a large amount of strength degradation due to the relatively large axial compression. The model reasonably simulates the test.



Case B Test Results

Case B Adaptive Model

Fig. 14 – Comparison of Case B hysteretic response (axial force: 30 % yield).

Figure 15 shows the Case B moment versus cumulative absolute rotation (pseudo-time history of moment response). The model reasonably tracks the moment degradation in the test.

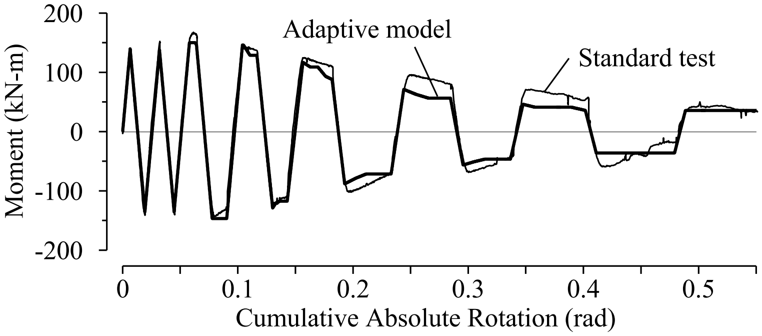


Fig. 15 – Case B (axial force: 30 % yield) moment versus cumulative rotation (pseudo-time history).

The above demonstrates how a simple adaptive model can reasonably mimic component moment response under monotonic as well standard loading patterns. The model incorporates a skeleton curve derived from decomposition of standard test data. Alternatively, should monotonic test curve be available, it can be used in place of the skeleton curve.

7. Realistic Seismic Loading Patterns

The response of the adaptive model from realistic seismic loading patterns (Figure 2) is presented in this section. The near-fault and collapse consistent protocols represent building response at an incipient collapse state. The deformations have a one-direction bias with peak drifts in the 7 to 8 % range. The MCE-Level protocol represents a modern code-conforming building response to a maximum considered earthquake. It also has a one-direction bias but with a smaller peak drift of 4 %.

7.1 Hysteretic Response

Figures 16, 17 and 18 show the adaptive model hysteretic behaviors. Both in-cycle and cyclic degradation are apparent. Case A, having no axial compressive force, has only a modest amount of strength degradation even out to 0.08 rad. This suggests that strength degradation (local buckling) plays only a minor role in the component seismic performance when there is little axial force (e.g., girders in steel moment frame structures). Case B, having significant axial compression, the situation is quite different with significant strength degradation. Hence, columns in steel moment frames are likely to be more susceptible deterioration from the effects of local buckling.

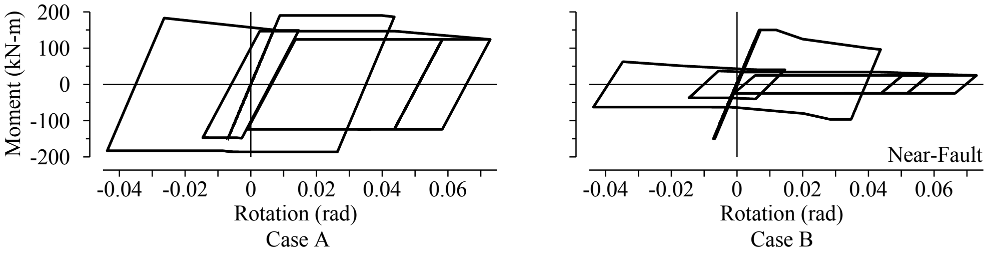

Fig. 16 – Adaptive model hysteresis from *near-fault* loading protocol.

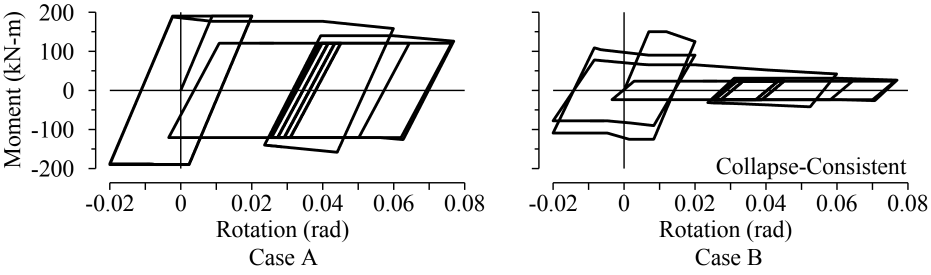

Fig. 17 – Adaptive model hysteresis from *collapse-consistent* loading protocol.

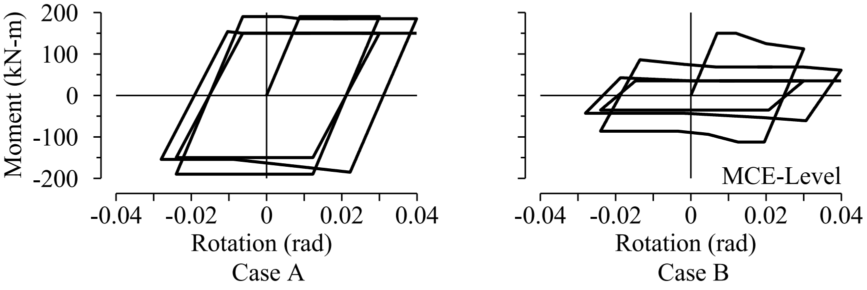

Fig. 18 – Adaptive model hysteresis from *MCE-level* loading protocol.

7.2 In-Cycle vs. Cyclic Degradation

The relative influence of in-cycle and cyclic strength degradation is illustrated in Figures 19 and 20. The adaptive model having both in-cycle and cyclic degradation is compared to the situation having only in-cycle degradation. Case A has a total 34 % strength reduction of which about one-half (17%) is from cyclic degradation. Case B has a huge total strength reduction of 83 % of which about two-thirds (64 %) is from cyclic degradation. For this example, the adaptive model in-cycle and cycle strength reduction features both had significant contributions.

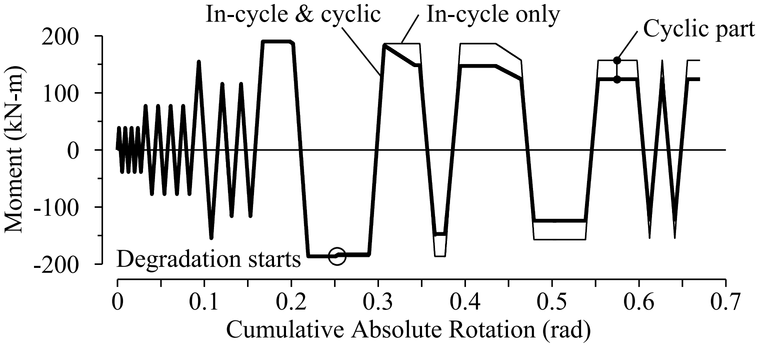

Fig. 19 – Case A (no axial force) moment versus cumulative rotation (pseudo-time history) from *near-fault* loading protocol.

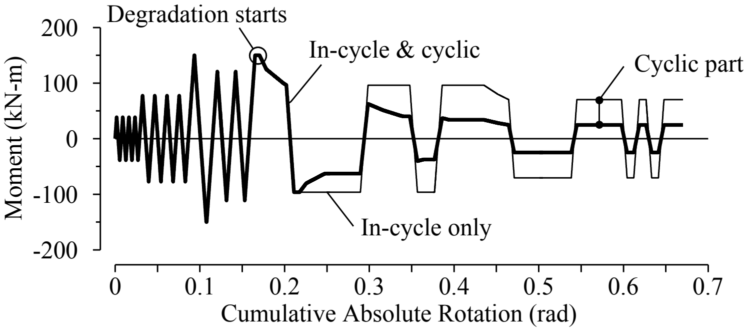

Fig. 20 – Case B (axial force: 30 % yield) moment versus cumulative rotation (pseudo-time history) from *near-fault* loading protocol.

8. Conclusion

Performance-based engineering requires good estimates of component behaviors during actual earthquakes. Customary U.S. practice describes component seismic performance by a backbone curve taken as an envelope of hysteresis loops from experimental tests. Standard tests use loading protocols consisting of fully-reversed cyclic loading unlike the loading patterns posed by earthquakes. Standard tests can lead to overly pessimistic estimates of component behavior.

There are two underlying shortcomings when using standard test data: (1) ductility can be underestimated, which in turn, can lead to very restrictive acceptance criteria, and (2) derived backbone curves used in analysis models for seismic evaluation can lead to over-estimation of peak inelastic displacements, unless those models explicitly account for degradation. These have a compounding effect causing rejection of buildings that would otherwise be considered acceptable should component behaviors be based on tests using realistic earthquake loading patterns. Hence, it is encouraged that future lab tests include realistic earthquake loading protocols so that the results are better suited for performance-based engineering.

There are large numbers of standard tests as opposed to relatively few realistic and monotonic tests. The Japanese skeleton curve concept provides a way to obtain additional useful information from standard test data. Skeleton curves resemble monotonic curves. They can provide less conservative estimates of ultimate rotations (and therefore acceptance criteria) compared to the conventional backbone approach of taking an envelope of the standard test hysteretic loops. In addition, skeleton curves can be used a simple adaptive component model as presented here. The model accounts for both in-cycle and cyclic strength degradation, and is shown to mimic observed monotonic and cyclic behaviors depending on the displacement loading history. The model is simple and can be easily incorporated into structural analysis computer programs used for building evaluation.

Ongoing work includes: more validation of the adaptive model; possible extension to other materials such as reinforced concrete and wood components; and implementation of the adaptive model into structural analysis computer programs to assess the importance of degradation in building global seismic response.

9. Acknowledgement

The authors appreciate Prof. Yamanishi of Hiroshima Institute of Technology, and Dr. Suzuki and Prof. Kimura of Tohoku University in Japan for kindly sharing the experimental test data used in this study. This project is dedicated to the continued cooperation of the Japan and United States earthquake engineering communities. Sharing of our knowledge is the best way toward the advancement of earthquake engineering thereby mitigating hazards posed by earthquakes.

***Abstract*— Carbon nanotubes (CNT) resistance-change memory devices were assessed for neuromorphic applications under high frequency use conditions by employing the ultra-short (100 ps -10 ns) voltage pulse technique. Under properly selected operation conditions, CNTs demonstrate switching characteristics promising for various NN implementations.**

***Index Terms*-- Neuromorphic computing, CNT, RRAM.**

I. Introduction

Mobile neuromorphic computing systems impart specific requirements to memristors for microelectronic "synapses". Carbon nanotube (CNT) nano-switch devices are a promising class of resistive memory technologies due to excellent retention and endurance, and low operating current. A CNT memory cell (Fig. 1) consists of TiN electrodes sandwiching a ~30 nm layer of a conductive fabric representing a disordered network where CNTs are bound to each other via van der Waals forces [1]. Rearrangements of the CNT contacts, Fig. 2, results in higher (~1-10 MΩ) and lower (~10-100 kΩ) cell resistance states. Due to asymmetry of the CNT fabric engineered by varying nanotubes density, orientations, doping, etc., an applied to the bottom electrode positive voltage increases a number of nanotubes connections resulting in higher cell conductance, while negative voltage decreasing conductance of a NRAM device.

To assess the suitability of CNT nano-switch technology for neural network applications, we investigate stability of NRAM responses to program signals under the conditions, which are close to high frequency circuitry operations. For that purpose, an ultra-short (100 ps -10 ns) voltage pulsed technique [2] was employed. Here we focus on deep neural network (DNN) applications where cell resistance (representing synaptic weight) is required to increase/decrease gradually and quasi-linearly depending on the polarity of the programming pulse [3]. To evaluate how synaptic weight is modulated by incoming signals, we investigated dependency of memristor resistance on pulse durations, voltages, and sequences of SET (program operation increasing conductivity) and ReSET (program operation decreasing conductivity) pulses.

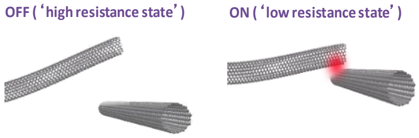

Figure 2. *Schematics of resistance switching between high and low resistance states on a single-point contact.*

II. Experimental setup

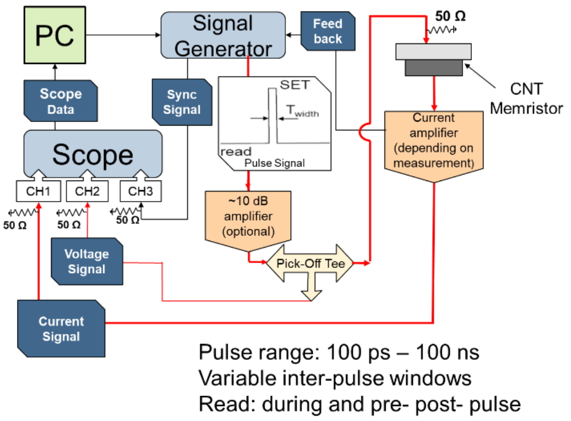
The ultra-short pulse (USP) technique [2,4-8] has several advantages over traditional memristor evaluation methods:

(i) Pulse duration are relevant to actual circuitry operating conditions, and allow realistic assessment of memristor characteristics;

Veksler, Dmitry; bersuker, gennadi; Bushmaker, A; Mason, Maribeth; Shrestha, Pragya; Cheung, Kin (Charles); Campbell, Jason; Rueckes, T; Clevlend, L; Luan, H; Gilmer, D. "Memory update characteristics of carbon nanotube memristors (NRAM) under circuitry-relevant operation conditions." Paper presented at 2020 International Reliability Physics Symposium, Dallas, TX, US. April 28, 2020 - May 30, 2020.

(ii) Short pulses allow precise control of switching energy delivered to devices, which was shown to improve switching stability and reduce variability [2];

(iii) USVP removes the need for a current compliance circuitry because this technique delivers well-controlled small conductance changes.



Pulse range: 100 ps – 100 ns
Variable inter-pulse windows
Read: during and pre- post- pulse

Figure 3. *Experimental setup.*

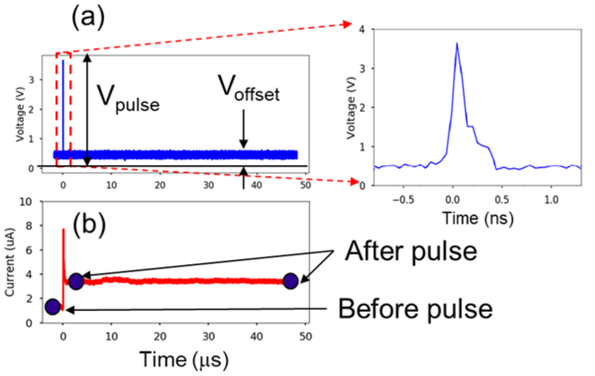


Figure 4. *Applied voltage pulse (a) and resulted current (b) through the NRAM cell, monitored using small DC offset. V_{offset} = 100 – 500 mV.*

Schematic of the experimental setup is shown in Fig. 3. Current through the memristors is monitored using a current amplifier and by applying a constant small DC offset (below the switching voltage threshold) coupled to the programing signals, Fig. 4. Pulses of positive (SET) or negative (ReSET) polarities change conductance to higher and lower values, respectively. Note that CNT memristor devices can operate in a wide conductance range: here we show data on the switching current in the 1 μA and 100 μA range.

III. Results and Discussion

To verify switching stability of NRAM devices, trains of 50 SET pulses followed by 50 ReSET pulses were applied. Pulse duration was fixed at T_{pulse} = 100 ps, and low (1 Hz) repetition rate was used to eliminate cross-correlation (energy-wise) between program pulses. The conductance response to short programing pulses is shown in Fig. 5a,b. both SET and ReSET operations include abrupt and gradual phases of strong and smaller conductance changes, respectively. The first pulse in the 50 SET pulses tends to induce a large conductance increase followed by smaller increases under subsequent pulses; conductance eventually saturates with minimal continuous increase. The current saturation value, $I_{SET,}$ linearly depends on the pulse amplitude, Fig. 6. ReSET typically features an initial gradual conductance decrease followed by an abrupt drop towards the target HRS. In subsequent SET/ReSET switching cycles (performed with sequences of multiple SET and ReSET pulses), stronger initial SETs correlate to larger final steep ReSET drops, Fig. 5c. This indicates that the same sites within the CNT fabric (connections between specific CNTs) control SET-ReSET switching steps: the inter-CNT contact which was activated first (e.g., easier to connect) is the last to be de-activated (harder to disconnect). These sites in the NRAM cell, which are responsible for the initial (SET) - final (ReSET) abrupt conductance changes may represent a cluster of connected CNTs in the film fabric: higher current through the contact in a single CNT pair may assist (via energy dissipation and temperature increase) with bending of surrounding CNTs and promoting contact. Indeed, higher SET voltage results in higher saturation current accompanied by a larger conductance change in both initial SET and final ReSET, Fig. 7 a, b. This is consistent with the proposed understanding that saturation is due to the fact that most (if not all) of available CNT sites capable to connect under a given condition are activated; higher voltage and longer pulse time (i.e. higher emitted energy) increases a pool of activatable sites that leads to both greater initial SET transition and a higher saturation level. To identify operation conditions contributing to conductance saturation in memory updates, we applied program pulses of various durations and variable sequences.

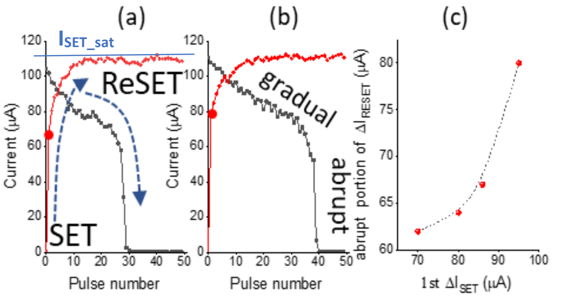

Figure 5. *(a,b) – Example of NMRAM cell response to 50 SET + 50 ReSET pulses in 10th and 20th switching cycles (T_{pulse} = 100 ps). Red circles indicate conductance increase after the 1st SET pulse; (c) correlation between abrupt SET/ReSET phases (multiple cycles on same device): intial SET and final ReSET.*

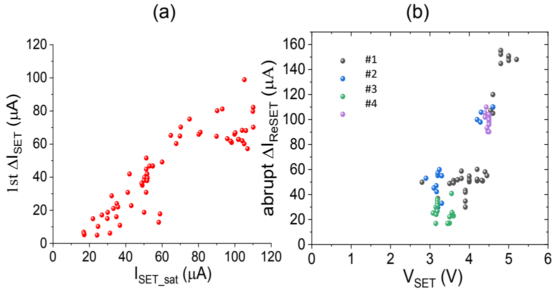

Figure 7. *(a) Correlation between ΔI after 1st SET pulse and saturated conductivity after 50 SET pulses. (b) Abrupt portion of the conductivity update in ReSET operation vs. amplitude of the preceeding train of SET pulses (data for 4 different samples are combined).*

Oscillograms of voltage and current through the NRAM device under 10 ns SET/ReSET pulses are shown in Figure 8. This relatively long voltage pulses of slow rise and fall times allow to directly measure a current during NRAM switching, thanks to low parasitic capacitance of tested devices. Collected data demonstrates strong SET/ReSET asymmetry, Figure 8 c,d. Comparison of switching characteristics of a single SET/ReSET pulse of 10 ns and a train of 5 Set/5 Reset pulses of 2 ns width (separated by 200 ns) further emphasizes the asymmetry between SET and ReSET processes, Fig. 9.

A longer ReSET pulse induces a runaway-like increase of the NRAM cell resistance. In SET, on the other hand, the conductance change is primarily determined by total duration of the applied voltage, either continuous (10 ns pulse) or interrupted (5 x 2 ns).

To assess the possible contribution of temperature increase, SET is performed by applying sequences of short or long pulses separated by a long time-window, Fig. 10. The sequence of 200 ps pulses demonstrates that conductance increase saturates within a short time (covering duration of several initial pulses) contrary to longer 2 ns pulses. This suggests that the energy released during the “short” pulse limits the size of the affected (heated) region of the CNT fabric that reduces possible CNT connections.

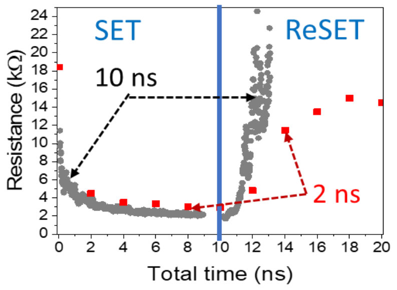

Figure 9. *Comparison of the resistance update in SET and ReSET operations during an applied train of five 2 ns pulses (red dots) and continuous single 10 ns pulse x-axis corresponds to the total time of applied pulse votage. RESET runaway in 10 ns pulse is observed.*

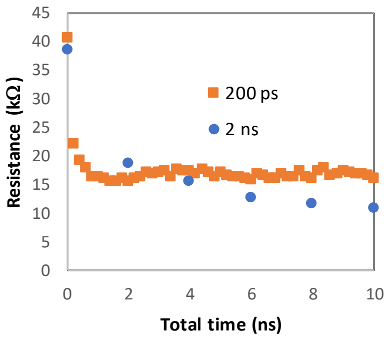

Figure 10. *Comparison of the resistance update in SET operations during applyed trains of five 2 ns pulses (circles) and fifty 200 ps pulses. X-axis corresponds to the total time of the applied pulse voltage.*

This understanding is verified by reducing the time window between the pulses, enabling heat buildup during the pulse sequence. SET cycles are performed by applying repeated pulse sequences of 5 pulses of 200 ps duration; each SET cycle had a specific inter-pulse time window, Fig. 11. The shortest inter-pulse time resulted in higher conductance increase within a given overall pulse cycle duration, while inter-pulse times longer than 200 ps had no effect (consistent with the longer

Veksler, Dmitry; bersuker, gennadi; Bushmaker, A; Mason, Maribeth; Shrestha, Pragya; Cheung, Kin (Charles); Campbell, Jason; Rueckes, T; Clevlend, L; Luan, H; Gilmer, D. ”Memory update characteristics of carbon nanotube memristors (NRAM) under circuitry-relevant operation conditions.” Paper presented at 2020 International Reliability Physics Symposium, Dallas, TX, US. April 28, 2020 - May 30, 2020.

pulses in Fig. 10). This indicates that no heat build-up "around" the forming conductive paths occurred under longer pulses since the emitted energy had sufficient time to dissipate throughout the film. Thus, extremely short pulses (< 200 ps) restrict the SET process by limiting energy supply. This suggests that SET is likely associated with a growing number of CNT contacts gradually establishing a conductive CNT cluster under applied voltage. In ReSET, however, a longer pulse results in drastic resistance increase, Fig. 9, suggesting that a dissociation of CNTs contacts is assisted by the local temperature increase driven by energy released around the conductive paths.

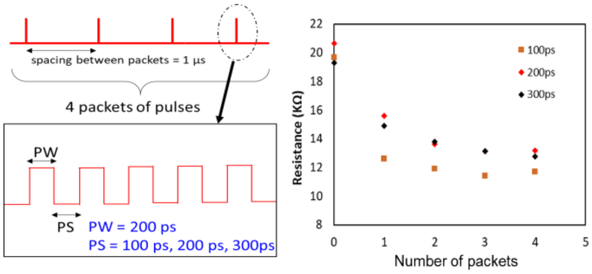

Figure 11. SET: *Resistance updates (r.h.s. graph) under four different pulse sets, each contains five 200 ps pulses. intervals between pulses (PS): 100ps, 200 ps, 300 ps (as marked in l.h.s. graph).*

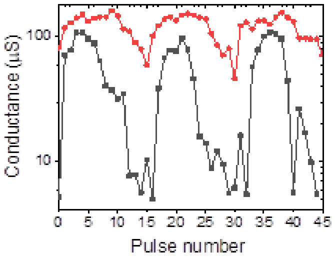

Figure 12. *Conductance switching under 400 ps SET/ReSET pulses Red curve: Vset = 2.5 V and Vreset = -2.4 V; black curve: Vset = 2.3 V Vreset = -2.0 V. . Switching stability and repeatability strongly depends on the pulse amplitude.*

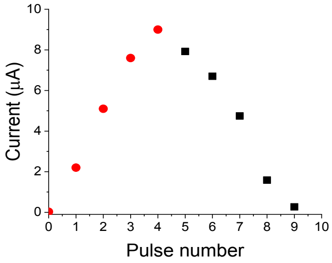

Figure 13. *Quasi-linear and symmetrical gradual conductance update achieved through optimization of switching conditions.*

I. Conclusion

Assessing device operations employing picosecond-range pulses is essential since characteristic time constants in both SET and ReSET processes are found to be on the order of a few hundred picoseconds. NRAM cell shows a stable switching characteristic under sequences of SET/ReSET pulses of 400 ps width at 200 ns intervals, Fig. 12, exhibiting higher resistance under lower pulse voltages. Under properly selected conditions, NRAM demonstrates symmetric quasi-linear memory updates, Fig. 13, making it a promising technology for DNN implementation. Future development of NRAM technology for neuromorphic applications may proceed with the focus on continuous improvements of switching stability and operational current range.

***Abstract*—Millimeter-wave (mmWave) communication is one of the cornerstone innovations of fifth-generation (5G) wireless networks, thanks to the massive bandwidth available in these frequency bands. To correctly assess the performance of such systems, however, it is fundamental to have reliable channel models, based on a deep understanding of the propagation characteristics of the mmWave signal. In this respect, ray tracers can provide high accuracy, at the expense of a significant computational complexity, which limits the scalability of simulations. To address this issue, in this paper we present possible simplifications that can reduce the complexity of ray tracing in the mmWave environment, without significantly affecting the accuracy of the model. We evaluate the effect of such simplifications on link-level metrics, testing different configuration parameters and propagation scenarios.**

I. Introduction

The next generation of Cellular and Wireless Local Area Network (WLAN) will be the first to exploit millimeter wave (mmWave) frequencies to provide connectivity in the access network, i.e., in the links between base stations and mobile users. In particular, 3rd Generation Partnership Project (3GPP) NR has been designed to support a carrier frequency up to 52.6 GHz in Release 15 [1], and future Releases will consider an extension to 71 GHz and the sub-THz band [2]. Similarly, IEEE 802.11ad and 802.11ay exploit the unlicensed bands at 60 GHz [3]. The mmWave frequencies, indeed, feature large chunks of untapped bandwidth that can increase the data rate provided to the end users, making it possible to target the 5th generation (5G) requirements of ultra-high peak throughput (20 Gbps) and average user experienced rate (50-100 Mbps) [4]. Moreover, the small wavelength enables the design of antenna arrays with tens of elements in a small form factor, which could fit even smartphones or VR headsets.

The propagation characteristics of the Radio Frequency (RF) signals in these frequency bands, however, complicate the design of reliable communication systems [5]. First, the high propagation loss, which is proportional to the square of the carrier frequency, limits the coverage region of the mmWave base stations. This can be compensated by using beamforming with large antenna arrays, which could concentrate the power in narrow, directional beams and increase the link budget. Additionally, mmWave signals can be easily blocked by obstacles (e.g., vehicles, buildings, human bodies), preventing direct Line-of-Sight (LoS) communications. Furthermore, at mmWave frequencies, the increased diffraction results in deep shadow regions, thus further degrading propagation performance [6]. By considering the combination of these phenomena, the mmWave channel appears extremely volatile to mobile users, whose quality of experience may be poor unless a proper network design is adopted.

A. Channel Modeling for mmWaves

As experimental platforms and testbeds at mmWaves are still at an early development stage [7], [8], analysis and simulation play a fundamental role for the performance evaluation of novel solutions for mmWave networks. Given the aforementioned behavior of the channel at such high frequencies, and the interplay with network deployment choices and beamforming design, the accuracy of analysis and simulation depends on that of the channel model even more than at conventional sub-6 GHz frequencies. Therefore, the research community has developed a number of channel modeling tools for mmWaves, with a varying degree of complexity and accuracy. Stochastic and analytical models are based on the combination of random variables fitted on traces and measurements, and are widely used for analysis [9], [10] and system-level simulations [11], [12]. However, the generality of these models and their stochastic nature fits poorly with the need to accurately characterize specific scenarios. Additionally, most stochastic models may not properly characterize the specific features of the mmWave channel that may affect the overall system performance, such as the temporally- and spatially-consistent updates of the LoS condition and the evolution of each single Multi Path Component (MPC).

These modeling challenges are instead addressed by Ray Tracers (RTs), which have been used to precisely characterize the propagation of RF signals in specific scenarios [13], [14], [15]. With ray tracing, the channel is modeled in terms of MPCs that generate from a certain location and angle of departure, are reflected (and, in complete models, diffused) on the scattering surfaces of the scenarios, and reach the position of the receiver with a certain angle of arrival, delay and power [16]. As the generation of MPCs is purely based on the geometry of the scenario, the channel is as accurate as the description of the scenario, and the MPCs are consistent

with the mobility model of the communication endpoints. Additionally, ray tracers can be easily integrated into system-level simulators, by computing the channel matrix $\mathbf{H}$ that combines the different multipath components and the antenna arrays of the network nodes.

With currently available channel modeling tools, however, a higher accuracy translates into a higher computational complexity for the MPC generation and the simulations. As we discuss in [17], the complexity is proportional to two elements, i.e., the number of MPCs which need to be combined to generate the channel matrix $\mathbf{H}$, and the number of antennas at the two endpoints of the communication link (which represents the number of columns and rows of $\mathbf{H}$).

B. Contributions

Based on the above introduction, in this paper we investigate whether it is possible to improve the trade off between accuracy and complexity in mmWave simulations, by studying simplification techniques for ray tracers that speed up the simulations and the ray tracer itself. Specifically, we consider processing only MPCs whose received power is above a certain threshold, which is relative to the strongest MPC, and limit the maximum number of reflections for each MPC. Our results show that it is possible to decrease the complexity of the simulations with a minimal reduction in accuracy, with respect to the baseline ray tracer implementation (i.e., without simplifications).

These promising results are a first step towards understanding and isolating which are the most fundamental channel modeling components at mmWave frequencies, and could stimulate further investigations into whether it is possible to develop simplified channel models (e.g., to be used also for mathematical analysis) that are more representative of the mmWave propagation than the widely-used Nakagami-m or Rayleigh fading models [18].

The rest of the paper is organized as follows. In Section II we provide details on the ray tracer we consider as baseline. We then introduce possible simplifications in Section III, while performance results are discussed in Section IV. Finally, we conclude the paper in Section V.

II. The Millimeter Wave Ray Tracer

To simulate a realistic channel, an open-source MATLAB ray tracer was used[1]. The ray tracer was built with mmWave propagation in mind and for this reason, given the deep shadow effect that diffraction yields at such high frequencies [6], only specular reflections are considered. In this work, diffuse reflections are ignored, but their importance is undoubted and will thus be part of our future analysis. Currently, the ray tracer accepts Computer-aided Design (CAD) files in AMF format with scenarios described by triangles of different materials.

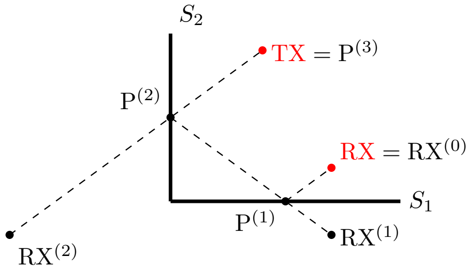

Fig. 1: Visualization for the Method of Images algorithm for a second-order reflection ($N = 2$).

Specular reflections are computed using the Method of Images (MoI), a basic principle from antenna theory [19]. Given two points in 3D space, i.e., the Transmitter (TX) and the Receiver (RX), and a surface S, the MoI defines the virtual image of the RX ($\mathrm{RX}^{(1)}$) to be the reflection of the RX ($\mathrm{RX}^{(0)}$) across the given surface S. By joining the TX with the $\mathrm{RX}^{(1)}$, it is possible to easily compute the point of specular reflection $\mathrm{P}^{(1)}$ as the intersection of the segment with S. It is necessary, though, to check if the reflection point is inside the bounded surface, otherwise the reflection will be discarded. Furthermore, it is also necessary to check that every other surface of the scenario does not intersect the two segments at any point, otherwise the whole ray will be considered obstructed and thus discarded.

When multiple reflections are considered, the MoI applies recursively. Specifically, given an array of reflecting surfaces $\mathcal{S} = (S_1, \dots, S_N)$, $\mathrm{RX}^{(n)}$ is computed as the virtual image of $\mathrm{RX}^{(n-1)}$ for surface S_n, $n = 1, \dots, N$. Then, defining $\mathrm{P}^{(\mathrm{N+1})} = \mathrm{TX}$, the reflection point $\mathrm{P}^{(\mathrm{n})}$ is computed as the intersection between the surface S_n and the segment joining $\mathrm{P}^{(n+1)}$ and $\mathrm{RX}^{(n)}$. Finally, a check is needed on every path segment $\left(\mathrm{P}^{(n)}, \mathrm{P}^{(n+1)}\right)$ to asses whether it is obstructed by any triangle of the environment. Fig. 1 shows a visual example of the MoI algorithm.

To compute all possible reflections between the RX and TX, a *reflection tree* is created, based on the geometric information extracted from the CAD file. In a reflection tree, all nodes except the root (the TX) correspond to triangles of the environment. For each node, its children coincide to all the visible triangles of the environment with respect to that node. Thus, the depth of the tree corresponds to the maximum reflection order $\eta_{\max}$ (given as an input configuration parameter), i.e., the maximum number of reflections per MPC that the RT computes, and each path from the root to a node at depth d corresponds to an ordered array of d reflecting surfaces. By following all the paths for each tree depth d, all possible array of triangles are tested and thus every reflected ray is computed.

An accurate profiling of the software shows that the most demanding parts of the RT operations are the geometric computations (i.e., computing the position of virtual RXs, computing the point of specular reflection, check if the point is inside the bounded surface) and the obstruction checks. The complexity of the geometric computations is proportional to $\eta_{\max}$, while obstruction checks scale both with $\eta_{\max}$ (every segment has to be checked) and the environment complexity (any triangle can potentially block the propagation of the ray).

Finally, if the ray reflections are valid and it is not ob-

[1] Ray tracer implementation: https://github.com/wigig-tools/qd-realization

structed, path gain is computed as

$$PG = \left(\frac{\lambda}{4\pi d}\right)^2 - \sum_{n=1}^{N} RL_n, \qquad (1)$$

where λ is the wavelength (that is a function of the carrier frequency f_c), d is the total distance traveled by the ray, and RL_n is the reflection loss of the material associated to the n-th reflecting surface [16]. Together with the delay, phase, angle of departure, and angle of arrival, the path gain is returned as an output by the ray tracer and written to a file in a specified format, which can be fed as input to other simulators (e.g., link-level or system-level simulators) to compute the channel between the two nodes.

To further simplify the software, no polarization is considered, and rays reflected by a surface experience a 180° phase rotation and a reflection loss of $RL_n = 7$–25 dB, depending on the material but irrespective of the angle of incidence.

III. How to Simplify the Millimeter Wave Channel

As introduced in Sec. II, the number of multipath components of the channel between two endpoints heavily affects both the RT computational complexity and the performance of network-level simulators [17]. For this reason, in this work we propose two different strategies to reduce the total number of MPCs, and analyze the effects that this simplification yields on the system behavior. The two strategies we introduce are based on considerations related to the power of each single MPC, based on the idea that weak MPCs do not significantly contribute to the overall signal at the receiver.

For the first simplification approach, we reduce the number of reflections $\eta_{\max}$ that the RT computes. Indeed, when considering an increasing number of reflections, the MPC experiences a decreasing path gain PG, as the absorption on the reflecting surfaces severely degrades the power of the ray and the length of the ray increases. Therefore, MPCs that bounce across multiple scattering surfaces do not impact very much the power at the receiver, and can be omitted from the RT computations. Limiting the maximum reflection order corresponds to setting a bound to the depth of the reflection tree, whose size, as mentioned in the previous section, is exponential on the maximum reflections order $\eta_{\max}$. Therefore, reducing $\eta_{\max}$ reduces the complexity of both the RT and of the network simulators that use it to model the channel.

Following similar considerations, the second strategy aims at discarding the weakest MPCs based on how low their path gain is, regardlessly of how many reflections they actually experience. Using this method, the path gain PG for a ray still needs to be computed, therefore the geometric operations will not be spared. However, the obstruction check may not need to be performed in the case PG is below a certain threshold, and the ray is not accounted for when computing the channel matrix $\mathbf{H}$. The method we propose is based on a threshold γ_{th} which is relative to the $PG_{\max}$ of the strongest MPC for a given channel realization. Notably, the rays with path gain $PG/PG_{\max} < \gamma_{\text{th}}$ are discarded. The path gain associated with the strongest ray $PG_{\max}$ is updated on-line.

TABLE I: Parameters used for simulations.

P_{TX}	30 dBm	TX Array Config.	8×8
f_c	60 GHz	RX Array Config.	4×4
Noise Figure (F)	5 dB	Element pattern	Omni-directional
Bandwidth	400 MHz	Element spacing	$\lambda/2$

Selecting the MPCs with a relative, rather than an absolute threshold, makes it possible to dynamically adapt the simplification to the actual quality of the channel. For example, in Non-Line-of-Sight (NLoS) conditions, the strongest MPC will be given by a reflected ray. Therefore, its path gain $PG_{\max}$ will be comparable to that of a higher number of MPCs (given by other reflections) than in a LoS scenario, where the strongest ray is the direct path, with a much higher power than the reflections. If the reflections have a PG similar to $PG_{\max}$, then the receiver experiences a strong fading. In this case, a *relative* threshold combines accuracy (in NLoS, significant MPCs are still computed) and reduction in complexity (in LoS, several negligible reflected MPCs are not accounted for), more than an absolute threshold, which would apply the same cut in both cases.

We implemented the proposed simplification techniques on top of the open-source ray tracer described in Sec. II. Although such methods are beneficial from a computational point of view, they may have some drawbacks, depending on the reliability requirements of the application for which the ray tracer is used. The most evident downside is that the power spatial distribution can be affected in complex and non-foreseeable ways, as we will show in Sec. IV.

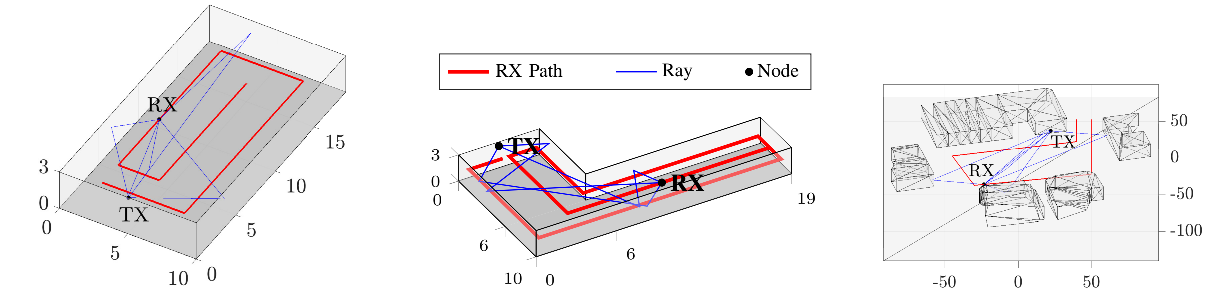
IV. Performance Results

In this section we evaluate through simulations the effects of the ray tracer simplifications we presented in Sec. III. In particular, we investigate the impact of (i) the maximum number of reflections $\eta_{\max}$ per MPC, and (ii) the received power threshold γ_{th} (relative to the strongest path) below which MPCs are are discarded by the ray tracer.

Three scenarios are defined as follows:

1) *Indoor1*: A simple scenario of a box-like room (Fig. 2a) of size $10 \times 19 \times 3$ m. A TX is positioned close to the ceiling, half-way through the wall at $(5, 0.1, 2.9)$ m while the RX, 1.5 m tall, moves inside the room at a speed of 1.2 m/s in spiral-like motion;
2) *L-Room*: Details of this scenario are shown in Fig. 2b. Similarly to the *Indoor1* scenario, the RX of the same height as the previous one moves at a speed of 1.2 m/s;
3) *Parking-Lot*: Outdoor scenario with building around a parking area of about 120×70 m. A TX is positioned on a building 3 m high and a RX is moving at a speed of 4.17 m/s (15 km/h) around the parking lot (see Fig. 2c).

All scenarios have been sampled every 5 ms, thus a total of approximately 9 000, 12 500, and 15 000 time-steps respectively. A list of parameters used in our simulations is shown in Table I. Optimal single-stream SVD-based beamforming is used.



(a) *Indoor1*

(b) *L-room*

(c) *Parking Lot*

Fig. 2: Visual representations of the proposed scenarios

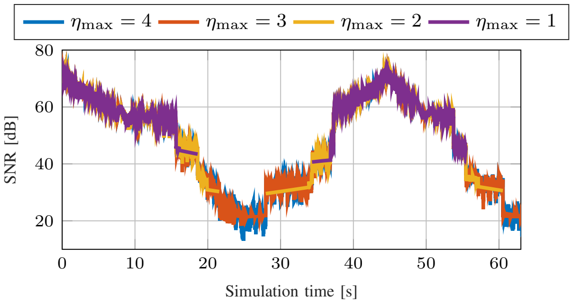


Fig. 3: Temporal evolution of the SNR experienced when a test RX moves in the *L-room* scenario vs. $\eta_{\max}$, fixing $\gamma_{\text{th}} = -\infty$.

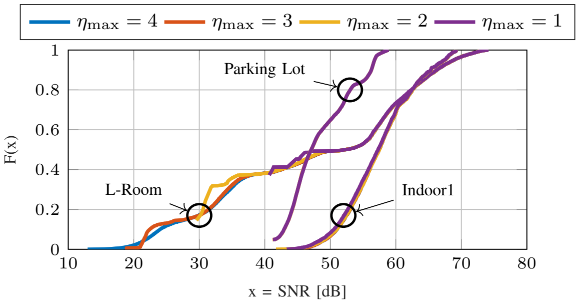

Fig. 4: Cumulative Distribution Function of the SNR when the test RX moves in different simulation scenarios vs. $\eta_{\max}$, with $\gamma_{\text{th}} = -\infty$.

The following performance metrics are considered:[2]

- The RT simulation time T_{RT} [s], i.e., the time taken by the RT software to compute the channel between each pair of nodes at each time-step;
- The MATLAB Net. Sim. Time T_{run} [s], i.e., the time taken by our custom MATLAB simulator to compute the relevant metrics starting from the output of the RT software;
- The Normalized Root Mean Square Error (NRMSE) of the Signal-to-Noise Ratio (SNR), an accuracy indicator that compares the SNR Γ_t experienced when the most accurate RT settings (e.g., with $\eta_{\max} = 4$ and $\gamma_{\text{th}} = -\infty$ for the *L-room* scenario) are considered and the SNR $\hat{\Gamma}$ experienced when different combinations of RT simplifications are applied. Formally, if σ_Γ represents the standard deviation of the baseline SNR Γ, we have

$$\text{NRMSE} = \frac{\text{RMSE}}{\sigma_\Gamma} = \frac{\sqrt{\mathbb{E}\left[\left(\Gamma - \hat{\Gamma}\right)^2\right]}}{\sigma_\Gamma}. \quad (2)$$

In Fig. 3 we consider two nodes and measure the SNR that the probing RX experiences when moving along the path shown in Fig. 2b vs. the maximum number of reflections per MPC $\eta_{\max}$. Rapid variations in the SNR are due to MPCs interfering constructively and destructively, since they observe slightly different path lengths and at least 5 of them have similar path gain in the LoS regions, specifically, the LoS ray and the first-order reflections from ceiling, floor and the two side walls, showing the strong fading in the order of $\lambda = 5$ mm (at 60 GHz). First, we notice that the SNR evolves consistently with the mobility of the RX: the SNR suddenly degrades when the RX enters a NLoS condition and is maximized when it is in LoS with its serving TX, i.e., around time $t = 0$ s and $t = 45$ s. At first glance, it appears that the effect of the RT simplifications is not negligible. In particular, considering the lowest possible value of the relative threshold, i.e., $\gamma_{\text{th}} = -\infty$, the trend of the SNR visibly changes when progressively limiting the maximum number of reflections for each MPC. The impact of those simplifications is particularly evident when the RX operates in NLoS, i.e., when the number of MPCs as little as one (when fading stops) or even none (when no power is received). Despite the above considerations, in the following results we will show more explicitly the accuracy vs. speed trade-off of these parameters in the different scenarios. Furthermore, we will suggest working points for which computation time is significantly reduced with only minor effects on the accuracy of the model.

In Fig. 4 we plot the Cumulative Distribution Function (CDF) of the SNR experienced in different scenarios as a function of the parameter $\eta_{\max}$. The abrupt termination of the CDFs for the *L-Room* and *Parking Lot* scenarios is due to positions of RX/TX for which no ray was able to reach

[2] In this paper, we focus on low-layer performance metrics. In turn, investigating the impact of the proposed RT simplifications on higher-layer performance metrics represents a very interesting research topic that will be part of our future work.

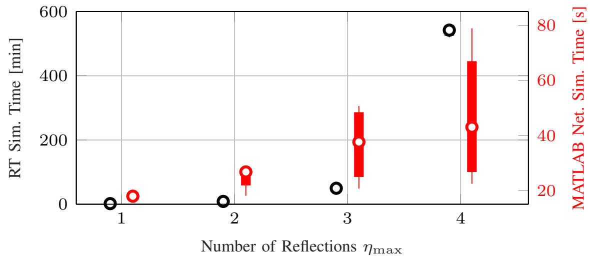

Fig. 5: Box-plots representing the computation time vs. $\eta_{\max}$ when a test RX moves in the *L-room* scenario for all values of γ_{th}. Each box is delimited by the first and the third quartiles of the simulation time, the box's center dot represents the median of the simulation time, and the lines extending from the box (*whiskers*) indicate variability outside the upper and lower quartiles. Each box includes every combination of γ_{th}.

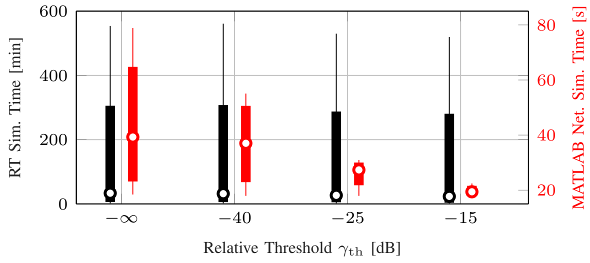

Fig. 6: Box-plots of the computation time vs. γ_{th} when a test RX moves in the *L-room* scenario for all values of $\eta_{\max}$. Each box is delimited by the first and the third quartiles of the simulation time, the box's center dot represents the median of the simulation time, and the lines extending from the box (*whiskers*) indicate variability outside the upper and lower quartiles. Each box includes every combination of $\eta_{\max}$.

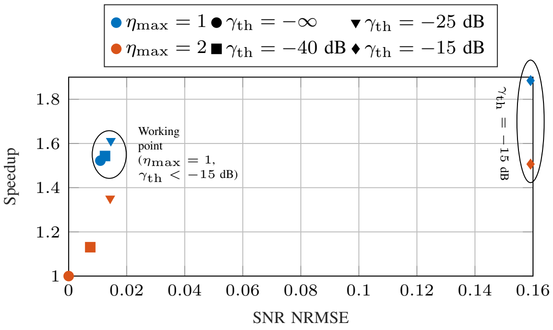

Fig. 7: Speedup vs. SNR NRMSE for different combinations of the RT simplifications when a test RX moves in the *Parking Lot* scenario. $N_{\text{run}} = 1000$ simulations are considered.

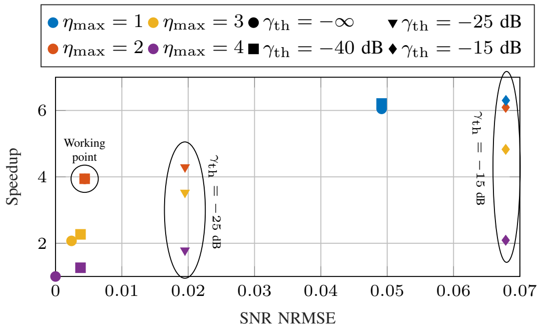

Fig. 8: Speedup vs. SNR NRMSE for different combinations of the RT simplifications when a test RX moves in the *L-room* scenario. $N_{\text{run}} = 1000$ simulations are considered.

with the given $\eta_{\max}$, thus resulting in a complete outage. We observe that, unlike in the *L-room* scenario, in the *Parking Lot* and *Indoor1* scenarios the RX preserves the LoS with its serving TX for the whole duration of the simulation, thereby maintaining very high values of SNR, i.e., above 40 dB. Moreover, Fig. 4 shows that, while in the LoS regime it is possible to reduce the number of reflections $\eta_{\max}$ for each MPC with a minor impact on the accuracy, in the NLoS regime of the *L-room* scenario (i.e., the leftmost part of the figure) the same operation significantly reshapes the CDF of the SNR, thereby confirming the results we obtained in Fig. 3.

On the other hand, decreasing $\eta_{\max}$ speeds up the simulations by several orders of magnitude, as exemplified by the boxplots in Figs. 5 and 6. We can see that the MATLAB simulation time can be reduced by a factor up to 2.4× going from $\eta_{\max} = 4$ to $\eta_{\max} = 1$. The improvement is even more remarkable considering the RT simulation time: the speedup is as significant as 25× considering $\eta_{\max} = 3$, and even 275× for $\eta_{\max} = 4$. Fig. 5 also shows that the configurations with $\eta_{\max} = 3, 4$ exhibit very diverse simulation run time, which is an indication of the increased variability of the channel due to scattering and reflection of the MPCs from nearby surfaces. Similarly, the box-plot in Fig. 6 illustrates that the speedup factor is inversely proportional to the relative threshold γ_{th}, since higher values of γ_{th} makes it possible to reduce the number of MPCs to be processed by the ray tracer as described in Section III, which represents one of the most computationally intensive steps of a simulation and which directly impacts on the channel generation process.

Overall, it is possible to identify which level of simplification is most adequate, i.e., which one provides accurate results while minimizing the overall simulation time. To this aim, in Figs. 7 and 8 we plot the trade-off between simulation speedup and NRMSE of the SNR for the outdoor *Parking Lot* and *L-room* scenarios, respectively. Since, typically, simulations are used to evaluate how changing a set of parameters affects the network performance, and should be repeated with several random seeds to increase the robustness of the obtained results, simulation campaigns would reuse the same RT channel traces for hundreds or thousands of simulations. For this reason, we consider the speedup relative to the total campaign time, which is roughly equal to $T_{\text{TOT}} = T_{\text{RT}} + N_{\text{runs}} T_{\text{run}}$, where T_{RT} is the RT computation time, N_{runs} is the number of independent simulations that are run, and T_{run} is the network simulation run time.

For the *Parking Lot* case (Fig. 7), we can see that all the investigated combinations of simplifications with $\gamma_{\text{th}} < -15$ dB deliver similar values of SNR NRMSE, while reducing the computational complexity with respect to the baseline implementation (i.e., with $\eta_{\max} = 2$ and $\gamma_{\text{th}} = -\infty$). In this scenario, the measured power has limited contribution from the reflected rays, and the optimal approach would be to opt for the configuration with $\eta_{\max} = 1$ and $\gamma_{\text{th}} = -25$ dB: the corresponding speedup is around 60% compared to the baseline ray tracing model.

For the *L-room* case (Fig. 8), instead, it is possible to identify two operational regimes. On the one hand, very high (low) values of γ_{th} ($\eta_{\max}$) would inevitably lead to a performance degradation in terms of SNR NRMSE, due to the dominant contribution of the reflected signals to the overall received power. On the other hand, reflected rays of order higher than the second have a negligible impact in terms of SNR NRMSE (the gap between the $\eta_{\max} = 2$ and $\eta_{\max} = 3$ configurations, with $\gamma_{\text{th}} = -40$ dB, is just 0.001) in the face of a speedup improvement of around 100%. In this scenario, further reducing γ_{th} would result in a considerable increase of the system complexity while leading to negligible accuracy gain, and the optimal approach would be to select $\eta_{\max} = 2$ with $\gamma_{\text{th}} = -40$ dB.

Finally, we highlight that, while limiting the number of MPCs reduces the ray tracer complexity, it may preclude the implementation of beamforming techniques that exploit the sparsity property of the channel to realize simultaneous beams in independent angular direction (e.g., MIMO techniques exploiting spatial multiplexing). Additionally, while simplifications might have minimal implication on low-layer performance metrics, e.g., the SNR, their effect on higher-layer metrics, e.g., end-to-end throughput and latency, is still unknown and deserves further investigation.

V. Conclusions and Future Work

In this paper, we presented possible simplifications to reduce the complexity of channel modeling through ray tracing. Notably, after an introduction on how a RT works, and on which are the sources of computational complexity for the RT, we discussed two strategies which aim at avoiding computations for MPCs which do not contribute significantly to the overall received power. The first limits the maximum reflection order, while the second removes MPCs with a path gain which is much smaller than that of the strongest ray. We then evaluated the impact of these simplifications on the SNR, in three different scenarios, and on the run time of the RT and of a network simulator. We highlighted that, for each scenario, there exists an optimal working point which minimizes the accuracy loss with respect to the baseline, but reduces the channel generation and modeling time by up to 4 times.

As future works, we will consider a more complex RT, which also includes diffuse components, according to a quasi-deterministic model [20]. Moreover, we will study the impact of the simplifications on the higher layers of the protocol stack, by using the ns-3 802.11ad module [21] (which already integrates the RT) and by extending the ns-3 mmWave module [12] to use RT traces.

***Abstract*—The magnet system for the Quantum Electro-Mechanical Metrology Suite (QEMMS) Kibble balance is being manufactured. The QEMMS Kibble balance will be used to measure masses nominally around 100 g and the magnet system will be able to generate forces up to 1 N. Some aspects of the magnet system and the measurement procedure used to determine the profile of the magnetic field are described here.**

***Index Terms*—QEMMS, Kibble balance, mass measurement, magnet system, gradiometer coil.**

I. Introduction

The Kibble balance is an instrument used to realize the unit of mass. In this instrument, the gravitational force generated by a mass prototype is compensated by the electromagnetic force of a current-carrying conductor in a magnetic field [1]. It is fundamental to measure the electromagnetic force with high accuracy in order to determine the mass of the prototype. By measuring the flux gradient Bl in the coil, it is possible to determine the relation between electromagnetic force and current. The flux gradient is equal to the product of the magnetic flux density in the coil region and the coil length. It is an advantage to have a flat Bl profile for determining the flux gradient in the coil region with high precision. In the following, a brief description of the magnet system, the electromagnetic force, and the measurement strategy used are provided.

II. Magnet system

The magnet system is shown in figure 1. It is composed of two permanent magnets and one iron yoke made of soft steel. The design of the magnet system is described in detail in [2]. The permanent magnets are comprised of TC-16 ($Sm_2Co_{17}Gd$) arc segments. This material exhibits a temperature coefficient for the remanent magnetization of $-0.001\,\%/\mathrm{K}$. The magnet system is responsible for generating the magnetic flux through the coil, which is necessary to produce the electromagnetic force. A stable remanent magnetization for the permanent magnets is necessary in order to perform the mass measurement with high precision.

III. Electromagnetic force

The original equations for the Kibble balance principle are shown in [1]. Consider a coil with inductance L which encloses a magnetic flux Φ_R. When a current I flows, the total magnetic flux through the coil is $\Phi = \Phi_\mathrm{R} + LI$ and the energy is $W = -I\Phi_\mathrm{R} - I^2L/2$. If Φ_R and L are a function of displacement z of the coil, then a component of force exists:

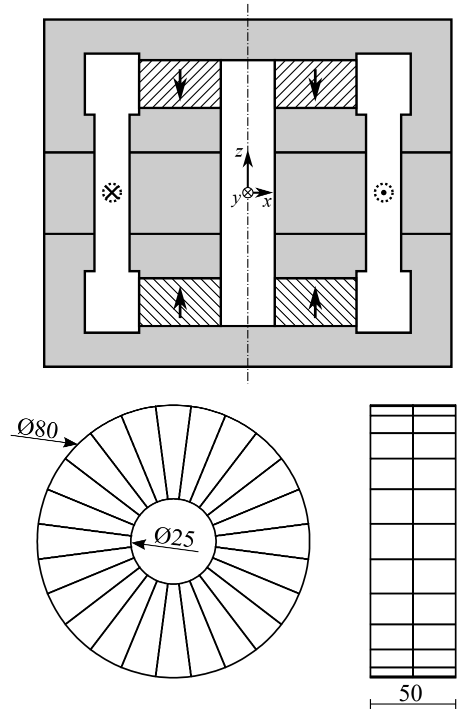

Fig. 1. Upper part: Magnet system with the coil. Axes x and y represent the horizontal directions and z axis represents the vertical direction. Lower part: Permanent magnet ring composed by TC-16 ($Sm_2Co_{17}Gd$) arc segments. The numbers are dimensions in millimeter.

$$F_\mathrm{z} = -\frac{\partial W}{\partial z} = I\frac{\partial \Phi_\mathrm{R}}{\partial z} + \frac{I^2}{2}\frac{\partial L}{\partial z} \tag{1}$$

If the coil moves with a velocity v in the same direction, an induced voltage U is obtained:

$$\frac{U}{v} = -\frac{\partial \Phi}{\partial z} = -\frac{\partial \Phi_\mathrm{R}}{\partial z} - I\frac{\partial L}{\partial z} \tag{2}$$

In the Kibble balance experiments, equation (1) is known as the force mode and equation (2) is known as the velocity mode. For the NIST Kibble balance, there is no current during the velocity mode (equation 2). In order to minimize measurement deviations caused by $\partial L/\partial z$ during the force mode, a symmetric weighing with mass-on/mass-off strategy is performed [2].

Marangoni, Rafael; El Haddad, Darine; Seifert, Frank; Chao, Leon; Newell, David B.; Schlamminger, Stephan. "Measurement of the magnet system for the QEMMS." Paper presented at 2020 Conference on Precision Electromagnetic Measurements (CPEM), Denver, CO, US. August 24, 2020 - August 28, 2020.

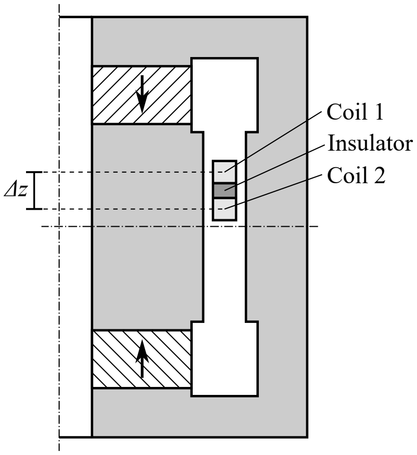

Fig. 2. Gradiometer coils used for measuring the magnetic field profile. Two coils separated by an insulator are used for the measurement.

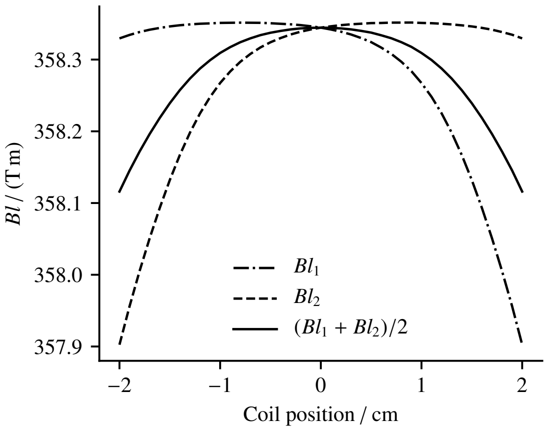

Fig. 3. Profile of the product Bl for the coils 1 and 2 and the mean value between both profiles. This is a result of finite element analysis.

The magnetic flux Φ_{R} is generated by a magnet system with permanent magnets. It is given as a function of coil position and angle x, y, z, θ_{x} and θ_y:

$$\Phi_{\mathrm{R}} = Bl\left(z + \frac{\theta_{\mathrm{y}}x + \theta_{\mathrm{x}}y}{2}\right) \tag{3}$$

where B is the radial flux density in the region where the coil resides and l is the total length of the coil. The coordinates x, y and z are given by a reference frame fixed to the center of the magnet system (figure 1). In a yoke based magnetic system, the coil inductance can be written as

$$L = L_0 - k_{\mathrm{z}}z^2 + k_{\mathrm{x}}x^2 + k_{\mathrm{y}}y^2 - k_{\theta\mathrm{x}}\theta_{\mathrm{x}}^2 - k_{\theta\mathrm{y}}\theta_{\mathrm{y}}^2 \tag{4}$$

where the quantities k_{z}, k_{y}, k_{x}, $k_{\theta\mathrm{y}}$ and $k_{\theta\mathrm{x}}$ are positive real numbers. The gradient of the flux and inductance in the vertical direction is related to the electromagnetic force component used to measure the mass. Ideally the weighing is performed in a position such that the gradient of the flux and inductance in the horizontal and angular directions can be neglected.

As previously mentioned, a flat Bl profile, or a region along z where $\mathrm{d}B/\mathrm{d}z$ approaches 0, is advantageous and can be achieved by implementing shimming techniques found in [3].

IV. Measurement strategy

The gradiometer coils shown in Fig. 2 are used to measure the magnetic flux profile. Two coils separated by a distance Δz of $15.9\,\mathrm{mm}$ are used. This distance is given between the center of both coils. When these coils move in the magnet system with a velocity v, the induced voltages U_1 and U_2 are obtained:

$$U_1 = -v\frac{\partial\Phi}{\partial z}\bigg|_{z+\Delta z/2} \tag{5}$$

$$U_2 = -v\frac{\partial\Phi}{\partial z}\bigg|_{z-\Delta z/2} \tag{6}$$

As described in [3], the profile of the magnetic field can be obtained by performing the following calculation:

$$\Delta Bl(z) = \frac{1}{\bar{v}\Delta z}\int_{z_0}^{z} U_1(\zeta) - U_2(\zeta)\mathrm{d}\zeta \tag{7}$$

The advantage of using this method to measure the Bl profile is the fact that it is not necessary to measure the velocity of the coil v with high precision. In this way, it is possible to use a simple setup to measure the profile.

Figure 3 shows the Bl profiles for the coils 1 and 2, indicated as Bl_1 and Bl_2 respectively. This is a simulation result obtained with finite element analysis. The mean value $(Bl_1 + Bl_2)/2$ between both profiles is shown in the same figure. As described in [2], a value of about $700\,\mathrm{T\,m}$ will be used for the magnet system and coil of the QEMMS. The gradiometer coils were designed in a way that it is possible to connect both coils in series and obtain the desired value for Bl. By doing so, it is possible to use the same coil for the profile measurement and balance operation.

V. Conclusion

The Quantum Electro-Mechanical Metrology Suite will be used to measure masses nominally around $100\,\mathrm{g}$ aimed at achieving absolute uncertainties around $2\,\mu\mathrm{g}$. The magnet system has been designed and is currently being manufactured. The gradiometer coil described in this paper will be used for measuring the profile of the magnetic field and ultimately for balance operation.

***Abstract*—The design status of the Kibble balance for the Quantum Electro-Mechanical Metrology Suite is provided. The balance is being developed with the objective to obtain a simple and robust design while performing high precision measurements. Aspects related to the vacuum vessel and balance mechanism are described. This includes some design information and simulation results.**

***Index Terms*—QEMMS, Kibble balance, mass measurement, vacuum chamber, balance mechanism**

I. Introduction

The Kibble balance is used to realize the kilogram unit since last revision of the International System of Units (SI) [1]. According to the SI, the unit of mass can be realized based on the Planck constant, the speed of light in vacuum and the hyperfine transition frequency of the caesium-133 atom. The Quantum Electro-Mechanical Metrology Suite (QEMMS) is composed by a Kibble balance, a Josephson voltage standard and a Quantum Hall resistance standard. With this system, it is possible to measure mass, length, time, voltage, electrical resistance and current traceable to the SI. The Kibble balance is being developed for measuring masses of 100 g with an uncertainty of 2 µg. The magnet system of the balance has already been designed is currently being manufactured [2]. Further aspects include the balance mechanism and the vacuum chamber, which are discussed in the following.

II. General aspects of the design

The Kibble balance of the QEMMS is being designed to be robust, precise and simpler than the NIST-4 [3]. It will be smaller and will have less operational requirements. Figure 1 shows the general design of the balance with the mechanism, permanent magnet, vacuum chamber, vacuum pump, test mass, counterweight and magnet system for the counterweight side. Some ideas of mechanism and pivots are described in [4]. There are different choices for the mechanism and the pivot, most of them using flexure strips or knife edges.

The balance mechanism is responsible for moving the coil during the velocity mode and acting as a weighing mechanism in the force mode. For the force mode, it is desired to have a stiffness as small as possible. The position of the coil in the vertical direction is measured by using a single laser interferometer. A corner cube located in the center of the coil is used for that. The laser beam (not shown in the figure) is launched outside the balance under the corner cube.

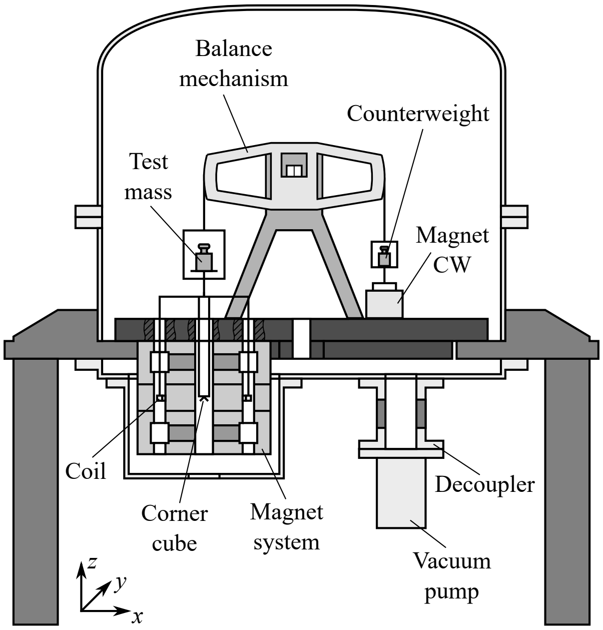

Fig. 1. Design for the QEMMS Kibble balance including the balance mechanism, vacuum chamber and magnet system.

The balance is operated in vacuum in order to avoid measurement deviations caused by the buoyancy force of air in the mass prototype, and also deviations caused by the refractive index of air during the length measurement. For this reason, a vacuum chamber is necessary.

III. Vacuum chamber

A drawing of the vacuum chamber is shown in figure 2. It is basically composed by four parts: dome, base, vessel bottom and bucket. The vessel is designed to operate under pressures down to 1×10^{-4} Pa. The components are made from 304 stainless steel and the inside of the chamber is electropolished. The bucket has to be removed in order to obtain access to the magnet system of the balance. As described in [2], the magnet system was designed with the objective to be split in situ. By removing the dome, it is possible to obtain access to the balance mechanism. This will be done by using a motorized hoist. As shown in figure 1, the vacuum pump is located under the balance and an electrical decoupler is used to mount the pump to the balance.

Marangoni, Rafael; El Haddad, Darine; Seifert, Frank; Chao, Leon; Pratt, Jon R.; Newell, David B.; Schlamminger, Stephan. "Design of the Kibble balance for the QEMMS." Paper presented at 2020 Conference on Precision Electromagnetic Measurements (CPEM), Denver, CO, US. August 24, 2020 - August 28, 2020.

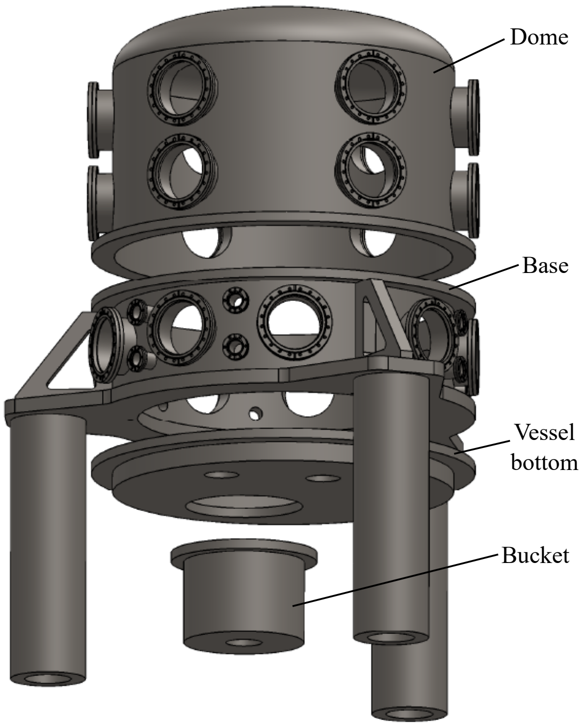

Fig. 2. Vacuum chamber for the QEMMS Kibble balance. The balance is composed by four parts: dome, base, vessel bottom and bucket.

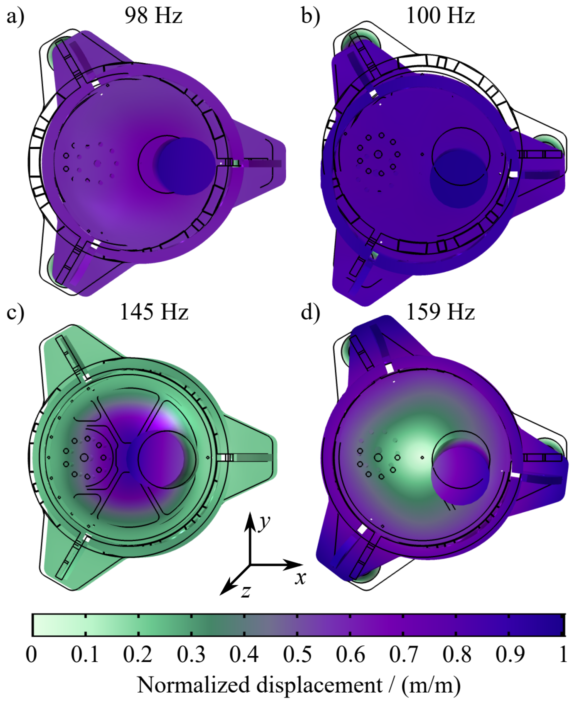

Fig. 3. Vibration modes of the vacuum chamber and respective eigenfrequencies: a) vibration mode along x; b) vibration mode along y; c) drum vibration mode; d) torsional vibration mode about z. Color scale shows the normalized displacement.

Figure 3 shows a result of finite element analysis used to determine the vibration modes and the frequencies of vibration of the vacuum chamber. The dome is not shown in this figure. Since the balance mechanism and its weight are not exactly known yet, an equivalent mass with an estimated weight value was added to the simulation model. The lowest frequencies of vibration are given by the vibration modes in the x and y directions. The natural frequencies are 98 Hz and 100 Hz respectively. The drum vibration mode, which is mostly present in the base plate of the balance, has a natural frequency of 145 Hz. The torsional vibration mode about the z direction has a frequency of 159 Hz. These frequencies are much higher when compared to the frequencies of the balance mechanism. By doing so, the influences of vibrations of the vacuum chamber in the balance mechanism are reduced.

A preliminary design of the vacuum chamber that fulfills the operational requirements of the balance was performed. The size of the vacuum chamber for the QEMMS Kibble balance is at least 7 times smaller in volume than the NIST-4 vacuum chamber. The design itself is simpler and avoids the use of bellows. With the new design, it is possible to access the magnet system without disassembling the balance. The vacuum pump can be assembled under the balance and, by doing so, a more compact design is obtained.

IV. Conclusion

The Kibble balance of the Quantum Electro-Mechanical Metrology Suite (QEMMS) will be used to realize the kilogram unit in a range under 100 g with high precision. The magnet system of the balance was designed and is being manufactured. The vacuum chamber and the balance mechanism are currently being designed. Some simulation results used to determine the vibration modes of the vacuum chamber and the natural frequencies are shown.

***Abstract*—This paper describes a method for calibrating an ac source using a Josephson Arbitrary Waveform Synthesizer (JAWS) by summing the sources in series and tuning the magnitude and phase of the JAWS to null the combined output voltage. The method requires an ac source that can generate a signal that is phase-synchronous with the JAWS. As a demonstration of this method, we measure the output of a calibrator at an rms output of 4 V and a frequency of 1 kHz.**

***Index Terms*—Digital-analog conversion, Josephson junction arrays, measurement standards, signal synthesis, superconducting integrated circuits, voltage measurement.**

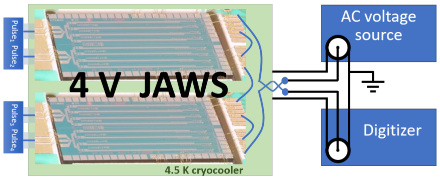

Fig. 1. Diagram of the JAWS source (low-frequency biases are not shown), an ac voltage source under test, and a digitizer used to determine the residual difference between the voltages generated by the JAWS and the source.

I. Introduction

AC voltage metrology is currently based on thermal transfer standards. These standards are broadband rms detectors that typically achieve better than 10 μV/V accuracy and 1 μV/V repeatability in determining the voltage generated by an ac source at voltages less than 10 V and frequencies less than 100 kHz [1]. However, rms detectors are inherently unable to provide information about the spectral purity and phase stability of a source; thus, the measured value incorporates the rms contribution of all input signals spread over the greater-than 10 MHz bandwidth of the detector.

We can improve on this approach based on thermal rms-detectors by directly comparing ac voltage source signals to quantum-based ac voltages generated by a Josephson Arbitrary Waveform Synthesizer (JAWS). A JAWS-based approach results in quantum-based calibrations that are directly linked to the revised SI, and offers a different paradigm of source-based, instead of detector-based, ac metrology. It could also lead to shorter calibration times and improved accuracy.

The basic measurement setup is effectively an ac bridge measurement, shown in Fig. 1. The JAWS source is in series with the output of the ac voltage source under test, and a high-impedance digitizer is used to measure the summed voltage. Since the JAWS is a floating voltage source, it is placed on the "high" side of the ac voltage source and digitizer. The "low" side of the ac voltage source and digitizer are grounded.

Using this setup, the magnitude and phase of the quantum-based JAWS source is tuned to null the voltage measured at the digitizer. Use of a null measurement reduces the importance of the digitizer calibration, and makes it significantly easier to measure small changes in the relative phase and magnitude over time. It is also crucial to confirm that the JAWS source is operating correctly during the measurement. There are two steps to this test. First, it is important to measure the full quantum-locked range (QLR) of the JAWS at the required output voltage magnitude and phase, that is, to confirm that the output of the JAWS source is independent of the JAWS bias parameters over a reasonable range of bias parameters. Second, mini-QLRs should be taken during the ac voltage comparison by making changes to the JAWS bias parameters, which are small enough that the changes are not expected to affect the JAWS output but large enough to observe problems [2].

II. AC Source Requirements

This null measurement approach requires that the ac source be able to operate in a phase-synchronous manner with the JAWS source. There are a number of different ways this requirement can be achieved. One approach is to have the JAWS and ac source share a fast clock signal, typically at 10 MHz, which ensures that the two instruments have synchronous waveforms. Then the two signals can be phase-synchronized by having one system provide a trigger signal at the beginning of a waveform period. Another approach is to force the ac voltage source to phase-lock to a signal provided by the JAWS system at the frequency of interest.

The key feature of both of these approaches, and the requirement for other phase-locking schemes, is that the magnitude and phase of the JAWS output voltage can be changed relative to the ac voltage source in a stable, repeatable manner.

III. Preliminary Results and Discussion

As a demonstration of this technique, we use a JAWS to measure a Fluke 5700A calibrator[1] generating an rms voltage

[1] Commercial instruments are identified in this paper in order to adequately specify the experimental procedure. Such identification does not imply recommendation or endorsement by NIST, nor does it imply that the equipment identified is necessarily the best available for the purpose.

Flowers-Jacobs, Nathan; Rufenacht, Alain; Fox, Anna; Dresselhaus, Paul; Benz, Samuel P. "Calibration of an AC Voltage Source Using a Josephson Arbitrary Waveform Synthesizer at 4 V." Paper presented at Conference on Precision Electromagnetic Measurements, Denver, CO, US. August 24, 2020 - August 28, 2020.

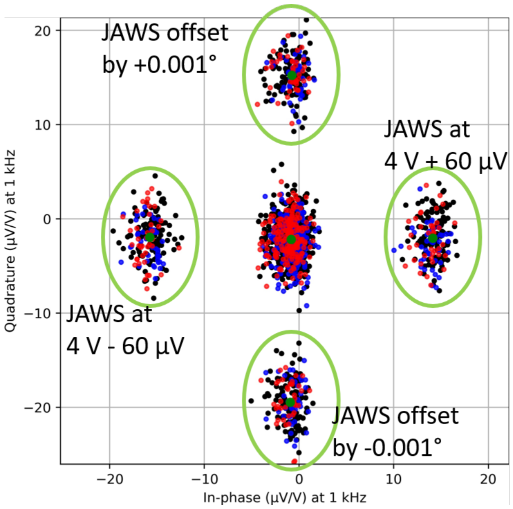

Fig. 2. Residual difference between the 1 kHz 4 V waveforms generated by the JAWS and a calibrator over 13 hours, plotted in the complex plane. The difference after optimizing the JAWS output is in the center (not circled). The JAWS output is also offset by ±0.001°or ±60 μV (labeled green circles). We also take mini-QLRs during the measurement: a JAWS DC bias current of 0 mA (black), +0.5 mA (blue) or -0.5 mA (red) is applied to test the JAWS operation.

of 4 V at 1 kHz. To phase-lock the two systems, the JAWS source provides a stable, optically isolated, 1 kHz square wave to the ”PHASE LOCK IN” port of the calibrator. The phase of the JAWS source is then tuned relative to this square wave, along with the magnitude of the JAWS source, to minimize the voltage measured at 1 kHz on a Zurich Instruments MFLI digitizer. After optimizing the JAWS source, the dc offset current QLR of the JAWS is greater than 1.4 mA with the calibrator generating 4 V and the JAWS generating 4 V in opposition at 1 kHz.

In Fig. 2, we show the results of this measurement over 13 hours. Each data point is the result of analyzing 0.5 s of data. The data are plotted in the complex plane, with small differences in phase along the quadrature/vertical axis and small differences in amplitude along the in-phase/horizontal axis. We also changed the JAWS output by ±0.001°and ±60 μV to characterize the digitizer. Finally, we performed mini-QLRs by applying a dc bias offset of ±0.5 mA to the JAWS arrays during some of the measurements. Since we did not observe any resolvable effects or trends due to these bias variations, we conclude that JAWS produced accurate voltages during the entire measurement. Using all of these data, we note that the calibrator produces a 4 V signal that is, on average, +0.8 μV/V or 3 μV larger than 4 V.

This technique can also be used to look at the short-term phase stability of ac voltage sources. In Fig. 3 we show the results of analyzing in finer detail the data that were used to create a single point in Fig. 2. In Fig. 3, we separately plot the in-phase and quadrature data as a function of time; each data point is taken from four periods of the 1 kHz waveform. We detect short-term changes in the relative phase of the systems which are both significantly larger than the amplitude changes and clearly resolvable over the system noise; similar phase jitter has been seen before [3].

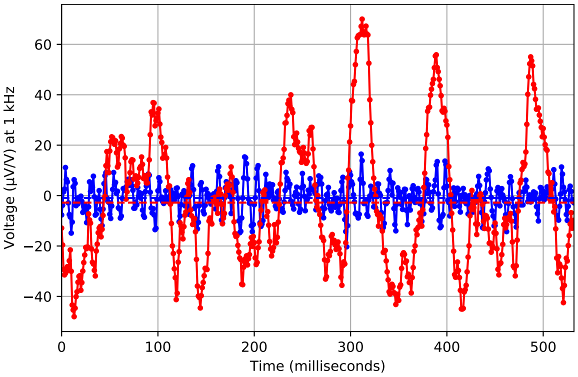

Fig. 3. Residual difference between the 1 kHz 4 V waveforms generated by the JAWS and calibrator plotted versus time. The short-term fluctuations in the quadrature component of the data (red, proportional to phase) are significantly larger than those in the in-phase component (blue, proportional to amplitude).

These results demonstrate the important aspects of this measurement method. At CPEM 2020, we will provide more results and a more detailed uncertainty analysis for evaluating phase and amplitude stability of ac sources. We will also provide results of measurements taken over a wide range of amplitudes and frequencies.

A similar type of analysis can also be used to characterize distortion in ac signals by either directly using the higher frequency information gathered by the digitizer or by distorting the JAWS waveform to cancel the higher frequency content generated by the ac source. The first approach may require calibration of the digitizer, but digitizer non-linearity is less important because the fundamental tone is the predominate signal, and it has already been nulled by the JAWS signal in opposition. The second approach removes any dependence on the digitizer calibration, but requires that the distortion produced by the ac source be stable.

IV. Conclusion

We demonstrated that a quantum-based JAWS voltage source can be used to calibrate other ac voltage sources using a null measurement method where the magnitude and phase of the JAWS is tuned to cancel the other ac voltage source. In the future, this approach can also be used to investigate the short-term stability and distortion of ac voltage sources.

ABSTRACT

Manufacturers currently struggle with the assessment of a machine/robots' accuracy degradation that limits the efficiency of machine/robots in high precision applications. Current best practice in industry is to inspect the final products or add redundancies (local calibration, etc.) during the process to determine the machine's accuracy and performance. These create complexities in the process and increase the maintenance costs of applications such as high precision robot operations (welding, robotic drilling/riveting, and composite material layout), in-process metrology, and machines in mobile applications. A higher speed, more precise control of position and orientation is required to remedy these complexities. A novel smart target was designed at the National Institute of Standards and Technology (NIST) to integrate with a vision system to acquire high-accuracy, real-time 6-D (six-dimensional x, y, and z position, roll, pitch, and yaw orientation) information. This paper presents the development of the smart target and the image processing algorithm to output 6-D information. A use case is presented using the smart target on universal robots (UR3 and UR5) to demonstrate the feasibility of using the smart target to perform the robot accuracy assessment.

INTRODUCTION

Machines and robots are key automation instruments that are widely used in manufacturing, material handling, construction, medicine, and aerospace [1]. In recent years, robots have become more accurate due to improvements in motion control, actuators, and other technologies [2]. These improvements enable the broader use of robots in many new applications. Machines and robots' accuracy assessment is crucial to these applications. Unexpected disturbances due to accuracy degradation may lead to a degradation of the system performance, causing losses in productivity and business opportunities [3]. With current industry practice, it is difficult to detect the accuracy degradation because the machine or robot is continuously running and appears to be making parts that wouldn't not meet the quality requirements, including accuracy requirement.

As shown in Fig. 1, the typical robot errors contain static errors and dynamic errors. Static errors of a 6-axis robot include geometric error (e.g., linkage length, tools, and object in workspace), elasticities (e.g., base, runout, and gears), and temperature change created errors (quasi-static errors); dynamic errors include the trajectory following errors, gear cyclic errors, and axis dynamic limits [2, 4]. Because these errors influence robots' absolute accuracy, traditional hard automation must depend on robot teaching, which is very time-consuming thus increasing the costs of manufacturing. To work around the accuracy problems, many extra sensors and redundancies are added. For example, flexible grippers or extra sensors are implemented to increase task tolerance. Local calibrations are developed to improve local accuracy for the success of precision operations. Sometimes external guidance, for example, a laser tracking system, is added to guide the robot's precision operations [5, 6]. These workaround methods significantly increase the complexity of the manufacturing system and the cost of system maintenance. Moreover, there are new emerging robot applications that require more precise robot operations, for example, high precision assembly, welding, robotic drilling/riveting, robot metrology, and composite material layout. There needs to be an innovative way to design new robot systems instead of continuously using 20-year-old methods. The robot accuracy needs to be measured, assessed, monitored, and improved to support the development of an optimized and simplified production line by enhancing the absolute accuracy. Moreover, economic factors also motivate facilities and factories to perform accuracy degradation assessment and monitoring the robot performance to detect faults and failures. The purpose is to improve maintenance techniques and operations, especially eliminating unexpected shutdowns.

The program is created and simulated offline
Optimize the maintenance strategy

Figure 1. Robot accuracy degradation and influences

A robot's position (x, y, z) and orientation (pitch, yaw, roll) need to be measured to assess the robot's accuracy. The measured 6-D information can be used to calculate the deviations of robot position and orientation, allowing for accuracy degradation monitoring of a robot. The data can also be used as feedback for more accurate control, or as the input of an algorithm to perform calibration for robot performance improvement.

A novel smart target (patent pending) was developed at the National Institute of Standards and Technology (NIST) to integrate with a vision system to acquire high accuracy 6-D information of a moving object. The smart target is mounted on the object of interest, for example, the end effector/tool of a robot arm or the last link of a machine tool to measure/track the object's 6-D position and orientation. The smart target development is a part of the Prognostics and Health Management for reliable operations in Smart Manufacturing (PHM4SM) research at NIST. The PHM4SM project works on developing and deploying measurement science to promote the implementation, verification, and validation of advanced monitoring, diagnostic, and prognostic technologies to increase reliability and decrease downtime in smart manufacturing systems. This paper will present the research background, advanced sensing development, and a software tool to efficiently measure, monitor, diagnose, predict, and maintain the health of a robot. A use case was developed at NIST using Universal Robot UR3 and UR5 to demonstrate the feasibility of the smart target in accuracy assessment application.

RESEARCH BACKGROUND AND APPROACH

There are various measurement systems to acquire 3-D/6-D information [7, 8]. Some old methods including gauges, pose matching, and coordinate measurement machines are very slow. Trilateration with a theodolite, using cable potentiometer systems, or laser interferometers and other methods usually lack orientation information [9-13]. The laser tracker and vision-based system are gaining more attention in recent years.

Laser trackers are one type of high precision 3-D/6-D measurement system [18]. As an important part of the measurement system, measurement targets define what dimensional information can be captured by the system. If a 3-D target is used, 3-D information is captured. If a 6-D target is used, 6-D information is captured. Retro-reflective spheres are an example of a 3-D target for laser trackers. A laser tracker tracks the target to measure distance from the reflected laser beam. Encoders on the laser tracker provide two angular orientations of the tracker's two mechanical axes. By combining the distance and two encoders' angles, the center (x, y, z) of the retro-reflective target is measured [14, 16]. For 6-D information measurement, extra sensors are added to the existing 3-D target, for example, multiple light-emitting diodes (LEDs), thus making a already-expensive system more complex. The retro-reflective target needs to be held in contact with the object of interest. Also, laser tracker systems need to maintain line-of-sight between the laser tracker and the target. This means that the tracker will ultimately lose its view of the target when observing the target on a robot rotating to an angle.

Vision-based systems have the advantages of cost-effectiveness and broader application potentials with advanced image processing technology. The vision-based system includes camera array and structured light technology.

The camera array approach uses multiple cameras placed at different positions to capture multiple images of the same target [17, 19]. A dual-camera system is the simplest yet most popular camera array. Two cameras are separated by a distance, usually with a similar angle of view to benefit the disparity calculation. For each point in space, there is a measurable disparity between its positions in the two camera images. The depth of the point is then calculated using geometry. The main challenge of a camera array is how to find matching points in multiple images with good accuracy. Non-ideal point matching decreases the system's accuracy. Particularly, when multiple cameras are placed with a certain angle to enlarge the overlap of cameras' imaging for larger measurement capability, the non-ideal point matching problem gets more severe. Also, when the measured parts do not have enough features, for example, a smooth surface, the measurement accuracy decreases.

Structured light is an example of a special version of a camera array. Additional active projectors are added to solve the image matching problem in camera array. Projected patterns include fringes, random pattern laser dots, or other known patterns. These known patterns created a phase map to match the matching points in multiple images. A receiver detects the distortion of the reflected pattern to calculate a depth map based on geometry. The structured light system has better depth accuracy performance compared to the camera array system. However, the structured light system may be more expensive because of the costs of active projectors.

Both the camera array and structured light system are sensitive to environmental light. For the camera array, a bright environment works best. Structured light systems work best in a dark environment. When the brightness of the environment changes, images captured by a camera array may become noisy, and contrast becomes poor. This makes point matching extremely difficult resulting in inaccurate depth estimates. Moreover, structured light systems usually need to scan through a set of projected patterns. The measurement instrument and the measured part need to stay stationary during the measurement, which is not suitable for dynamic measurement.

Thus, although a variety of 6-D measurement systems and targets are available, these conventional systems do not have acceptable accuracy and dynamic features that are sufficiently accurate as required by some applications. As such, a new smart target was developed at NIST working with vision-based systems to overcome the challenges presented by complex industrial environments, enabling the measurement of dynamic poses.

ADVANCED SENSING DEVELOPMENT

The smart target system (patent pending) is a novel design to exceed the performance of existing vision-based measurement systems, especially with respect to accuracy and real-time processing potential. As shown in Fig. 2, the smart target consists of fixed-wavelength light pipes and two high-precision rotary gimbals. Three cylindrical light pipes, each a different color, are used to define line features that construct the 6-D information of a coordinate frame. The fixed-wavelength design makes the target stand out from an industrial background. At the same time, the target is not sensitive to environmental light. The red cross allows the vision system to detect the cross center as a coordinate origin. The gimbals are motorized to constantly rotate the red cross toward the measurement instrument for non-blocking dynamic measurement. It maximizes the target's line-of-sight to the vision system, thereby reducing measurement uncertainty. The blue and green pipes move with the object of interest and allow the camera system to determine orientation. This novel design enhances the matching of features across multiple images, especially in the presence of complex, industrial backgrounds. The smart target is mounted on the object of interest, for example, the end effector or tool of a robot arm, or the last link of a machine tool to measure and track the object's 6-D position and orientation. The smart target provides:

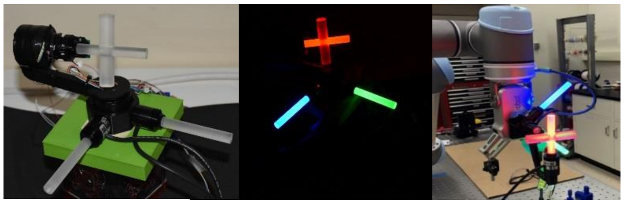

Figure 2. NIST designed smart target

1) High accuracy. Traditional targets have large uncertainty in measuring orientation. The most common traditional targets for vision systems are spheres. With infrared camera systems, the spheres are coated with reflective material or wrapped with reflective tapes. The center of the sphere is the feature to be measured. Multiple spheres are put together to define a coordinate frame. One sphere center may be used to define the origin of the coordinate frame. An axis is defined by two spheres centers. For this type of target, the measurement uncertainties of the sphere center are transferred one-to-one to the coordinate origin definition. Since only two points are used to define the axial direction, the angle measurement uncertainties are enlarged since a small distance error of the sphere center can create a large angular error. On the contrary, the axial direction of the smart target is defined using many points along the cylindrical target's centerline. Thus, the constructed center line is more accurate by fitting multiple points instead of only two points. For the same reason, the origin of the coordinate is created by intersecting two centerlines, which leads to an accuracy increase of 3 times compared to the traditional method of defining the origin using a sphere center. Moreover, extra features of the light pipe, including the fixed-wavelength color, the edge features of cylinders, etc., give more redundant information to improve the line detection accuracy.

2) Non-blocking measurement design to measure both static and dynamic robot tool center point (TCP) data. Traditional targets have the problem of bad pose (perpendicular to the

camera) when the target pose is not sensitive to camera measurement, or the target may block itself in some poses. The smart target has the red cross mounted on rotary axes. The red cross can constantly rotate toward the measurement system. The red cross center is defined as the coordinate system's origin. The rotation mechanism makes the smart target's origin good for measurement in different views without self-blocking.

3) A unique definition of a coordinate frame. Traditional spherical targets do not have a unique definition of a frame. With the bad pose problem, spheres that define the origin may be blocked for measurement. Traditional sphere targets usually use best-fit transformation to find translation and rotation of two sets of center points. Best-fit usually uses the minimum least square errors for the conversing condition, thus not guaranteeing the consistent and minimum error for the origin. The 6-D smart target has a consistent and unique definition of a frame to avoid confusion when multiple coordinates exist in a system.

The 6-D smart target allows the continuous measurement of the 6-D information of a moving object with high accuracy. Applications of the smart target can be any general measurement system that requires high accuracy 6-D information of a moving object, for example, the robot and machine calibration, or multiple machines/tools/objects registrations, or adaptive objects location for unplanned adaptive control, or precisely tracking the pose of an object.

SOFTWARE TOOL DEVELOPMENT

A software tool is needed to process smart target-captured images, extract features, and output 6-D data. Software development was divided between creating a graphical user interface (GUI) to interface with the stereo camera system and designing and implementing an image processing algorithm to identify the smart target and determine its position using stereo images.

The GUI interfaces with the stereo camera system to allow for image processing is shown in Fig. 3. The software implements basic features such as image capture from each camera, video recording from one or both cameras, video playback, live video feeds, and smart target identification. An event handler responds to cameras connecting and disconnecting, as well as image transfer including transfer errors. The software receives images from the two cameras, displays them, and processes them as the user desires.

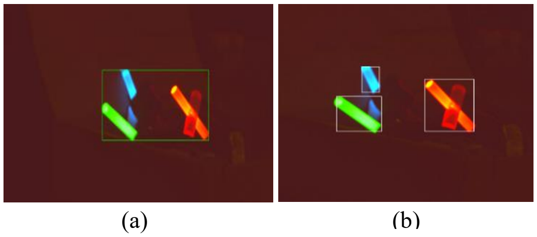
□ Find Whole Target

Figure 3. GUI to interface with the stereo camera system

While the GUI is receiving images from the cameras, the smart target can be tracked. An area of interest is drawn around the smart target in the live video feeds on the GUI to indicate the portion of the image to be used for further processing for location and orientation.

The image processing algorithm uses multiple layers of processing to identify the smart target and extract its location in 3D space. A software filter is applied to images from the two cameras to accentuate the red, blue, and green colors of the smart target. The filter accentuates both the horizontal and vertical cylinders of the red cross so the two can be distinguished. In each image, an area of interest (AOI) is found that encompasses the entire target as shown in Fig. 4 (a). The AOI reduces the size of the frame that must be further processed to reduce processing time for each frame.

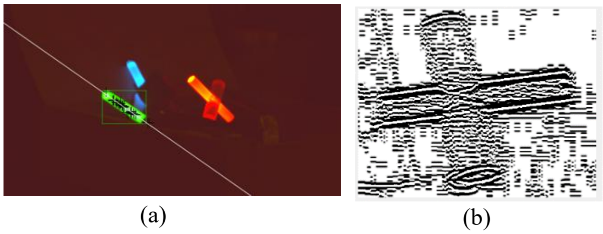


(a) (b)

Figure 4. Identify target from complex background

To find the AOI, a threshold filter is applied to identify the bright smart target. A morphological opening is also applied to reduce noise and to remove unwanted pixels that pass through the threshold filter. The detected AOI is drawn on top of live video feed on the GUI to display the part of the frame that will be processed further. To identify the three parts of the smart target and differentiate them based on color, a HSV filter is used. The three parts of the smart target can be identified (as shown in Fig. 4 (b)).

The next important part of the image processing is to identify the center lines of the green and blue cylinders and the center point of the red cross. The center of the red cross is found by finding the intersection of the lines running through the center of the red cross. A Laplacian of Gaussian (LOG) filter is applied to each colored part of the smart target. The filter marks the edges of the cylinder by a sharp jump from negative intensity to positive intensity. The zero crossing on each edge can be found and from there the centerline. Zero crossings on either side of the cylinder correspond with a point along the center of the cylinder. A line of best fit is found through the center points (Fig. 5 (a)). The center points, shown in black in Fig. 5 (a), come from the



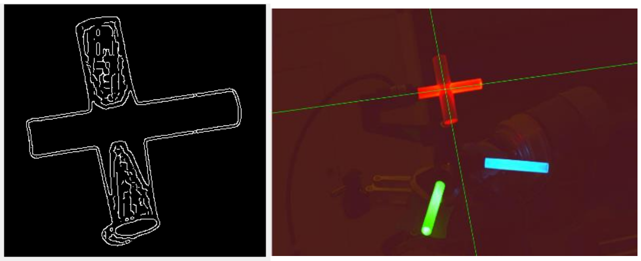
(a) (b)

Figure 5. Feature detection of the smart target

edges of the cylinder. The line of best fit, shown in white in Fig. 5 (a), is found from the center points.

The red cross presents a challenge due to its more complex shape and unequal lighting. One cylinder of the red cross is evenly lit while the other is dim and uneven. This requires different processing techniques for the two parts. The evenly lit section of the cross is processed the same way as the blue and green cylinders using a LOG filter. The output of the Laplacian of Gaussian filter is shown in Fig 5 (b). The bright cylinder of the cross is the horizontal cylinder in Fig. 5 (b), and the dark cylinder is the vertical cylinder.

After the LOG filter, the two edges of the cylinder are found, then the center points, and the line of best fit of the centerline. The darker cylinder of the red cross is processed using a Canny filter to clearly identify the weaker edges of the vertical cylinder as shown in Fig. 6 (a). The Canny filter is not used in place of the LOG filter in other parts of the processing as it is prone to noise and weak edges found in the background. The LOG filter is more effective at singling out the edges of the bright cylinders. The results of the two processing methods for the cross are combined to find the center point of the red cross (Fig. 6 (b)). To determine the smart target position in 3D space, the location of the red cross center point, and the line of best through the green and blue cylinders are used from the two stereo images. The image pixel coordinates of the red cross and equations of the two lines are undistorted and normalized to using parameters from the camera calibration to account for distortion in the camera lenses. Camera calibration is determined beforehand and loaded into the GUI for processing. The camera calibration includes information such as focal length, rotation matrix, and translation vector between the two stereo cameras.



(a)
(b)

Figure 6. Center point identification on red cross

The 2-D to 3-D construction uses two cameras calibrated poses (not detailed in this paper). In each camera, a vector is found from the pinhole camera origin to the cross center. The intersection of the two vectors is found as the location of the red cross in 3D space as shown in Fig. 7.

For both green and blue cylinders from the two images, a plane is found using the origin and the specific line. The line of intersection of the corresponding blue or green planes between the two frames is found. This line of intersection is the centerline through the green or blue cylinder in 3D space.

The position information about the smart target can be displayed on the GUI and will update with each new pair of images from the cameras. The position data is also written to a user-specified file with a timestamp. The next step is to optimize the algorithm to speed up the calculation. To capture dynamic movement, the measurement speed needs to be above 30 frames per second. Adding GPU (Graphics Processing Unit) and parallel calculation will help to speed up the image processing process.

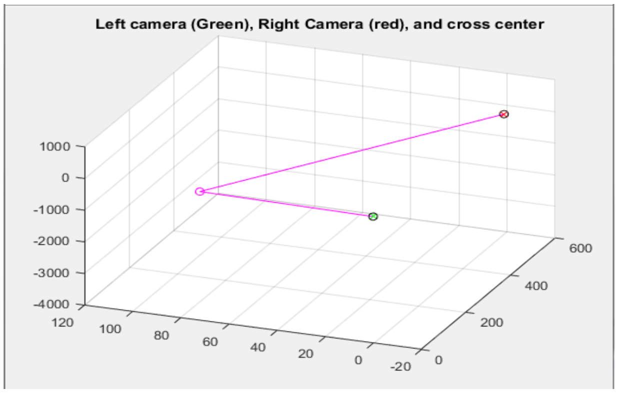


Figure 7. Intersecting vectors from pinhole cameras to center of the red cross

USE CASE DEVELOPMENT

NIST is developing a quick health assessment methodology using a smart target to assess the accuracy degradation of the TCP throughout the robot workspace. The methodology includes the advanced sensing development (the smart target) to acquire the robot TCP's 6-D information, a test method to define the robot movements and a robot error model to reflect the robot geometric and non-geometric errors, and algorithms to process measured data to assess the robot's accuracy degradation.

As shown in Fig. 8 (a), the 6-D smart target is mounted on the last joint of the UR3 robot. A vision-based measurement instrument is set up in the environment, which is at the opposite end of the kinematic chain from the target. The idea is to compare the measured TCP position to nominal positions. A set of predefined robot movements is created (as shown in Fig. 9) based upon the robot's kinematics, geometry, available working volume, and expected operational activities. The left picture of Fig. 9 shows the generation of the target positions. The right picture of Fig. 9 shows the simulation of the robot moving to the

Figure 9. Auto-generation of pre-defined robot movement for quick health assessment

planned positions with collision detection algorithms embedded. Unreachable positions or positions having collision problem is removed and updated in the display. The robot movement is measured by the vision-based instrument. The measured TCP 6-D data is used to calculate the deviations from robot normal positions. The calculated deviations are input into the robot error model. The error model handles both the geometric/non-geometric errors and the uncertainties of the measurement system. An algorithm is developed to process the data to assess the robot's accuracy degradation [15]. The first output is the derived error from the calculation of the robot tool center accuracy of the robot through the workspace Fig. 8 (b). The results are more accurate because they are derived from the error model instead of directly calculating from the limited size of sample measurements. This output can be used to view the overall accuracy of a robot within the working volume and find the sweet zone of the robot where the accuracy is suitable for production. The second output is the identified maximum likelihood estimation of axis error parameters. By observing the error pattern, users can monitor the change of robot accuracy. Further analysis can be used to identify the potential error sources of the given errors (for example, zero shift of a joint encoder).

The quick health assessment can be used to swiftly (within 10 minutes) detect degradations in robot accuracy by finding the robot pose deviations from the nominal poses. The use of this methodology will monitor the degradation of robot performance, reduce unexpected shutdowns, and help the optimization of maintenance strategy to improve productivity.

CONCLUSION

Accuracy degradation impacts machine/robot's performance. NIST's development of smart target can be integrated with a vision system to acquire high accuracy position and orientation information of a moving object, allowing for machine/robot's accuracy degradation assessment and accuracy improvement. This paper presented the novel design of the smart target and a software tool. With smart target's measurement, deviations of machine/robot position and orientation are quantified, leading to more accurate calibration or control, improving overall performance. NIST is seeking to develop additional industrial use cases for further applications.

Abstract

Codes and standards developing organizations, such as American Society of Civil Engineers (ASCE) and American Concrete Institute (ACI), rely on experimental data to develop modeling parameters and acceptance criteria to be used in the performance-based seismic design (PBSD) approach. This data is especially important when developing best practices using materials and techniques that are not covered in current PBSD standards, such as the use of fiber reinforced polymers (FRP) for seismic retrofit. Currently, guidance on the design of a retrofit system for reinforced concrete (RC) shear walls with FRP is missing from standards such as ACI 369.1 and ASCE 41. This paper describes the development of a database of FRP retrofitted shear walls that can assist in filling the information gap in the retrofit design guidance of RC shear walls. The main purpose of this database is to aid in the development of modeling parameters and acceptance criteria that standards developing organizations can adapt in order to provide guidance on the design of FRP retrofitted shear walls. The database includes over 200 experimental tests of shear walls from around the world, which can be filtered into categorized bins, like bins of walls with and without openings, or bins based on the premise of the test (i.e., pre-damaged and repaired vs. undamaged and retrofitted). The database will be available through the DesignSafe-CI platform in the near future, in a format that can be easily accessed and utilized by practicing engineers and researchers. This paper will conclude with recommendations for future experimental tests that would fill in the gaps in the data.

Dukes, Jazalyn; Sattar, Siamak. "Development of a Database of Experimental Tests on FRP Retrofitted Reinforced Concrete Shear Walls."
Paper presented at 17th World Conference on Earthquake Engineering, Sendai, JP. September 13, 2020 - September 18, 2020.

1. Introduction

Retrofitting of structural components has become an essential technique for engineers and practitioners to reduce the seismic risk associated with existing buildings. The aging of infrastructure and buildings, as well as changing and improved structural codes has led to the need to retrofit many structures, particularly in the United States (U.S.). Retrofitting of reinforced concrete structures and components is increasingly being performed using fiber reinforced polymer (FRP) composites. Application of externally bonded FRP composites onto structures can help repair deteriorated structural components due to degradation or an excessive loading event. Building components can be retrofitted for increased seismic and gravity loads, or to meet current code requirements. Compared with traditional reinforcement materials, FRP composites are light weight and flexible for ease of application, low profile additions to existing structures, and corrosion-resistant. These unique characteristics make FRP composites a desirable retrofit material for existing buildings.

While the benefits of using externally bonded FRP composites to retrofit a structure are known, there is still uncertainty surrounding the initial and long-term performance of these retrofitted components [1-5]. While the use of FRP in structural applications has increased over the past 20 years, entities such as the National Cooperative Highway Research Program (NCHRP) recommend that guidelines, commentary, and examples be developed for design, construction, and maintenance of FRP composites before the material can fully mature and proliferate [6]. One way that engineers and users understand and come to trust the performance of FRP for retrofit of a structure is through experimental testing. There have been many experimental testing programs of FRP retrofitted structural components in the U.S. beginning in the 1980s, including testing of reinforced concrete columns, beams, and beam-column joints [7, 8, 9]. However, experimental research on FRP retrofitted reinforced concrete (RC) shear walls within the U.S. is limited. This lack of available information is concerning, especially as structural walls are continuing to be retrofitted without an equivalent level of knowledge about performance that is available for other components.

This paper describes a database that was developed to fill in the gap of knowledge about available experimental tests that have been performed on FRP-retrofitted reinforced concrete shear walls. There is no other published database that focuses exclusively on FRP-retrofitted reinforced concrete shear walls, to the knowledge of the authors. The database described in this paper details available published research on retrofitted shear walls and compiles them into one location. The database includes over 200 experimental tests of shear walls from around the world, which can be filtered into categorized bins, like bins of walls with and without openings, or bins based on the premise of the test (i.e., pre-damaged and repaired vs. undamaged and retrofitted). This paper details the format and structure of the database, characteristics of the walls studied in the paper, and key research gaps in the database. The intent is to make this database available through the DesignSafe-CI platform [10] in the near future for researchers to use in order to 1) further the understanding of the performance of FRP-retrofitted shear walls, and 2) determine research gaps in the data and develop research programs. Research programs should address gaps in the data that represent the typical walls in existing buildings that are in need of retrofit. Throughout the paper, research gaps and future research needs are noted.

2. Motivation

Several factors motivated the development of this database. First, a workshop held at the National Institute of Standards and Technology (NIST) in 2018 identified the need to understand the extent of experimental testing of FRP-retrofitted structures and components. NIST Special Publication 1244 [11] details the results of the workshop that invited experts and practitioners who use and manufacture FRP materials for design and construction. One of the main concerns identified at the workshop is the lack of large-scale experimental testing of FRP-retrofitted components, and the corresponding lack of understanding of the performance of those structures. From the workshop, as well as a literature review of current research, the idea to focus on

FRP-retrofitted walls was concluded. There is currently no known database that contains all of the information regarding experimental tests performed on FRP-retrofitted walls, so the authors decided to develop the database for future study and for the benefit of the wider community.

Another motivating factor for creating the database is to gather the data needed to enhance current building codes and standards since there are currently no provisions in U.S. design standards such as ACI 369 and ASCE 41 for the design of FRP-retrofitted components. If a designer were designing an FRP-retrofitted wall, for example, there would be no modeling parameters or acceptance criteria that directly relate to that component. The designer may use the backbone curve of an unretrofitted, code-compliant concrete shear wall, but that may not accurately capture the performance of a retrofitted wall. The proposed database will be used to develop modeling parameters and acceptance criteria for inclusion in future iterations of buildings codes and standards. The inclusion of modeling parameters specific to retrofitted components will improve the accuracy of the assessment of the retrofit, and subsequently increase the confidence of the designer in their design of retrofitted components.

3. Database Development

The proposed database contains over 200 reinforced concrete wall tests collected from almost 40 research programs reported in the literature. In the database, each specimen is given a unique specimen identification number (ID) and also retains the specimen name given in the research paper. The digital object identifier (DOI) number that links to the publication from which details about the experimental testing were retrieved is noted in the database, when available. A citation of the paper is also included.

Fig. 1 illustrates the countries of origin of the research programs that are included in the database. Canada has contributed the largest number of research programs of any country to this database. European countries, such as France and Greece, contribute about 30 % of the research programs. Asian countries, such as Singapore and Japan, contribute about 35 % of the research programs. In this database, only 3 of the research programs originate out of institutions based in the U.S. This information suggests that most of the research on the performance on FRP-retrofitted shear walls were on specimens that may not have been designed to the U.S. standards and codes or designed with similar material properties. This is a research gap that should be addressed: to increase the number of experimental tests on FRP-retrofitted shear walls that are designed to prior editions of U.S. codes in order to represent typical shear wall construction in existing structures within the U.S.

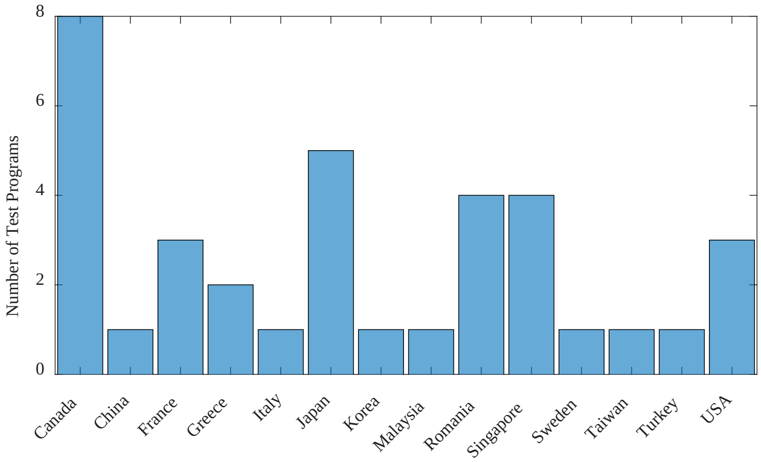

Fig. 1 – Country of origin of all research programs in the database

Experimental research on FRP-retrofitted shear walls began in the late 1990s, according to the research programs included in the database. Approximately ten percent of the papers in the database were published before 2000. About 30 % of papers were published between 2000 and 2009. Almost 60 % of the papers were published in the last decade. This could suggest that interest in determining the performance of FRP-retrofitted walls has been increasing in recent years, and that there may be areas of research yet to be explored.

Wall specimens are categorized in several ways in the database. Two distinctions among the wall specimens were quickly apparent after collecting the information: the presence of openings, and the type of retrofit application. The wall specimens tested in the database either had openings that were built into the wall or created after the solid wall was built, or no openings. The presence of openings in the walls is denoted by a "Y or N" entry, "Y" meaning openings are present, "N" meaning the specimen is a solid wall. The other distinction is related to the presence of damage and repair before the application of the FRP retrofit. For example, many programs built plain (unretrofitted) RC walls, tested them under cyclic loads, repaired then applied FRP and retested the specimen again under a cyclic loading protocol. These specimens are denoted as "Repair" specimens in the database. The other RC walls which were built in the lab and immediately treated with an FRP retrofit without prior testing are denoted as "Retrofit" specimens. The walls that acted as control walls without any FRP retrofit are denoted as "Control". By noting these important distinctions, users of the database can filter out the specimens based on their research needs. Table 1 shows subsets of walls from the database based on these two distinctions. Details about Subsets A and B will be referred to later in this paper, and will also be referred to as Retrofit and Repair subsets, respectively. Subsets A and B represent about half of the total number of specimens in the database and are discussed in more detail in this paper. Details about Subsets C and D are not discussed in this paper.

Table 1 – Subsets of database based on presence of openings and prior damage

Wall Test and Condition	Retrofit No damage prior to FRP		Repair and Retrofit Damage prior to FRP	
No Openings	Subset A Retrofit, no openings	62 specimens	Subset B Repair, no openings	54 specimens
Openings	Subset C Retrofit, with openings	55 Specimens	Subset D Repair, with openings	33 Specimens

4. Characteristics of the walls

4.1 Wall parameters

The data and details stored in the database describe the types of walls that have been tested in the literature. These details include wall parameters such as geometric and material properties, FRP design and material properties, the loading types and testing protocols, and the results from the test including maximum drift ratio and maximum lateral force and the backbone curves. Table 2 shows the ranges of the following wall parameters for the Retrofit and Repair subsets: concrete compressive strength (f'_c), wall aspect ratio (a/l_w), yield strength of the longitudinal steel reinforcement (f_y), horizontal steel reinforcement ratio (ρ_t), longitudinal steel reinforcement ratio (ρ_l), and axial load ratio ($P/A_g*f'_c$). Figs. 2 and 3 show four wall characteristics in the form of histograms for Subsets A and B of the database. By viewing the data in this way, gaps in representation of wall or test conditions become apparent, and wall characteristics which have been tested more than others or have not been tested at all can be identified. For example, most of the tested walls in the database were tested without any axial load (i.e., axial load ratio equals zero), and the highest axial load ratio was less than 10 % for most of the tests in Subsets A and B. Knowing this limitation in available data can direct future research programs, as testing FRP-retrofitted walls under higher load ratios could be of interest for researchers or designers. The same analysis can be performed for the wall aspect ratio, longitudinal steel reinforcement ratio, and horizontal steel reinforcement ratio.

Table 2 – Summary of wall parameters for Subsets A and B

Subset	f'_c (MPa)		a/l_w		f_y (MPa)		ρ_t, %		ρ_l, %		$P/(A_g{*}f'_c)$	
	Min	Max	Min	Max	Min	Max	Min	Max	Min	Max	Min	Max
Retrofit (A)	14	45	0.44	3.12	235	500	0.09	0.57	0.16	1.83	0	0.09
Repair (B)	16.6	42	0.85	2.5	320	585	0.25	0.57	0.28	3.0	0	0.2

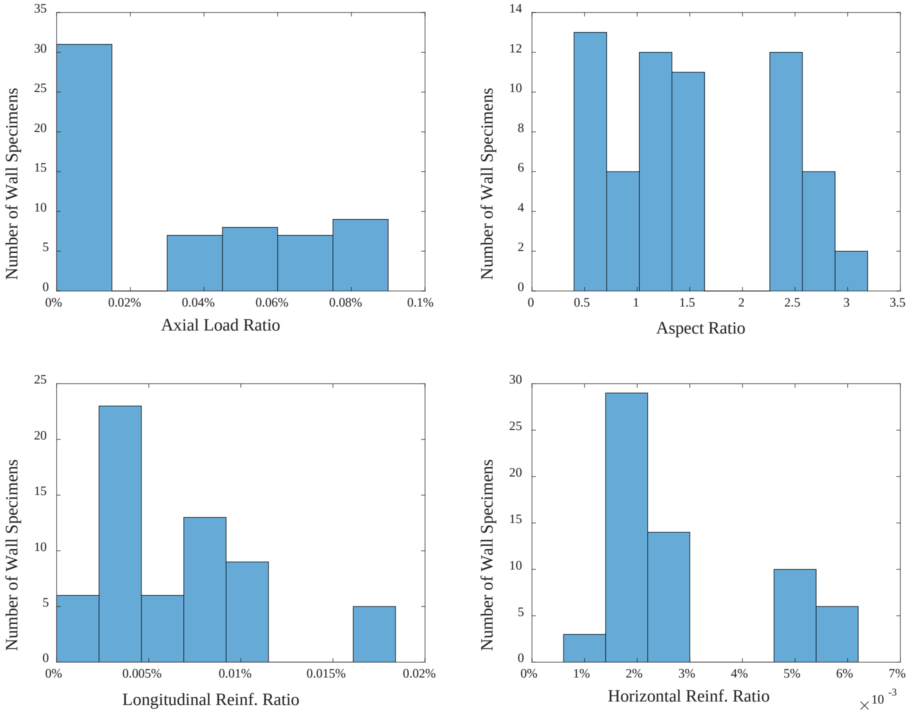

Figure 2 – Histograms of wall parameters of Subset A (Retrofit)

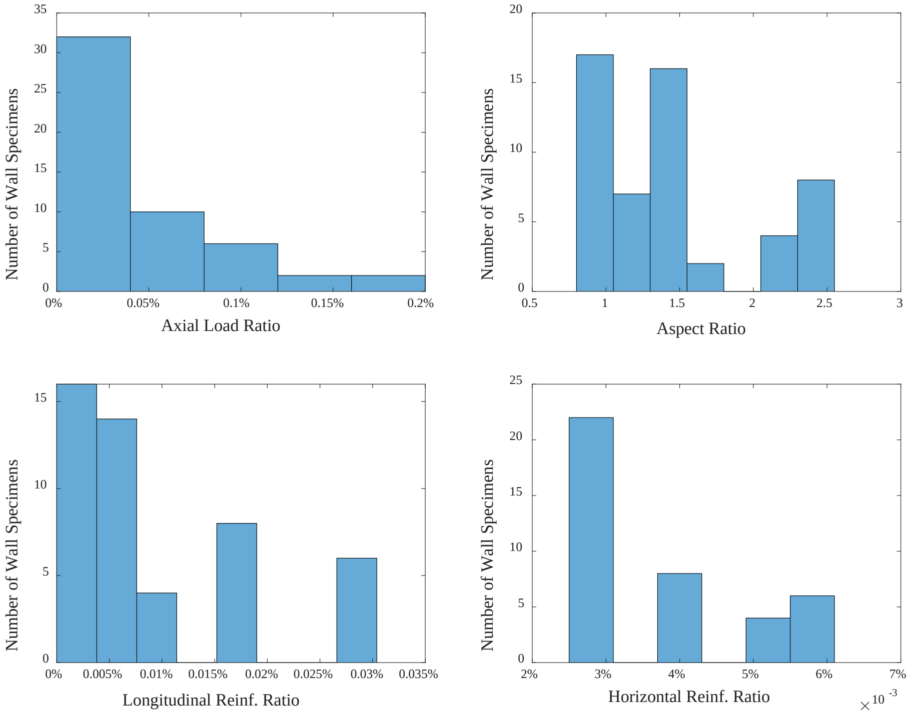

Figure 3 – Histograms of wall parameters of Subset B (Repair)

All of the walls have rectangular cross sections (no L, C or T shaped sections). Most of the walls in the Retrofit subset were loaded with cyclic lateral loading, while a few (~ 12 % of walls) were tested under monotonic lateral loading. All walls in the Repair subset were tested under cyclic lateral loads except for one experimental program that tested walls on a shake table. Less than ten percent of the walls in Subsets A and B were tested to the point of loss of axial load-carrying capacity or significant loss of lateral strength. However, there is value in testing structural components to significant strength loss to observe the behavior of the component as the strength degrades. This information is useful for developing nonlinear models capable of capturing the response of the components in post-peak range of the response. The testing of FRP-retrofitted walls to a state of significant strength loss is an area of research that should be explored. Another area of research to explore is various shapes of walls, including L, C, or T shapes, since these shapes present challenges related to FRP retrofit application as well as a difference in behavior from rectangular walls. This may be a consideration for researchers in the future when creating testing programs.

4.2 Wall design and test objective

The initial wall design of the test specimens in the database varied based on two main objectives found in the test programs featured in the database: shear strengthening or flexural strengthening of the wall. Fig. 4 illustrates the difference in the objective of strengthening that is applied to shear walls. Because FRP is being used as a retrofit technique, it is appropriate that most of the walls were designed to have deficiencies. Several research programs describe their walls to have been designed to older design codes that are now known to have produced walls that perform poorly under seismic loads. Other walls were designed to be shear deficient, or under-reinforced in order to fail in shear. Walls that were designed with built-in deficiencies in shear were then retrofitted with FRP to improve shear strength and ductility of the walls and to determine the effectiveness of the retrofit system. Another group of wall specimens were designed to measure the effectiveness of FRP to enhance the flexural strength of a shear wall. These walls were designed to behave in a ductile manner before the expected shear strength was reached. Still other wall specimens were designed for the FRP to improve both shear and flexural strengthening. This information is important to researchers in determining the past research as well as areas of research that have not been explored in terms of wall design and test objectives.

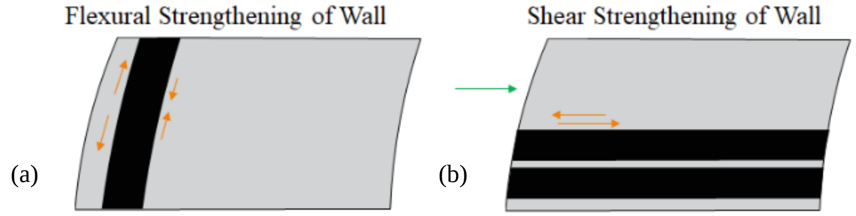

Fig. 4 – Types of FRP strengthening for walls (a) flexural strengthening, and (b) shear strengthening

4.3 FRP retrofit design details

The design of the FRP retrofit varied between test programs, and even between specimens within a test program. No two FRP retrofit designs were the same. Some of the differences between designs include FRP material, number of layers, thickness of the layers, use and spacing of horizontal and vertical laminates, and use of anchors. Fig. 5 shows the types of FRP material used in the walls of subset A and B. Carbon FRP (CFRP) is the most common type of material used, followed by glass FRP (GFRP). Some walls included two or more types of FRP material in the design (designated as “combo”). The focus on CFRP and GFRP in the testing programs are appropriate since these FRP materials are the most common materials used in the U.S. However, if one wanted to determine the performance of a wall retrofitted with FRP material other than carbon or glass, this database does not contain many examples of the performance of alternative materials. This may be a consideration for researchers in the future when creating testing programs.

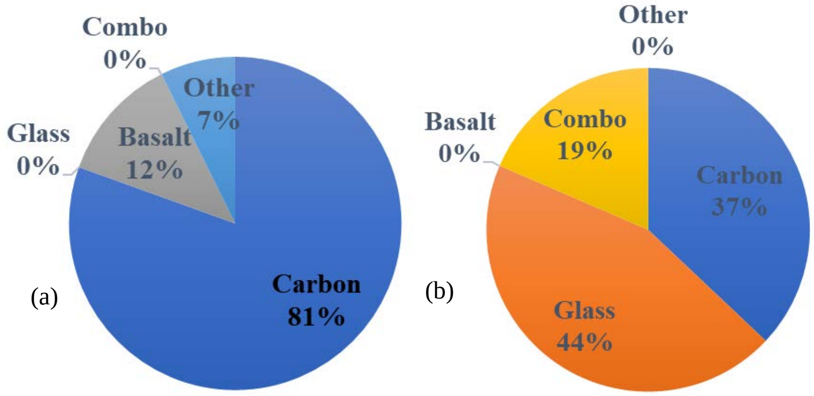

Fig. 5 – Pie chart of FRP material types for (a) Subset A (Retrofit), and (b) Subset B (Repair).

The number of layers and the orientation of FRP layers also varies widely among the tested walls. Walls were either reinforced on one side or both sides. While reinforcing a wall on both sides may provide better confinement and better performance, sometimes it is only practical to retrofit one side of a wall in the field due to limited access to both sides of the wall. Many of the walls included FRP anchors to prevent premature debonding of the FRP from the concrete substrate during testing. FRP anchors are an important part of an FRP retrofit design and are becoming more prominent in the field. However, there are currently no provisions in U.S. design standards on how to design the FRP anchors. Tests that include FRP anchors in the design are helpful for the researchers and practitioners that develop codes and standards to create guidelines related to the FRP anchor design. Fig. 6 illustrates the portion of wall specimens that had FRP anchors and the type of anchors for Subsets A and B.

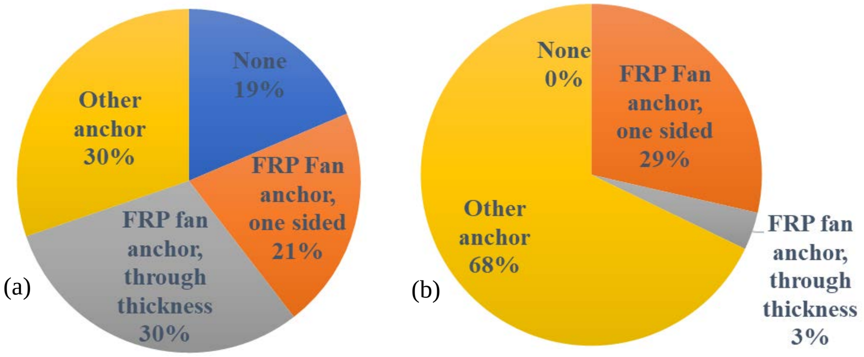

Fig. 6 – Pie chart of FRP anchor types for (a) Subset A (Retrofit), and (b) Subset B (Repair).

5. Conclusion

This study develops a database of experimental tests that have been performed on FRP-retrofitted reinforced concrete shear walls. This database includes all experimental research on FRP-retrofitted walls known to the authors at the point of publication. This database will be published on the DesignSafe-CI platform for future use by researchers to further the understanding of the performance of FRP-retrofitted RC walls. It will also be available for review by researchers who have experimental data to contribute, who can submit their data to the authors for future iterations of the database. In this way, the database will have the most up-to-date collection of experimental data on FRP-retrofitted walls.

This database also helps identify gaps in the existing research, which may lead to future experimental testing programs. One gap that was apparent was the lack of tests that had an axial load ratio above ten percent. About a third of the tested specimens had no axial load applied during testing. Another gap in the database is the lack of tests that tested the specimen to significant lateral strength loss. There is a lot of information to be learned from testing components to collapse or significant lateral strength loss, especially for those interested in capturing the response all the way to reaching the residual strength. It is important to understand the post peak range of the response of FRP retrofitted walls as the wall can potentially experience a brittle mode of failure, i.e., abrupt loss of capacity, when the failure is initiated. Finally, research that investigates the effect of FRP anchors on the performance of the wall specimen is important to practitioners in the field in order to effectively design an FRP retrofit system with anchors. The current standards currently do not provide guidance on the use of anchors for designing the FRP retrofit system for walls. Practitioners need guidance on how to design these anchors, including the spacing, shape, and angle of the anchors in order to achieve the desired performance of retrofitted walls and prevent premature failure/debonding of the FRP retrofit system. A structured research program that systematically varies these parameters on shear walls would be useful in the development of design guidance of FRP anchors.

6. Disclaimer

Commercial software may have been used in the preparation of information contributing to this paper. Identification in this paper is not intended to imply recommendation or endorsement by NIST, nor is it intended to imply that such software is necessarily the best available for the purpose. No formal investigation of uncertainty or error is included in this study.

I. Introduction

The Josephson arbitrary waveform synthesizer (JAWS) has been demonstrated to be an invaluable tool for synthesizing quantum-based voltage signals for metrology in the audio-frequency range [1]. Our goal is to extend the metrology capability of the JAWS system as a quantum-based source to the radio-frequency range. Our initial effort has extended the maximum waveform synthesis frequency to several gigahertz, while our goal is to eventually increase it to tens then hundreds of gigahertz [2].

The synthesis of arbitrary waveforms using pulse-driven Josephson junctions (JJs) is detailed in [1],[3]. Briefly, waveforms are encoded into a pattern of return-to-zero pulses with two or more levels using a delta-sigma modulation algorithm that modulates the separation of the pulses. The output patterns have calculable spectra with high spurious-free dynamic range (SFDR) and signal-to-noise ratio (SNR) near the fundamental synthesis frequency, despite the large digitization error resulting from the limited number of encoded pulse levels. When this pulse pattern is generated by a standard room-temperature digital-to-analog converter (DAC), the output signal will fluctuate with time and environmental conditions and will have degraded SFDR and SNR compared to the calculated spectrum. The signal from this DAC output can be conditioned by an array of JJs, which acts as a pulse quantizer. The resulting signal is stable, has an amplitude with quantum-based accuracy, and a spectrum that has exceptionally high SFDR and SNR.

Under the proper conditions, when a JJ is biased using a current pulse it will generate a quantized voltage pulse with an integrated time area that is exactly equal to a multiple of a magnetic flux quantum $\Phi_0 = h/2e$, where h is the Planck constant and e is the elementary unit of electric charge. Through this effect, an array of JJs can be used to generate quantized output pulses that have stable and invariant time-integrated area based on quantum effects and tied to fundamental constants.

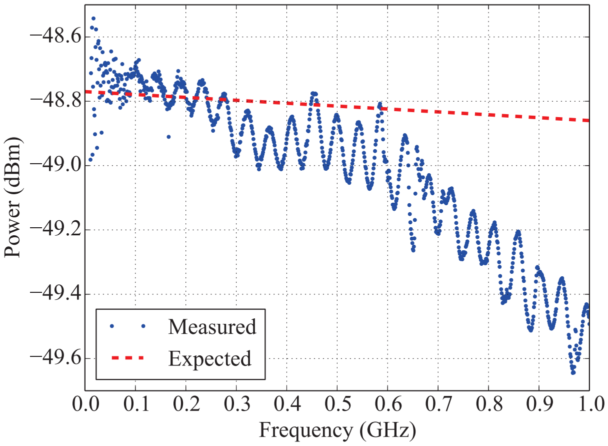

Fig. 1. The calibrated output power versus synthesis frequency for the JAWS system (dots) and the expected frequency-dependent value (dashed line).

Unique to JJ circuits, the quantized pulses are generated over a range of bias current amplitude and other conditions called the quantum locking range (QLR). When the JAWS system operates within its QLR, every incident bias pulse is transformed by every JJ in the array into a quantized output voltage pulse. This ensures that the output amplitudes of the synthesized waveforms are quantum-based, stable, independent of operating location, and immune to small variations in operating bias, temperature and other conditions.

JAWS systems have synthesized waveforms up to 1 GHz, but those signals were not corrected for the errors occurring between the JJ devices and the room-temperature measurement [4]. In this work, we used a cryogenic probe station to measure the output signals of a JAWS circuit and a set of cryogenic calibration standards to reference the signals measured at room temperature to the signals generated on chip, where they have quantum-based accuracy [5],[6].

II. Experimental Setup

As a first step in demonstrating the quantum-based output of the JAWS system, we have measured and corrected its output power versus synthesis frequency (frequency response) up to 1 GHz, as shown in Fig. 1. The goal of the experiment was to demonstrate that the frequency response could be

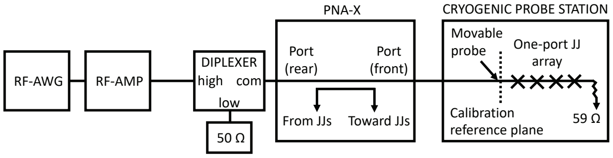

Fig. 2. Block diagram of the measurement setup.

generated and properly corrected so that it is in agreement with the expected value and independent of the synthesis frequency, within the limits discussed in section III-C. Calibrated phase measurements of the JAWS output signals will be included in future experiments.

A schematic representation of the measurement setup is shown in Fig. 2. The main equipment used in the experiment includes a cryogenic probe station with a cryogenic chip containing the JJ circuit and standards, a Keysight N5242A precision network analyzer (PNA-X), and a Keysight M8195A 65 gigasample-per-second arbitrary waveform generator (RF-AWG)[1]. The RF-AWG was used to apply the current bias pulses to the JJ array, and an RF amplifier was used to increase their amplitude. The bias signal was transmitted to the high-frequency port of a diplexer with a 5 GHz crossover frequency. The low-frequency port of the diplexer was terminated with a 50 Ω resistor, and the common port was connected to the rear-panel input to one port of the PNA-X. The front panel of that port was connected to a movable cryogenic microwave probe via a feedthrough port on the probe station.

The current bias pulse signal contains a component at the fundamental synthesis frequency that drives the distributed inductance of the JJ array coplanar waveguide (CPW), creating a frequency-dependent voltage error that adds vectorially to the desired signal [3]. The diplexer was used to high-pass filter the current bias pulses and reduce this so-called "feedthrough" error. However, the high-pass port presented a high impedance to the low-frequency synthesized (<5 GHz) signal traveling from the JJ array toward the PNA-X. To limit the reflection of the synthesized signal from the high-pass port, a diplexer was used instead of a high-pass filter so that a $50\ \Omega$ termination was presented to the JJ output signal.

We used a PNA-X to measure the signals from the JJ array and to measure the calibration standards. Only one port of the PNA-X was used for the JJ device measurement, but two ports were used during the on-chip calibration standard measurements. The PNA-X port that was connected to the JJ circuit includes an internal bias tee, which was used to apply an additional dc bias current to the bias pulse pattern when the QLR was measured. A comb generator, triggered by a 10 MHz square wave generated by a synchronized channel of the RF-AWG, was used as a phase reference for the PNA-X.

For this first experimental iteration, we measured a one-port JAWS circuit, as shown in Fig. 2. In this circuit, the JJs are embedded in a CPW in 500 vertical stacks with three JJs per stack, for a total of 1500 junctions [7]. One end of the CPW is connected to the ground plane via a termination resistor with a design impedance of $50\ \Omega$ to absorb the residual bias pulse signal. The opposite end of the CPW has contact pads to accept a microwave probe that was used to apply the bias signals and measure the JJ output signal. This circuit topology provides roughly half of the full signal of the quantized output pulses generated by the JJ array, as explained in section III-C.

A set of calibration standards were fabricated in niobium on the same chip as the JAWS circuit. These superconducting calibration standards provide the basis for the second-tier calibration of the PNA-X down to the wafer reference plane. They include a multi-line ("thru"-reflect-line) TRL kit with five line standards ranging in length from $70\ \mu\mathrm{m}$ to $9\ \mathrm{mm}$, and several short, thru, open, and load standards. Additional details about the calibration kit can be found in [6].

We used a cryogenic probe station to measure the signals generated by the JAWS circuit and to perform the cryogenic calibration of those signals. The chip containing the cryogenic standards and JJ device was mounted on a cryogenic stage that was controlled at 4 K. The cryogenic probe station has two microwave probes that can each be controlled along three axes of motion using cryogenic piezoelectric nanopositioners. The microwave probes were used to measure the complex voltage waveforms traveling toward and away from the device under test, and one probe was also used to apply the bias signals to the JJ array. An optical microscope was used to image the 4 K stage through transparent windows in the cryostat jacket and radiation shields to position the probes on the cryogenic chip.

III. Measurement

A. Measurement Procedure

We measured the frequency response of the JAWS output signal by measuring the power at the fundamental of single output tones that were synthesized in steps of 1 MHz from 10 MHz to 1 GHz. These 991 single-tone bipolar waveforms were each encoded into a bias pulse pattern with a minimum of $10\,000$ waveform periods using a second-order, three-level $[-1, 0, +1]$, bandpass delta-sigma modulator at a 64 gigasample-per-second rate. To reduce the signal at the fundamental in the bias pulse pattern and decrease the feedthrough error, the three-level codes were transformed to five-level codes so that each bias pulse had bracketing half-amplitude pulses and each pulse block had effectively zero average current [3]. For this experiment, quantum-locked operation could be achieved across the entire synthesis frequency range only by reducing the amplitude of the waveforms to 2.5 % of the full scale possible with the given sample rate. The limitation on the mark density of the pulses is under investigation, but an increase in the signal amplitude should be possible in future measurements.

[1] Commercial instruments are identified in order to adequately specify the experimental procedure. Such identification does not imply recommendation or endorsement by NIST, nor does it imply that the equipment identified is necessarily the best available for the purpose.

We performed the measurement by sequentially programming each of the 991 pulse patterns into the RF-AWG, setting the PNA-X measurement frequency to the corresponding value of the synthesis frequency, and measuring the forward and backward complex waveforms at the input of the JJ circuit. During these measurements the dc offset bias was set to zero and the cryostat windows were closed.

B. Calibration

After measuring the JAWS signals, we performed the calibration measurements that were used to correct the raw frequency response data. The calibration procedure is described in detail in [5],[6], but a brief description of the procedure follows. We measured the on-chip cryogenic standards on a 991-point frequency grid matching the single-tone synthesis values. To establish the second-tier calibration reference plane at the end of the microwave probes, we used both probes and PNA-X ports to measure the two-port cryogenic TRL standards. Next, we disconnected the PNA-X coaxial cables from the probe station and performed a short-open-load-thru (SOLT) calibration at the end of the cables to determine the first-tier calibration reference plane. We then calibrated the absolute amplitude using a power meter that is traceable to the NIST calorimeter power reference, and calibrated the absolute phase using a frequency comb generator that is traceable to the NIST electro-optic sampling system. We used the NIST microwave uncertainty framework (MUF) software to compute the error correction [8], which we then used to correct the JJ signal measurements to produce the frequency response shown in Fig. 1. The uncertainty for the correction has not yet been calculated.

C. Expected Signal Level

When generating quantum-based JAWS signals, the exact dc value of the quantized pulse area across the JJ array is calculable. There are several additional effects that must be considered when calculating the expected output signal level, especially at higher frequencies, that are discussed below. The calculable dc signal level—assuming the pulses are ideal delta functions and synchronized—depends on the number of JJs in the array, the maximum density of pulses, and the number of quantized pulses generated for each input bias pulse. The codes used in this experiment were all designed for a -42 dBm output signal.

Because we measured a one-port JJ device in this experiment, only a portion of each quantized output pulse area was collected and an additional correction to the calculable signal level is required. As detailed in [9], the quantized output pulses split with a portion propagating along the CPW in the direction of the bias pulses and the other portion traveling in the opposite direction. The ratio of the split is determined by the voltage division of the impedances seen in either direction from the point of generation. The measured dc impedance of the nominally 50 Ω termination resistor was 59 Ω, and the measured dc impedance at the probe looking toward the PNA-X was 50 Ω. Therefore, approximately 46 % of the quantized pulse area was measured, reducing the total power by -6.8 dB to a total expected dc power level of ~ -48.8 dBm.

The quantized pulses are not perfect delta functions but have a finite pulse width that causes the signal level to decrease at higher synthesis frequencies. There are two main contributions to the finite pulse width. The first is simply due to the finite characteristic frequency (~ 20 GHz) of our JJs, which we expect to reduce the signal by -0.06 dB at 1 GHz [4]. The second effect relates to pulse propagation. Due to the finite distribution of the JJs along the CPW, the sum of the quantized pulses that propagate in the same direction as the incident bias signal has a narrower overall pulse shape than the summed pulse traveling in the opposite direction. Since a one-port circuit was used in this work, we measured the broader composite pulses. Given 500 JJ stacks at the standard 6.5 μm stack spacing, the estimated output power reduction is -0.8 % or -0.03 dB at 1 GHz [9]. These two pulse width effects have negligible impact on the total expected power at 10 MHz, but reduce it by -0.09 dB to around -48.9 dBm at 1 GHz. There is a corresponding negative slope in the expected frequency response between 10 MHz and 1 GHz of -0.09 dB, which is a 2.1 % error in power. This error can be reduced in the future by increasing the characteristic frequency of the JJs.

In previous measurements, the contribution of the feedthrough error was considerable, especially at 1 GHz [4]. In this experiment, the feedthrough was effectively eliminated by the improved filtering provided by the stop-band of the high-pass diplexer filter. The feedthrough error was reduced below the noise floor of the PNA-X for even a 1 Hz measurement bandwidth, setting its upper limit at -120 dBm at 1 GHz.

D. Verification of Quantum Locking Range

It is critical that the system operates within the QLR of the JJ circuit at each synthesis frequency step to ensure that the output power at the fundamental synthesis tone is quantum-based and constant, within the limits described in the previous section. We verified the QLR for each of the 991 synthesis steps by measuring the JAWS output with respect to a dc offset current applied to the JJ array. As the magnitude of the dc offset increases from zero, the JJs will eventually either fail to emit a quantized output pulse for each bias pulse or will emit more quantized pulses than intended, thus defining the boundaries of the QLR. When this boundary is crossed, there is little change in the output power at the fundamental. However, any omission or addition of pulses in the quantized pattern will cause the noise floor of the calculable output spectrum near the fundamental to change in an appreciable way.

We measured the QLR by stepping an offset current bias applied to the array and recording the power at the 50 noise spurs above and the 50 spurs below the fundamental synthesis tone that make up the calculable noise floor. The PNA-X was configured for 10 Hz bandwidth and 101 measurement points on a frequency grid that captured the synthesis tone and the 100 nearest noise spurs. The power was recorded for each

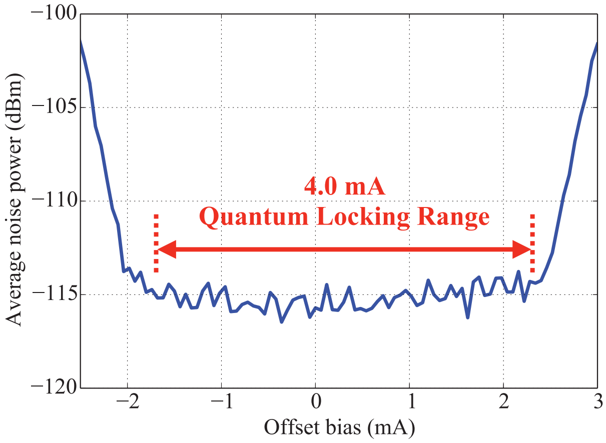

Fig. 3. Characteristic measurement of the quantum locking range (QLR) with respect to offset bias current for a single synthesis frequency step (300 MHz). The average power of the noise floor near the synthesis tone is plotted against the offset bias current. The dashed lines indicate the boundaries of the 4.0 mA QLR measured for this synthesis frequency step.

of the 101 frequency points while stepping the offset bias from -3 mA to +3 mA. The average of the power for the 100 noise spurs was then plotted against the offset bias as in Fig. 3, which shows a characteristic QLR measurement for a single-tone synthesis step. An inflection point occurs where the average noise power starts to increase with the bias offset, corresponding to the boundaries of the QLR. The span in current from the negative to positive inflection points was calculated for each synthesis frequency. We measured a minimum QLR of 3.8 mA across the entire synthesis range, demonstrating the output of the JAWS source was measured while in quantum-locked operation.

E. *Calibrated Frequency Response*

The resulting calibrated frequency response is shown in Fig. 1, along with the calculated frequency-dependent power from section III-C. At low frequency there is reasonable agreement between the measured and expected values. However, as the synthesis frequency increases, the measured value drops further below the expected value and we observe an excess frequency-dependent "roll-off." In addition, the response shows a ripple with roughly 0.2 dB peak-to-peak amplitude. The maximum deviation in the measured power from the expected frequency-dependent value occurs at 967 MHz, where the measured power is -49.6 dBm. This error is equivalent to about -0.8 dB or 17 % in power.

The source of the additional roll-off is under investigation. It is possible that we have underestimated the width of the quantized output pulses and therefore have underestimated the expected roll-off. We plan to make calibrated measurements of the widths of the input bias and quantized output pulses at the wafer reference plane to re-evaluate our estimate. The origin of the ripple is also under investigation, and we should be able to remove it in future measurements.

IV. Conclusion

We have produced a preliminary calibrated measurement of the frequency response of the output power of a JAWS circuit up to 1 GHz. The calibrated output power differs by a maximum of -0.8 dB, or 17 % in power, from the expected value. This large deviation is due to a combination of ripple and excess roll-off of the signal at higher synthesis frequencies. The latter contribution is the dominant source of error, and we attribute it to a larger than expected quantized pulse width. This will be mitigated in the future by optimizing the bias pulses and by increasing the characteristic frequency of the JJs. The output power is currently about -49 dBm, but we should be able to increase this to -30 dBm, which is the level where the source becomes most useful for RF metrology. We can do so by transitioning to two-port device measurements, by increasing the encoded signal amplitudes, and by increasing the number of JJs in the array. Finally, we plan on estimating the uncertainty of the calibration procedure in our next measurement campaign and including it in our error analysis.

***Abstract*—Advanced persistent threats (APT) have increased in recent times as a result of the rise in interest by nation-states and sophisticated corporations to obtain high profile information. Typically, APT attacks are more challenging to detect since they leverage zero-day attacks and common benign tools. Furthermore, these attack campaigns are often prolonged to evade detection. We leverage an approach that uses a provenance graph to obtain execution traces of host nodes in order to detect anomalous behavior. By using the provenance graph, we extract features that are then used to train an online adaptive metric learning. Online metric learning is a deep learning method that learns a function to minimize the separation between similar classes and maximizes the separation between dis- similar instances. We compare our approach with baseline models and we show our method outperforms the baseline models by increasing detection accuracy on average by 11.3 % and increases True positive rate (TPR) on average by 18.3 %.**

I. Introduction

Advanced Persistent Threat (APT) [13] attacks are attacks that are usually conducted by nation state actors. These attacks target the victim's network in order to gain access to confidential information for espionage or compromise the network to destroy the victim's systems.

One example of an APT attack is the Sykipot attacks. In the Sykipot attacks, attackers targeted U.S. and U.K. organizations such as defense contractors, computer hardware manufacturers, and government departments. The attackers used spear-phishing to send emails that contained malicious attachments or links. If a user were to click on a malicious link or open a malicious attachment, then this could harm the organization's system. APT attacks are stealthy and are designed to avoid detection. Therefore, it is difficult to detect the APT attacks [10]. This is a significant challenge.

In a traditional machine learning based approach, we may train a machine learning model with class A and class B attacks, but a new attack which belongs to a novel class may suddenly appear. These novel attack classes can be termed as a zero-day attacks since the new class is not part of the training data but it may appear in the test class [16]. In this case, a traditional machine learning approach may not be able to detect the newly appeared class as a malicious attack class effectively. Due to the limitation of a traditional machine learning approach, we use a deep learning method based on Online Metric Learning (OML) [7] which learns a function to minimize the separation between similar classes (attack classes) and maximizes the separation between dissimilar instances (attack classes versus benign). Therefore, our method can recognize some of the zero-day attack more clearly from the benign instances in latent space and it performs effectively better than traditional machine learning approach. However, there is no guarantee our method will always detect all the zero-day attacks.

There has been much work regarding APT detection that attempt to address this challenge. Different methods have been proposed. For example, Milajedri et al. [17] propose the HOLMES system that gathers computer audit data and ranks the severity of the APT attack in real time. In HOLMES, an APT attack is classified based on the seven stages of the APT kill chain: 1) Initial Compromise, 2) Establish Foothold, 3) Escalate Privileges, 4) Internal Reconnaissance, 5) Move Laterally, 6) Maintain Presence, and 7) Complete Mission.

While much work has been done in the field to identify certain existing APT attacks, currently, a method to detect new APT attacks as they are being carried out does not exist. New APT attacks can only be detected after the attack had already occurred. Therefore, adversaries can still inflict significant damage when they conduct a zero-day APT attack. We propose a method to address this problem that generates an alert if a novel APT attack occurs. Our method could prevent damage from the novel APT attacks. More specifically, we train our model on a subset of the attacks, for example, shell-shock attack and test on other types of attack such as database command injection attack.

In addition, most APT attackers leverage traditional non-malicious tools to complete their attacks. For example, an attacker may exploit a bash vulnerability to open a backdoor on the victim system without installing any malicious software and can then perform lateral movement to access high target systems like the databases to steal data. By tricking the victim into running a bash script, the attacker gains access to

"Evolving Advanced Persistent Threat Detection Using Provenance Graph and Metric Learning." Paper presented at IEEE International Conference on Communications and Network Security (CNS 2020), Avignon, FR. June 29, 2020 - July 01, 2020.

the victim system. Detecting such attacks is challenging if the behaviour of the attack flow is not taken into consideration. In this case, a reverse-shell connection from the victim's machine to the attacker's machine takes place. A benign network flow will just involve connection to the database server from a regular network host. Our aim is to be able to detect when a non-malicious tool is used in a malicious attack flow.

Our contributions include:

- We propose and implement a system that leverages provenance graphs derived from system events for detection of APT attacks
- We propose and implement a metric learning based approach to detect novel APT attacks by learning a latent space that effectively separates benign classes from attack classes.
- We show our method OML outperforms traditional machine learning classifiers in detection of novel APT attacks by an average of 12 % in detection accuracy.

The rest of the paper is organized as follows. Section II discusses the challenges encountered in APT detection systems. Section III discusses our approach and gives an overview of the system. Section IV provides a detailed architecture of our system. Section V shows our classification method using online metric learning. Section VI presents a summary of our implementation and Section VIII shows the evaluation of our approach. Finally, Section IX provides the related work and Section XI provides a conclusion and possible future work.

II. Challenges

When designing and implementing our method, we encountered some challenges that are listed below.

- **Limited training data for novel APT attacks**: Since data for novel APT attacks is limited or non-existent, it will be difficult for us to train our machine learning model for novel APT attacks.
- **There is no signature for the zero-day APT attack**: When a novel APT attack occurs, it does not leave a specific signature that can be used to identify the attack. For novel APT attack identification, we need to analyze the victim machine's log files. Because the log files can be very large, it is challenging to filter out the attack activities from benign activities.
- **Detection in real time**: It is also challenging to detect the APT attacks in real-time. Our system needs to detect attacks quickly and alert the system users to prevent the attack from causing damage.
- **Reduce false positives**: Events that are benign could be incorrectly identified as a novel APT attack. Our goal is to accurately detect APT attacks with a low false positive rate.

III. Approach

Figure 1 shows a simplified example of a provenance graph for an example APT attack. The provenance graph is usually much larger, but for readability, we have only depicted a small portion of the graph. In this APT attack, a user goes to evilsite.com and then downloads a Trojan horse. The Trojan executes malicious commands in the background via the malicious executable file evil.exe while also providing functionality that the user is aware of. For example, a Trojan could be a malicious calculator that appears to be a normal calculator but is secretly executing malicious commands in the background as the calculator application is running. In this example, the Trojan from evilsite.com is able to successfully read the /etc/shadow file and a file containing confidential information that is named 'Top-secret'. Therefore, the Trojan is able to successfully spy on the victim and gain unauthorized access to the victim's confidential information.

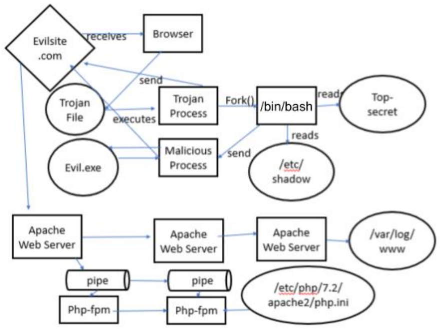

Fig. 1. Sample Camflow provenance graph data

We generate provenance graphs that look like the graph depicted in Figure 1. However, the generated provenance graphs are much larger and show all system activities and processes instead of a small snippet. For APT attack detection, we detect vulnerabilities in the provenance graph. For this, we construct a provenance labeled graph (PLG). Here, PLG is an undirected graph that is defined as $G = (V, E)$ where V is the set of vertices which include `processes`, `tasks` and, `network socket` events, $E \subset V * V$ is the set of undirected edges which include interaction between system events such as `write` and `read` events. Given a set of training examples $T = (x_i, y_i)$ where $x_i \subset X$ is a graph, and $y_i \subset Y = +1$, 1 is a target label, the graph classification problem is to induce the mapping f: $X \Rightarrow Y$. For this, after PLG extraction, we need to convert it to a feature matrix vector by using node2vec [11], GraphSAGE [12], etc. Then, we apply our novel supervised learning technique to detect APT attacks in the stream of data including novel APT attacks.

IV. Architecture

Figure 2 illustrates our approach. Our approach leverages metric learning based detection to classify unknown APT attacks in real time. We use the provenance data to visualize the activity on the machine, and then we filter this provenance data to target attack traffic. Data *provenance* is a representation of the relationships among entities (data items), activities (changes applied to the entities), and agents (people or organizations that are associated with the activities and/or

"Evolving Advanced Persistent Threat Detection Using Provenance Graph and Metric Learning." Paper presented at IEEE International Conference on Communications and Network Security (CNS 2020), Avignon, FR. June 29, 2020 - July 01, 2020.

entities) [21]. We use this provenance to gather information about all of the activities occurring on the machine that could be representative of an attack tactic.

Figure 2 illustrates the steps of our proposed solution. First, we perform simulated advanced persistent attacks on the targeted victim machine. The data from these attacks is transformed into provenance data by CamFlow [21]. Second, we convert the provenance logs generated by CamFlow to a provenance graph using the CamQuery tool [22]. Third, once we have a provenance graph, we filter out sections of the graph to generate sub graphs that contain the events that are commands executed on the system. We filter out extraneous noise that are common activities that occur on the machine regardless if the events are attacks or benign. Fourth, we build a supervised model from these training graphs to detect novel APT attacks, existing APT attacks and benign events.

For feature extraction, we convert the graph into vectors using graph embedding by leveraging node2vec. An embedding vector is learned for each unique node in the graph. The vectors for the nodes in a graph are then aggregated together using the average function for each of the instances of the attack. Our feature extraction method is further discussed in Section IV-B. We train our OML method to detect attacks based on the extracted features.

More specifically, supervised learning is utilized to incrementally learn from the data. For supervised learning, we learn accurate models by leveraging attack and benign data, which are initially gleaned from benign data, synthetic attacks and existing APT attack traces, and later from live attack detection for detecting the novel type of APT attack.

We capture the data on a machine. We capture provenance data using the tool, CamFlow [21]. The provenance data is a record of all of the activities occurring on the machine. We then generate a provenance graph using CamQuery [22]. We adopt a similar strategy to HOLMES [17], but we extend this strategy further to detect novel APT attacks.

We generate existing APT attack data by simulating the attacks on an Ubuntu Linux Virtual Machine. We simulate these attacks by performing various malicious activities on the machine such as downloading vulnerable software and running malicious programs on the machine. While we attack the machine, CamFlow [21] and CamQuery [22] capture the provenance data from the machine in the W3-PROV-JSON format and the provenance graph respectively.

A. Provenance Graph

The provenance graph is collected as a set of JSON files. Listing 1 shows an example of a node and write edge. The nodes contain the provenance type such as `fifo`, `file`, or `socket` [1]. It contains the machine id, boot id and unique node ids. The edges contain additional information such as provenance activity and entity nodes which are interacting together. In our case, we extract the interaction between the different provenance event types using CamQuery to form the nodes and edges in our graph. The Camquery extracts the node ids from the provenance graph and forms a pairwise list of the graph interaction nodes which we use as input to our feature extraction system.

Listing 1. Sample node data for a provenance graph with FIFO type

B. Feature Extraction

Node2vec. We use Node2vec [11] to pre-process the provenance graph before classification. Node2vec is a semi-supervised algorithm for learning features from network graphs. Node2vec uses a similar approach to skip-gram by learning a vector that preserves the neighbourhood relationship of graph nodes similar to word2vec. By representing the graphs by performing a breadth-first search walk on the graph, a sequence of nodes can be generated similar to words in a document. We leverage this method to learn a vector for each node which is used for generating features for attack detection.

For our approach, we extract the node id from the provenance graph. Since the graph is a representation of how each process interacts with other processes and tasks, we model the process task as nodes and the interactions as edges. The list of edges is then passed to the node2vec algorithm to generate an embedding vector for each unique node in the graph. The embedding vector for the nodes in the graph is then combined by finding the average vector representation which is used as a feature for the attack instance.

V. Attack Detection

A. Emerging Attack Class Detection

Traditional machine learning approach is not effective at detecting novel attack classes. For example, a traditional machine learning model may be trained with instances that belong to class A and class B. However, a new attack class may emerge over time and the model may not be able to detect the new attack class effectively. In addition, in many real-world scenarios of APT attacks, instances of patterns associated with the attack type may change over time. Therefore, classifier performance is affected by the occurrences of instances from unknown or novel patterns.

For our novel class detection, we leverage online metric learning or distance based learning where malicious instance points can be well separated from benign class instances so that when novel attack classes emerge, we can detect it effectively. We provide more discussion in the next section.

B. Online Metric Learning

Online Adaptive Metric Learning (OAML) [9] [5] [4] is based on a deep learning architecture that transforms an instance feature from an original feature space to a latent feature space. By transforming to a latent feature space,

Ayoade, Gbadebo; Akbar, Khandakar; Sahoo, Pracheta; Gao, Yang; Singhal, Anoop; Jee, Kangkook; Khan, Latifur; Agarwal, Anmol. "Evolving Advanced Persistent Threat Detection Using Provenance Graph and Metric Learning." Paper presented at IEEE International Conference on Communications and Network Security (CNS 2020), Avignon, FR. June 29, 2020 - July 01, 2020.

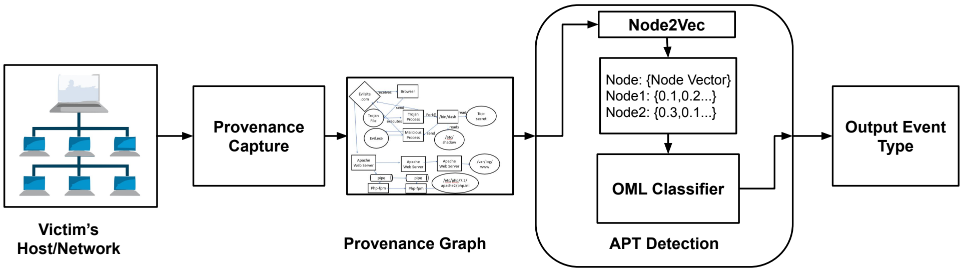

Fig. 2. Architecture

the metric distance between dissimilar instances is increased and distance between similar classes is reduced. The work leverages methods which use *pairwise* and *triplet* constraints.

Our OAML method learns a non-linear similarity metric unlike others which uses a pre-selected linear metric (e.g., Mahalanobis distance [26]). Our OAML method overcomes bias to a specific dataset by using an adaptive learning method. Our OAML leverages neural networks where the hidden layer output is passed to an independent metric-embedding layer (MEL). The MELs then generate an n-dimensional embedding vector as output in different latent space.

1) Problem Setting: Let $S = \{(x_t, x_t^+, x_t^-)\}_{t=1}^T$ be a sequence of triplet constraints sampled from the data, where $\{x_t, x_t^+, x_t^-\} \in \mathcal{R}^d$, and x_t (anchor) is similar to x_t^+ (positive) but dissimilar to x_t^- (negative). The goal of online adaptive metric learning is to learn a model $F : \mathcal{R}^d \mapsto \mathcal{R}^{d'}$ such that $||F(x_t) - F(x_t^+)||_2 \ll ||F(x_t) - F(x_t^-)||_2$. Given these parameters, the objective is to learn a metric model with adaptive complexity while satisfying the constraints. The complexity of F must be adaptive so that its hypothesis space is automatically modified.

2) Overview: Consider a neural network with L hidden layers, where the input layer and the hidden layer are connected to an independent MEL. Each embedding layer learns a latent space where similar instances are clustered and dissimilar instances are separated.

Figure 3 illustrates our Artificial Neural Network (ANN) . Let $E_\ell \in \{E_0, E_1, E_2, \ldots, E_L\}$ denote the ℓ^{th} metric model in OAML (i.e., the network branch from the input layer to the ℓ^{th} MEL). The simplest OAML model E_0 represents a linear transformation from the input feature space to the metric embedding space. A weight $\alpha^{(\ell)} \in [0, 1]$ is assigned to E_ℓ, measuring its importance in OAML.

For a triplet constraint (x_t, x_t^+, x_t^-) that arrives at time t, its metric embedding $f^{(\ell)}(x_t^*)$ generated by E_ℓ is

$$f^{(\ell)}(x_t^*) = h^{(\ell)}\Theta^{(\ell)} \quad (1)$$

where $h^{(\ell)} = \sigma(W^{(\ell)}h^{(\ell-1)})$, with $\ell \geq 1$, $\ell \in \mathbb{N}$, and $h^{(0)} = x_t^*$. Here x_t^* denotes any anchor (x_t), positive (x_t^+), or negative (x_t^-) instance, and $h^{(\ell)}$ represents the activation of the ℓ^{th} hidden layer. Learned metric embedding $f^{(\ell)}(x_t^*)$ is limited to a unit sphere (i.e., $||f^{(\ell)}(x_t^*)||_2 = 1$) to reduce the search space and accelerate training.

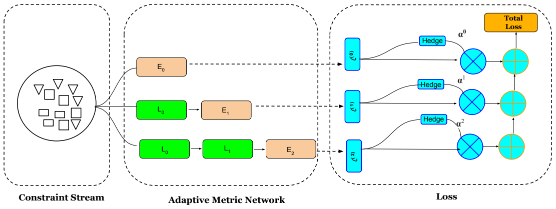

Fig. 3. OAML network structure consist of L_i linear layer and Embedding layers E_i layer.

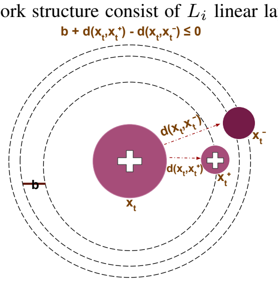

Fig. 4. Data instance before applying Online metric learning

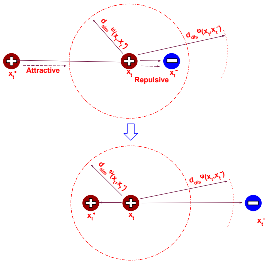

Fig. 5. Data instance after projection using OML

During the training phase, for every arriving triplet (x_t, x_t^+, x_t^-), we first retrieve the metric embedding $f^{(\ell)}(x_t^*)$ from the ℓ^{th} metric model using Eq. 1. A local loss $\mathcal{L}^{(\ell)}$ for E_ℓ is evaluated by calculating the similarity and dissimilarity errors based on $f^{(\ell)}(x_t^*)$. Thus, the overall loss introduced by this triplet is given by

$$\mathcal{L}_{overall}(x_t, x_t^+, x_t^-) = \sum_{\ell=0}^{L} \alpha^{(\ell)} \cdot \mathcal{L}^{(\ell)}(x_t, x_t^+, x_t^-) \quad (2)$$

Parameters $\Theta^{(\ell)}$, $\alpha^{(\ell)}$, and $W^{(\ell)}$ are learned during the online learning phase. The final optimization problem to solve in OAML at time t is therefore:

$$\begin{aligned} &\underset{\Theta^{(\ell)}, W^{(\ell)}, \alpha^{(\ell)}}{\text{minimize}} && \mathcal{L}_{overall} \\ &\text{subject to} && \|f^{(\ell)}(x_t^*)\|_2 = 1, \forall \ell = 0, \ldots, L. \end{aligned} \quad (3)$$

We evaluate the similarity and dissimilarity errors using an *adaptive-bound triplet loss* (ABTL) constraint [9] to estimate $\mathcal{L}^{(\ell)}$ and update parameters $\Theta^{(\ell)}$, $W^{(\ell)}$ and $\alpha^{(\ell)}$.

3) Why OML works: A typical machine learning algorithm like k-NN will misclassify the instances shown in Figure 4, since x_t^+ is closer to x_t^- and further from x_t. In our case, most APT attacks use non-malicious software to complete their attack activities making the attack events and traffic look non-malicious. To overcome this challenge, we use ABTL.

Figure 5 illustrates the main idea of ABTL. The objective is to have the distance $D_{update}^{(l)}(x_t, x_t^+)$ of two similar instances x_t and x_t^+ to be less than or equal to a similarity threshold $d_{sim}^{(l)}(x_t, x_t^+)$ so that the attractive loss $\mathcal{L}_{attr}^{(l)}(x_t, x_t^+)$ drops to zero; on the other hand, for two dissimilar instances x_t and x_t^-, we desire their distance $D_{update}^{(l)}(x_t, x_t^-)$ to be greater than or equal to a dissimilarity threshold $d_{dis}^{(l)}(x_t, x_t^-)$, thereby reducing the repulsive loss $\mathcal{L}_{rep}^{(l)}(x_t, x_t^-)$ to zero.

4) Adaptive-Bound Triplet Loss: Here $y_t \in \{+1, -1\}$ denotes whether x_t is similar $(+1)$ or dissimilar (-1) to x_t' and $b \in \mathcal{R}$ is a user-specified fixed margin. While triplet loss simultaneously learns both similarity and dissimilarity relations, the pairwise loss can only focus on one of the relations at a time, which leads to a poor metric quality. In addition, triplet loss requires a proper margin be specified. In addition, the selected margin is highly dependent on the data and it requires extensive domain knowledge. Our aim is to automatically learn the margin for our triplet-loss constraint irrespective of the available data.

With $\tau \in (0, \frac{2}{3})$, by optimizing the proposed adaptive-bound triplet loss, different classes are separated in the metric embedding space. Let $D(c_1, c_2)$ denote the minimal distance between classes c_1 and c_2, i.e., the distance between two closest instances from c_1 and c_2 respectively. Consider an arbitrary quadruple $(x_1, x_2, x_3, x_4) \in \mathcal{Q}$ where $\{x_1, x_2\} \in c_1$, $\{x_3, x_4\} \in c_2$, and $\mathcal{Q}$ is the set of all possible quadruples generated from class c_1 and c_2. Suppose (x_2, x_3) is the closest dissimilar pair among all possible dissimilar pairs that can be extracted from (x_1, x_2, x_3, x_4). We first prove that the lower bound of $D(c_1, c_2)$ is given by $\min\limits_{(x_1,x_2,x_3,x_4) \in \mathcal{Q}} D^{(l)}(x_1, x_4) - D^{(l)}(x_1, x_2) - D^{(l)}(x_3, x_4)$.

$$\begin{aligned} D^{(l)}(x_1, x_4) &\leq D^{(l)}(x_1, x_2) + D^{(l)}(x_2, x_4) \\ &\leq D^{(l)}(x_1, x_2) + D^{(l)}(x_2, x_3) + D^{(l)}(x_3, x_4) \end{aligned} \quad (4)$$

$$\begin{aligned} D(c_1, c_2) &= \min_{(x_1,x_2,x_3,x_4) \in \mathcal{Q}} D^{(l)}(x_2, x_3) \\ &\geq \min_{(x_1,x_2,x_3,x_4) \in \mathcal{Q}} D^{(l)}(x_1, x_4) - D^{(l)}(x_1, x_2) \\ &-D^{(l)}(x_3, x_4) \end{aligned} \quad (5)$$

By optimizing the adaptive-bound triplet loss, the following constraints are satisfied.

$$\begin{cases} D^{(l)}(x_1, x_2) \leq d_{sim}^{(l)}(x_1, x_2) \leq \mathcal{T}_{sim}^{(l)} \\ D^{(l)}(x_3, x_4) \leq d_{sim}^{(l)}(x_3, x_4) \leq \mathcal{T}_{sim}^{(l)} \\ D^{(l)}(x_1, x_4) \geq d_{dis}^{(l)}(x_1, x_4) \geq \mathcal{T}_{dis}^{(l)} \end{cases} \quad (6)$$

$$\begin{aligned} D(c_1, c_2) &\geq \min_{(x_1,x_2,x_3,x_4) \in \mathcal{Q}} D^{(l)}(x_1, x_4) - D^{(l)}(x_1, x_2) \\ &-D^{(l)}(x_3, x_4) \\ &\geq \mathcal{T}_{dis}^{(l)} - 2\mathcal{T}_{sim}^{(l)} \\ &= 2 - \tau - 2\tau \\ &= 2 - 3\tau \end{aligned} \quad (7)$$

if $\tau \in (0, \frac{2}{3})$, we have $3\tau < 2$. Therefore,

$$D(c_1, c_2) \geq 2 - 3\tau > 0 \quad (8)$$

Equation 8 indicates that the minimal distance between class c_1 and c_2 is always positive so that these two classes are separated.

Note that our whole proof is solely based on the triangle inequality, which is correct as long as the triangle inequality holds. As L_2-norm is utilized to measure the distance, the metric space learned by our framework is indeed a normed vector space. The triangle inequality is a natural property in this space.

Moreover, our framework does not require the learned metric space to be convex, i.e., for any two distinct instances x and y in the metric space, there exists a third instance z in this space lying between x and y ($d(x,z)+d(z,y) = d(x,y)$). Whether or not the equality strictly holds does not affect the correctness of our proof, since it only considers the upper-bound of a distance. In our case, even the non-convex metric space is a valid solution, as the triangle inequality still holds in this space.

VI. Implementation

We developed an implementation of our system for the 64-bit Ubuntu Linux operating system with 128 GB space of RAM. Our system consists of the data generation and the machine learning detection module. For the data generation, we used bash scripts which consist of 100 lines of code. We leveraged the CamFlow tool [21] installed on VirtualBox using Vagrant. We modified the CamQuery module [22] to extract the ID of the provenance graph nodes and to generate edges of process interactions.

For the machine learning detection module, we leveraged scikit-learn for our baseline evaluation and the OAML components were implemented with approximately 500 lines of Python code using the PyTorch library.

Model Parameters. For our experiments, Support Vector Machine (SVM) uses Radial Basis Function (RBF) kernel with Cost = 1.3×10^5 and gamma is set to 1.9×10^{-6}. OAML uses a Rectified Linear activation Unit (ReLU) network with embedding $n = 200$, number of hidden layers $L = 5$, $k = 1$, learning rate = 0.3, learning rate decay = 1×10^{-4}, and uses ADAM (A method for stochastic optimizer) optimizer.

VII. Datasets

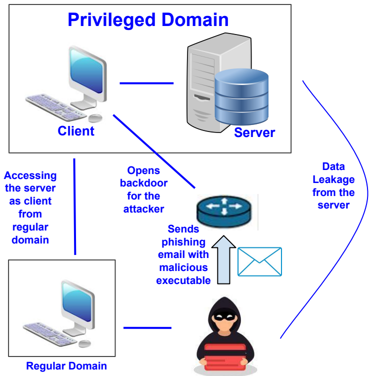
A. Attack Generation & Data Collection

Table I show the contents of our dataset. The dataset consists of different APT activities such as exfiltration of data, illegal login and access, opening of a reverse shell for command and control access, and illegal network scanning using **nmap** for the discovery of services on victim's network. All the classes were used for both benign and malicious scenario generation. For example, command line injection attacks were considered malicious when some third party injected some commands and executed them. Benign scenarios were mimicked with normal command execution flow which consists of usual executed commands. Table II shows properties of the provenance graph based on the trace of a single execution of an attack instance. A sample provenance graph contains an average of 10 332 edges for data ex-filtration attack events labeled as class 1, while the average in-degree is 48 and the average out-degree is 153 for the same class.

For our dataset, we collect the provenance graph which contains information such as provenance type and task type as discussed in section IV-A. Benign instances include web browsing activities on benign websites, normal login activity with Secure Shell (SSH) and benign connection from a client machine to a database server. We collected 100 traces for each attack type. Our dataset consists of activities derived from previously known APT attack campaign steps. We collect multiple traces of attack sequences to gather diversified training data and test on single instance of the attack sequence. We generated 7 benign cases and 7 attack cases since each attack type has a corresponding benign activity variation.

B. Attack Generation

Table I shows that the Data Leakage Attack & Remote Webservice Penetration (Shellshock) and Password Cracking attack are deployed through mimicking real-world scenarios. A server end user, a client end user, and an attacker are required to mimic the attack. In the data leakage attack scenario, a server consists of a database and owns it and has given access to its client to access data from the database through queries. In the server end, postgresql database is used for such service. If a database is dumped from the server end into any sql file or any other file format, a client can reconstruct the database or restore the database by having that file from the server end. In the attack scenario, a third user who is essentially the attacker makes the client download some malicious program (e.g., spear phishing e-mail (from outside) to open a backdoor or sending the software to the client end by any other means) and run it in the client's computer. With the execution of that software, the attacker gets access to the client's system (control over client's computer) and can now communicate with the server. The attacker can now make queries to the server and can even restore the database in its own end but it will make the behavior seem like a client as it will be doing these tasks from the client's system. In a nutshell, the attacker makes the victim end download some executable and execute it to open the backdoor for itself to the server end so that it can leak the data to the client end while having full access to the server as a client (a client acts as a privileged domain to the attacker). The attacker can leak the data through external storage or network transfer after the attack has been deployed from the client's computer. Benign scenarios for this case were created with normal operational and communication flow between the server and the client. These operations include normal database queries made by the client to the server, access to the database file and retrieving of the database by the client itself.



Privileged Domain
Client
Server
Accessing the server as client from regular domain
Opens backdoor for the attacker
Sends phishing email with malicious executable
Data Leakage from the server
Regular Domain

Fig. 6. Data Leakage Attack

The Remote Webservice Penetration (Shellshock) and Password Cracking attack is deployed when the client's system is somewhat hacked or deliberately used to attack the server end. In this scenario, an attacker exploits a remote shellshock vulnerability by sending crafted input to the CGI (Common Gateway Interface) service implemented using bash. Thus the attacker leverages the shellshock vulnerability as a backdoor to run malicious commands such as executing a password cracking tool.

C. Data Collection

1) Data Collection for Data Leakage Attack: Figure 6 illustrates the steps required to complete this attack. For the data leakage attack, data was captured in both the server and client end. For the attack scenario, the attacker sends an email with some malicious executable attached with it to the client's mail. The client downloads the attachment, executes it, and thus opens the backdoor for the attacker without any knowledge of it. The attacker now mimics the behavior of the client but from its own end and performs all the database queries and restoration. When the client executes the backdoor program, it goes straight to a vulnerable state

TABLE I
SUMMARY OF ATTACK WORKLOAD

Class	Description	Software
1	Data exfiltration	scp
2	Illegal network scanning	ping
3	Illegal network mapping	nmap
4	Reverse shell for Command and Control	nc
5	Data Leakage Attack	Deployed Through Mimicking Real-World Scenario
6	Remote Webservice Penetration (Shellshock) and Password Cracking	Deployed Through Mimicking Real-World Scenario
7	Command Line injection Attack	Deployed Through Mimicking Real-World Scenario

Attacks emulated from MITRE APT collection.

TABLE II
PROVENANCE GRAPH PROPERTIES

Class	Avg # of out-deg	Avg # of in-deg	Avg # of edges
1	153	48	10 337
2	545	13	9796
3	325	5	9781
4	511	96	10 236
5	561	922	9783
6	2,084	1,437	10 638
7	300	52	10 106

and from that time Camflow provenance data is collected both at the server and client end. The benign set of data corresponds to when the server and client are communicating regularly. No other connection is established in the meantime. The server receives database requests from the client in a regular manner in benign scenario data collection.

2) Data Collection for Password Cracking Attack: We carried out a password cracking attack using the John the ripper tool which implements a dictionary password attack. For the password cracking attack, the normal behavior or benign scenario simply involves a client connecting with the server using a curl command with no malicious payload. Benign data is collected while these normal operations take place using a Camflow provenance graph. For the attack scenario, the attacker exploits the shellshock vulnerability and then downloads a password cracker and executes a shell script for the backdoor creation. The attacker then executes commands for password collection and cracking from the victim's end. While these steps take place, data was collected at the victim's end using a Camflow provenance graph.

3) Data Collection for Command Line Injection Attack: For the command line injection attack, we only collected data for the attack scenario. The victim host (e.g., say embedded / IoT device that runs Linux) runs Mediaplayer (Kodi client), and it exports a remote control Application Program Interface (API) as a web service. One of its input sanitizations has an error that fails to filter invalid input from the outside, in turn allowing attackers to inject arbitrary commands blended in one of its requests. This attack is inspired by the Jeep-Cherokee attack case where the attacker from remote gains control over the vehicle. In parallel to the above steps, the data collection was done at the victim host using a Camflow provenance graph.

TABLE III
RESULTS BASED ON NOVEL APT ATTACK DETECTION

VIII. EVALUATION

A. Results

Table III and IV show the results of our experiment. For our experiment, we trained incrementally on the attack classes and tested on all the remaining classes which includes the benign class instances. Please note that the training data and the test data consists of the benign data instances. With this approach, we can determine if our algorithm can detect unseen novel attack classes. First, we train on all the benign classes and a single APT attack class and test on all the benign and APT attack classes. Second, we train on all benign

TABLE V
EXECUTION TRAINING AND TESTING TIME FOR OML

No of Training Instances	Train time(s)	Test time(s)
700	55.8	1.94
800	55.9	1.95
900	55.4	1.96
1000	55.5	1.96
1100	54.7	1.91
1200	55.9	1.97
1300	58.9	1.98
1400	59.5	2.00
1500	59.6	2.08

classes and two APT attack classes and tested on all attack classes. Third, we train on all benign classes and three APT attack classes and tested on all attack classes. Lastly, we train on all benign classes and all the APT attack classes and tested on all attack classes. We measured our performance by using the following metrics: **Accuracy**, **TPR**, **FPR**, and **F2**.

In the experiments, we measured the true positive rate (*tpr*), where true positive represents the number of correctly classified seen and novel APT attacks classes; false positive rate (*fpr*), where false positive represents the number of incorrectly classified seen and novel APT attacks; and F_2 score of the classifier, where the F_2 score is interpreted as the weighted average of the precision and recall. The F2 score ranges between the values 100 and 0 where 100 is the best value and 0 is the worst value.

The results show our approach performs better than traditional machine learning based classifiers such as k-NN, SVM and Decision tree. The accuracy of detection of novel attacks with our approach is 86 % compared to 79 % for k-NN, 68 % for SVM and 73 % for Decision Tree when we train on only five attack classes. Similarly, the TPR is 76 % for OML compared to 65 % for k-NN and 55 % for Decision Tree when we train on only five attack classes. The $F2$ is 80.5 % for OML compared to 70.69 % for k-NN and 61 % for Decision Tree when we train on only five attack classes. The $accuracy$ increases to 98 % for OML and 96 % for k-NN, 91 % for SVM and 93 % for Decision Tree when we train on 7 attack classes.

Our approach improves classification performance on average by **6.8 %** for accuracy, **10.19 %** for TPR and **11.4 %** for $F2$ when compared with k-NN method, while the performance improves by **17 %** for accuracy, **28 %** for TPR and **26 %** for $F2$ when compared with SVM. Likewise, our performance improves by **10 %** for accuracy, **17 %** for TPR and **16 %** for $F2$ when we compared our method with Decision Tree.

Our approach detected novel APT attacks with higher accuracy than k-NN, SVM or Decision Tree even with limited training on a subset of the APT attack classes. This is possible because OML can learn to minimize the distance in feature space for similar instances and maximize the distance for dissimilar instances as shown in Theorem V-B4.

B. Execution time for OML

Table V shows the summary of the execution time required to train our OML approach and then perform inference on the test data. The execution time for training the OML algorithm is approximately 60 seconds while the testing or inference execution time is approximately 2 seconds. As discussed in subsection V-B, OML learns a latent embedding space vector to satisfy a constraints. As a result of this algorithm, OML training time is higher than at inference. As we can see from the execution timing information, the testing time is fast as a result of just using the learned embedding vector to classify the test data. In addition, we only show the number of instances used for the training since the number of testing instances is always constant as discussed in section VIII.

IX. RELATED WORK

Our work specifically focuses on APT attack detection. An earlier approach was proposed by [23]. In their work they coined an automated technique to generate attack graphs using symbolic model checking algorithms. Later on [24] proposed a robust , flexible graph based approach for network vulnerability analysis which allows attacks from both outside and inside the networks. This method suffers from the scalability issue when state increase occurs. [3] proposed scalable attack graphs which do not require the idea of backtracking from the attacker side relying on the idea of monotonicity. [18] proposed an idea based on Decision Tree to prevent APT attacks. Recent work on APT attack detection include Milajerdi et al. [17] called HOLMES. HOLMES uses a set of manually generated rules to describe different APT information flows from an attack provenance graph. Our approach uses a deep learning based approach to learn the attack patterns without the need for manual generation of rules. Ghafir et al. [10] uses machine learning based correlation analysis MLAPT, but the approach does not focus on detection of novel attacks.

There are additional works that propose various methods for APT detection. For example, [6] proposes a novel deep learning stack for APT detection. In this method, they propose using deep learning for outlier detection to detect APT attacks and novel APT attacks. However, this method has not been implemented in practice. Cho et al. [8] propose a method for APT detection based on unusual or unknown domains that a malicious user could visit while conducting an APT attack. In [14] authors have proposed STREAMSPOT, a clustering based anomaly detection method in heterogeneous graph. Through this method, anomalous graphs, that are prominently different from others are identified. Tian et al. [25] proposed a deep learning representation for graph clustering.

Various methods for detecting attacks have been proposed. [15] uses host and network data for anomaly detection. Methods such as [20], [2] detect malware in evolving data streams. [19] uses a deep auto-encoder to learn features for novel class detection. Our work differs from these works by using provenance graphs, which take into consideration the information flow for the attack events.

X. Limitation and Future Work

In this work, we have not focused on multi-stage attack detection, however, our framework is able to detect a single stage in a APT attack as shown in the experiments. However, our method may not always detect all the zero-day attacks. In future work, we plan to address the challenge of multi-stage attack detection. Data collection is still challenging in cyber-attack space as the amount of standardized training data is limited. In future work, we opt to collect more data to train our machine learning models. In addition, we will perform experiments with real life attack data. Our work currently focuses on attacks based on Linux operating system, we plan to address attacks in other operating systems e.g. Windows operating systems platform.

XI. Conclusion

Detecting APT attacks is a challenging task based on the approach deployed by malicious actors. In this work, we focus on a machine learning based approach to detect APT attacks. We leverage provenance graphs for the collection of event data from host systems. We apply OML: a novel machine learning technique for detecting APT attacks. Our results show our approach has a higher detection accuracy compared to traditional machine learning techniques. In our future work, we will explore more novel detection machine learning methods to detect novel APT attacks.

Abstract

During a strong earthquake, commercial and residential buildings designed to meet current building codes and standards may sustain damage that significantly hinders the restoration of building functionality. Similarly, lifeline infrastructure systems can be damaged and loose ability to provide critical services. The impacted buildings and lifeline infrastructure systems and their associated consequences such as dislocation of people, disruption of key services, and lack of access to jobs and schools, pose a significant impediment for communities during recovery. In the wake of recent disasters across the globe, there is mounting evidence that the public finds these kinds of disruptions unacceptable. Buildings and lifeline infrastructure systems can be designed for higher performance so that they are able to serve their function or regain functionality with acceptable interruption after an earthquake. This will require shifts in design philosophy from safety-based objectives to recovery-based objectives across multiple aspects of current practice. The 2018 Congressional reauthorization of the National Earthquake Hazards Reduction Program (NEHRP), P.L. 115-307, requires two Federal agencies, the National Institute of Standards and Technology (NIST) and the Federal Emergency Management Agency (FEMA), to work with experts across the U.S. to address this issue of improving post-earthquake functional recovery. FEMA and NIST convened a committee of experts to develop the report to the U.S. Congress to identify and assess options for functional recovery and post-earthquake re-occupancy. As part of this effort, stakeholder workshops were held in February 2020 in five U.S. cities to gather public feedback to inform the final report to Congress. This paper summarizes the main findings of this effort, including a list of the key recommendations identified for improving the functional recovery of buildings and infrastructure. The report to the U.S. Congress serves as a starting point for improving timeframes for re-occupancy and functional recovery of the built environment and critical infrastructure after earthquakes through the development and adoption of functional recovery concepts, codes and standards, policies, and practice.

Keywords: Functional recovery, post-earthquake re-occupancy, NEHRP.

Sattar, Siamak; Johnson, Katherine. "Recommended Options for Improving the Functional Recovery of the Built Environment and Critical Infrastructure." Paper presented at 17 World Conference on Earthquake Engineering, Sendai, JP. September 13, 2020 - September 18, 2020.

1. Introduction

Earthquakes can affect communities through loss of life, injury, property damage, displacement of residents and businesses, and long-lasting economic and social impacts. The United States Geological Survey (USGS) estimates nearly half of Americans are at risk from potentially damaging earthquakes[1]. Despite decades of improvements in the seismic safety of the built environment, the economic and social systems of communities throughout the U.S. remain at risk of large scale, long-term disruption. The U.S. has not experienced a major damaging earthquake since 1994. However, the Federal Emergency Management Agency (FEMA) estimates the annualized cost of damage to U.S. building stock from earthquakes to be $6.1B per year [2]. A 2008 USGS exercise using a 7.8M earthquake in Southern California as a case study estimated 2,000 deaths, 50,000 injuries, and $200 billion in direct costs, in addition to staggering, destabilizing impacts to long-term community function. Depending on the size of the disaster, communities can also face significant and costly long-term consequences, including interruption of basic services (shelter, food, water, sanitation), loss of jobs and businesses, voluntary and forced relocation of residents, psychological trauma, and loss of important physical, cultural, and social assets [3].

The Federal Government has recognized the need to improve the state of practice in design and retrofit of multiple components of the built environment such that buildings and lifeline infrastructure systems can restore their function with minimum disruption in the services that they provide. Buildings and lifeline infrastructure support and enable society's continued economic, psychological, and social health, all of which may be severely interrupted or completely disrupted depending upon the magnitude of shaking and level of damage experienced. By strengthening the ability of the built environment to withstand earthquake effects, we can return community members to their homes, business, and normal activities more quickly. To move toward this desired performance state, the National Institute of Standards and Technology (NIST) and the Federal Emergency Management Agency (FEMA), as part of the December 2018 reauthorization of the National Earthquake Hazards Reduction Act, were charged to convene a committee of experts *"to assess and recommend options for improving the built environment and critical infrastructure to reflect performance goals stated in terms of post-earthquake re-occupancy and functional recovery time.*", P.L. 115-307, This paper summarizes the effort to fulfill this congressional mandate and presents some key findings on the recommended options for improving the recovery time.

2. Problem Statement

In the United States, building codes are the primary mechanism by which State and local jurisdictions manage earthquake risk for buildings. Most often, these building codes are adopted with the target of saving lives and reducing injuries, rather than preserving the structure's ability to be operational, or even recoverable, after an earthquake event. The primary, longstanding goal of building codes for most buildings is to protect lives by reducing the likelihood of structural collapse in rare extreme events (i.e., Risk-targeted Maximum Considered Earthquakes), and to provide some level of property protection in more frequent events. Current codes generally do not consider design of buildings to explicitly provide functionality after a hazard event. Buildings that are designed per these codes may sustain extensive damage in a significant event requiring lengthy and costly repair or rebuilding, which in turn can lead to lack of providing the intended function or service. This loss of function negatively impacts sociocultural and economic functions of the community and can lead to temporary or permanent dislocation or required relocation of community members after an event [3]. Older existing buildings may have been built with no (or earlier and less effective) seismic design considerations, and may pose an even greater hazard than newer buildings.

In most cases, the current design of lifeline infrastructure systems (such as water, wastewater, power, gas and liquid fuels, transportation, and telecommunications) does not take into consideration the functionality of the system after an earthquake event. Unlike building design, the state of practice for design of different lifeline systems to provide critical services is more complex due to their interdependencies and need to address the broad spatially distributed networks of specialized components. It is expected that various lifelines systems may not be able to provide their intended services after an earthquake. Because buildings and their occupants

Sattar, Siamak; Johnson, Katherine. "Recommended Options for Improving the Functional Recovery of the Built Environment and Critical Infrastructure." Paper presented at 17 World Conference on Earthquake Engineering, Sendai, JP. September 13, 2020 - September 18, 2020.

depend on lifeline infrastructure systems, the lack of their critical service would undoubtedly impact the operation and ability of buildings to function and provide their intended services.

The U.S. public, particularly in large urban areas, will find the disruption of sociocultural and economic services not only distressing, but unacceptable for the timeframes that it would currently take to restore infrastructure or building functionality—which may be in the range of months to years depending upon the earthquake event. There is a need to improve the ability of buildings and infrastructure systems to continue functioning at full or acceptably reduced capacity post-event. Ensuring a more limited disruption of sociocultural and economic services will require significant effort to move beyond the current design paradigm. A new functional recovery performance objective would improve the performance of buildings and lifeline infrastructure systems, so that they are less likely to be negatively impacted and more likely to maintain a sufficient level of functionality or regain it in a timeframe acceptable to community members. By providing the basic intended function or service of various components of the built environment within an acceptable time following an earthquake, communities can mitigate and recover more quickly from earthquakes and reduce vulnerability and long-term negative consequences. Greater emphasis on functional recovery has the potential to reduce the cost and social, psychological, and health consequences for communities at risk of seismic events, and will in turn improve resilience across the nation.

3. Congressional Mandate

The federal government has recognized the above-mentioned problems and the need for improving the state of practice in design and retrofit of buildings and lifeline infrastructure systems. The 2018 reauthorization of the National Earthquake Hazards Reduction Program (NEHRP) (P.L. 115-307), included a new requirement for the National Institute of Standards and Technology (NIST) and the Federal Emergency Management Agency (FEMA) to convene a "committee of experts" and develop a "report of recommended options" to Congress for moving the built environment and critical infrastructure:

> *(a) ASSESSMENT AND RECOMMENDATIONS.—Not later than December 1, 2019, the Director of the National Institute of Standards and Technology and the Administrator of the Federal Emergency Management Agency shall jointly convene a committee of experts from Federal agencies, nongovernmental organizations, private sector entities, disaster management professional associations, engineering professional associations, and professional construction and homebuilding industry associations, to assess and recommend options for improving the built environment and critical infrastructure to reflect performance goals stated in terms of post-earthquake re-occupancy and functional recovery time.*
>
> *(b) REPORT TO CONGRESS.—Not later than June 30, 2020, the committee convened under paragraph (1) shall submit to the Committee on Commerce, Science, and Transportation, the Committee on Energy and Natural Resources, and the Committee on Homeland Security and Governmental Affairs of the Senate and the Committee on Science, Space, and Technology, the Committee on Natural Resources, and the Committee on Homeland Security of the House of Representatives a report on recommended options for improving the built environment and critical infrastructure to reflect performance goals stated in terms of post-earthquake re-occupancy and functional recovery time.*

In response to this mandate, NIST and FEMA convened a committee of experts with two components: the Project Technical Panel (PTP), which is responsible for developing the report, and the Project Review Panel (PRP), which is responsible for providing subject matter expertise peer review throughout the writing process. The report to Congress, hereafter known as NIST-FEMA report [4], addresses a breadth of mechanisms for driving change, including codes and standards, education, and planning and preparedness. In addition, five stakeholder workshops were held in St. Louis, MO; Salt Lake City, UT; Seattle, WA; San Francisco, CA; and Los Angeles, CA to gather broad national input to the NIST-FEMA report.

4. Functional Recovery

The NIST-FEMA report defines functional recovery as follows:

> *Functional recovery is a post-earthquake performance state in which a building or lifeline infrastructure system is maintained, or restored, to safely and adequately support the basic intended functions associated with the pre-earthquake use or occupancy of a building, or the pre-earthquake service level of a lifeline infrastructure system*.

Using concepts from performance-based earthquake engineering framework, design for functional recovery would involve the creation of a new functional recovery performance objective, defined as follows:

> *A functional recovery performance objective is functional recovery achieved within an acceptable time following a specified earthquake, where the acceptable time might differ for various building uses and occupancies, or lifeline infrastructure services*.

The notion of functional recovery supports community resilience goals by focusing on the design, construction, and retrofit of individual buildings and lifeline infrastructure systems. A functional recovery performance objective is one component of community resilience and can help a community to achieve resilience by enabling buildings and lifeline systems to recover their basic functions in a timely manner. The definition of *basic* intended functions may be somewhat less than full functionality, but more than what would be considered sufficient for simple re-occupancy of buildings, or temporary provision for critical lifelines services. The determination of basic, necessary, or critical services may require community context and information on the dependencies among various aspects of a community's built environment.

Although the ability of buildings and lifeline infrastructure systems to provide services depend on interactions among different systems, a functional recovery objective will be most efficient at the individual building or lifeline infrastructure system level. In current design philosophy and practice, buildings and lifeline infrastructure systems are designed separately using different codes and standards and are regulated by different jurisdictions and sectors. A new recovery-based design paradigm envisions separate but parallel functional recovery objectives applied to the design of individual buildings and lifeline infrastructure systems. These objectives must be coordinated between buildings and lifeline systems, for example, a building design will be informed by the expected performance of lifeline infrastructure systems, but not controlled by it. The separate functional recovery objectives for buildings and lifeline systems will prevent delay in progress due to complications in either sector and will be easier to implement as assets are constructed at different times by different stakeholders, using the then-applicable codes and standards. In this way coordinated and simultaneous development of functional recovery performance objectives is expected to expedite the progress toward the goal of reducing the time it takes for communities to recovery.

5. Design Based on Recovery Time (Beyond Safety)

As mentioned earlier, the primary objective of building codes for most buildings is achieving life safety. The International Building Code (IBC) currently categorizes building use or occupancy using a building's Risk Category as defined in the Table 1604.5 of the IBC [5]. The Risk Categories are developed based on the level of protection or risk to public safety. The Risk Categories do not represent the desired recovery time for different building uses, except at the highest risk category for essential facilities. To develop functional recovery performance objectives, the Risk Category concept can be extended to consider the desired recovery time for various building uses. This new categorization could be called the Recovery Category. In this new design paradigm, buildings and lifeline infrastructure systems would be designed to meet specific recovery time goals at a specified hazard level. The recovery categories can be determined based on the needed basic services from a building or lifeline infrastructure system, and the timeline these services are needed during response and recovery. The time required for recovery of function varies by the use, occupancy, and criticality

Sattar, Siamak; Johnson, Katherine. "Recommended Options for Improving the Functional Recovery of the Built Environment and Critical Infrastructure." Paper presented at 17 World Conference on Earthquake Engineering, Sendai, JP. September 13, 2020 - September 18, 2020.

of function that a building or lifeline infrastructure system provides. Not all services are needed immediately after an earthquake, nor are all services necessarily needed at the same time. Possible Recovery Categories for buildings and lifeline infrastructure systems are described in Table 1, which is used strictly as a means to illustrate the Recovery Category concept; the target recovery times and descriptions provided in Table 1 will be influenced and likely modified by future research.

Table 1: Recovery Categories [4]

Recovery Category (RC)	Target Recovery Time	Description
RC-4	Hours	Emergency Response - Basic services and systems needed for immediate response, rescue, and event stabilization to ensure emergency response activities can be undertaken
RC-3	Days	Short-Term - Basic services and systems needed at the initial stages of recovery
RC-2	Weeks	Intermediate-Term - Basic services and systems needed to restore neighborhoods and the workforce, and to care for historically underserved populations
RC-1	Months	Long-Term - Basic services and systems needed for restoring vitality to economy, sociocultural institutions, and physical infrastructure

In current performance-based design practice, buildings are designed to meet specific performance level(s) at specified hazard level(s). In current practice, most buildings across the U.S. required to meet seismic provisions are designed to provide life-safety protection at a "design-level" hazard event. The design-level earthquake is an earthquake with a statistical likelihood of occurring once in every 300 to 700 years (also called a return period), at a particular location throughout the country. The seismic hazard level tentatively considered for functional recovery considerations in this paper, i.e., Table 1, is also taken to be the design-level event. Alternatively, scenario-based events may be more appropriate for the basis of design for locations with well-defined fault mechanisms. Future research is needed to inform selection of an appropriate hazard level for the design of functional recovery.

6. Recommended Options for Improving Built Environment and Critical Infrastructure

The NIST-FEMA report presents nine recommendations across four areas of emphasis including developing a national recovery framework, improving the built environment, improving planning, and raising awareness and understanding of potential earthquake impacts on the built environment and lifeline infrastructure systems. This section summarizes these nine recommendations. Further information regarding different options for implementation of each recommendation may be found in the NIST-FEMA report. Please note that the nine recommendations discussed here are preliminary recommendations and are subject to modification in the final draft of the NIST-FEMA report.

6.1 Develop a National Functional Recovery Framework

One of the fundamental steps identified in the NIST-FEMA report to support the development and implementation of functional recovery performance objectives is developing a functional recovery framework for buildings and lifeline infrastructure systems. This framework would address the multidisciplinary aspects of functional recovery. The framework needs to incorporate policy, social science, and engineering aspects of the issue. The framework would identify acceptable recovery times for different building uses and lifeline infrastructure services and would also address the required provisions to achieve the desired performance goals. A minimum standard is recommended for consistency across the nation, while still allowing local jurisdictions to exceed the minimum recommendations according to their priorities and distinctive challenges. The national framework should determine the functions that are critical to recovery as well as their desired timeline. The framework should also consider mechanisms to support coordination between the desired recovery times of buildings and lifeline infrastructure systems, as well as the costs and benefits associated with selecting particular hazard levels or recovery times. Future research will be needed to provide the information required for developing the national framework.

6.2 Design New Buildings to Meet Recovery-based Performance

Buildings designed according to current codes and standards may experience significant damage during a design-level earthquake that can hinder the intended function of the building. A cornerstone to all of the options for achieving functional recovery goals is to design new buildings to meet recovery-based design objectives. In this new design paradigm, in addition to designing for life-safety objectives, new buildings will also be designed to satisfy a specific recovery time after a design-level event. One of the first steps in this process is to benchmark the recovery time that current buildings codes and standards deliver. It is possible that some current building uses may already meet the desired recovery time. If the benchmarking results identify a need for reducing the desired recovery time, two alternative approaches may be pursued. In the first approach, the design requirement for a higher Risk Category building can be applied to a broader class of new structures. In an alternative approach, new buildings could be designed using new codes and standards with design criteria developed to achieve re-occupancy and recovery of function in an acceptable timeframe. Regardless of the chosen approach, the implementation of this recommendation may be achieved through either mandatory or voluntary mechanisms, and at the national, state, or local levels. Both mandatory and voluntary mechanisms are associated with implementation pros and cons that will require careful evaluation.

6.3 Retrofit Existing Buildings to Meet Recovery-Based Objectives

Enhancing the performance of existing buildings is a critical aspect of improving community resilience since existing buildings comprise the majority of the building stock and pose the greatest threat to the community. Existing buildings are more challenging to address than new buildings, as improving the performance of this building group is constrained by various factors including the technical feasibility of achieving higher performance goals, as well as the costs associated with retrofit. There is also a concern that aiming towards higher functional recovery targets (i.e., relatively short target recovery times), for retrofitting existing buildings may adversely impact safety-targeted retrofit actions. This would be an unintended negative consequence of aiming for greater resilience. One way to manage challenges related to existing buildings is to adopt lower re-occupancy or functional recovery goals than for new buildings. Such an approach will mitigate the greatest risks associated with marginally deficient buildings. In addition, retrofit programs can be paired with pre-event planning such as developing re-occupancy plans and relocation of critical uses to enhance the effectiveness of the retrofit programs. Regardless of the target recovery-based performance goal for existing building retrofits, local jurisdictions need to identify buildings that require re-occupancy and functional recovery design, as well as actionable triggers for retrofit and appropriate requirements. Similar to the design of new buildings, implementation of existing building retrofits can be done through mandatory or voluntary approaches, using national, state, or local design criteria. Both mandatory and voluntary mechanisms are associated with implementation pros and cons that will require careful evaluation.

6.4 Design, Upgrade, and Maintain Lifeline Infrastructure Systems to Meet Recovery-based Performance Objectives

Lifeline infrastructure systems have numerous operational requirements as well as regulatory environments. Most regulations for lifeline systems focus primarily on public health, as well as safe and reliable operations. These regulations are not currently intended to enable the provision of services in a specific timeframe after most hazard events, including earthquakes. Although there are multiple manuals and guidelines for design of the components of lifeline systems, design criteria are inconsistent among systems, and most of them do not incorporate seismic design. Lifelines infrastructure systems are vital components of the built environment and community recovery highly depends on the recovery of the services they provide. Therefore, there is a critical need for a shift in the design paradigm of lifeline infrastructure systems from protecting lives and property to focus on recovery of function after a hazard event within an acceptable timeframe.

To ensure consistent design and operations throughout the systems and among various owners and operators, national-level seismic design guidelines, standards, and codes are needed. These guidelines, standards, and codes would be based on functional recovery performance objectives. To develop the functional recovery design paradigm for lifeline systems, clear guidance and multiple implementation and support tools are needed. The development of codes, standards, guidelines, and tools will require additional research. Implementing the Earthquake Resistant Lifelines: NEHRP Research, Development and Implementation Roadmap [6] can serve as a stepping stone for this work.

Due to the interconnected, complex, and interdependent nature of lifeline infrastructure systems, coordinated efforts across various stakeholders are needed to develop and implement coherent and consistent performance goals for lifeline infrastructure systems. Continued support for the development of state or regional lifeline councils could significantly help engagement from different lifeline infrastructure owners and operators and is essential to implementing the framework at local levels. Besides the above-mentioned design and implementation activities, seismic resilience plans for each lifeline infrastructure system need to be developed. These plans should focus on improving (1) pre-earthquake integrated asset management plan to address aging/vulnerable components to enhance system-level resilience and (2) post-earthquake disaster recovery plans for rapidly repairing and recovering the systems. The re-establishment of the national program, as part of NEHRP, to advance the engineering of lifeline infrastructure systems could significantly assist with the leadership, management, and coordination of cross-country efforts.

6.5 Develop and Implement Plans Needed to Facilitate Functional Recovery

While codes and standards are necessary to achieve functional recovery goals, they are not sufficient in themselves. In addition, robust planning activities that enable the success of a functional recovery objective are needed. Planning is an essential step towards meeting functional recovery goals. Effective plans engage relevant and representative stakeholders in dialogue around mutually-agreed upon goals and objectives, strategies and tactics. Engaging diverse stakeholders, by educating them, getting buy-in, and feedback from them about functional recovery actions, will increase the chances of successful implementation of the functional recovery framework. Planning for functional recovery can be incorporated into all types of ongoing and future community plans.

One of the first steps related to planning efforts is to adjust the language and tools in the existing mitigation plans such as FEMA's local mitigation plan [7], that spells out requirements for communities to be eligible for FEMA post-earthquake aid for public and non-profit facilities. Similarly, functional recovery can be integrated into the community resilience activities undertaken by chief resilience officers, emergency managers, community development professionals, and other similar representatives. Moreover, state and local government can play an important role in achieving functional recovery goals by considering improvements to the development and implementation of regulatory incentives for mitigation plans, supporting planning for swift re-housing efforts after an earthquake, and the development of protective measures that can help communities to recover quickly and maintain their populations.

6.6 Perform Rapid Building Inspections and Evaluations to Facilitate Functional Recovery

Assessment of buildings' performance after an earthquake is essential to evaluate whether the they are safe to occupy and also to determine their post-hazard functionality level. Timely inspection and evaluation of buildings after an earthquake plays an important role in expediting the recovery process. There are multiple opportunities for improving the state of practice concerning inspection and evaluation of buildings ranging from development of technical guidelines to programs and policies that can support re-occupancy and functional recovery efforts [8], such as a pre-arranged plan to provision building inspectors.

From a technical standpoint, inspection guidelines need further development to effectively incorporate recovery-based assessment tools as current inspection guidelines primarily focus on the safety of buildings. Recent advances in remote sensing technologies make it possible to use seismic instrumentation to expedite the assessment and recovery of buildings and lifeline infrastructure systems. Improvements and development of these technologies are needed and may be essential for certain types of buildings. In addition, development of alternative standards for temporary habitability of buildings in post-earthquake scenarios may mitigate current stringent requirements for evacuation of buildings during the repair process. Another factor that can prevent unnecessary evacuation of residents is developing protocols for establishing safety cordons around damaged buildings that consider their associated risk with damaged buildings in conjunction with the disruption in the recovery process.

From the policy perspective, there is a need to enact policies and procedures that facilitate post-earthquake safety inspection of buildings by state and local government. For example, development and implementation of programs for funding and sharing local jurisdiction and county staff for earthquake inspection and recovery programs after an earthquake can significantly expedite the inspections and tagging process.

6.7 Explore Financial Resources to Facilitate Functional Recovery

Speedy access to financial capital after an earthquake event plays a key role in expediting recovery. There are currently different post-disaster funding mechanisms including federal programs, insurance, and loans; one common factor among these mechanisms is the slow process of administration that can significantly delay the recovery process. Improving the speed of access to resources plays an important role in expediting the recovery of buildings and lifeline infrastructure systems meeting functional recovery objectives; this can occur by modifying existing or developing new financial programs. Further coordination of existing federal programs to enable quicker access to and distribution of funds to local jurisdictions in post-event situations is also needed. One example related to access to federal financial support would be developing a Federal Case Management System and single application form, where one application can be submitted by the building owner for all applicable federal programs for disaster assistance. Consideration can be given to improving the availability of affordable housing loans after earthquakes as well as improving grant programs to expedite access to financial resources. Federal agencies may also encourage the use of parametric insurance for homes and businesses.

In addition, consideration can be given to improving the access to quick funds after an earthquake event through natural hazards insurance programs, and particularly by additional work to supporting the development of a fiscally viable and affordable earthquake insurance program. Other programs to facilitate access to post-disaster funds by private individuals, such as disaster accounts, or pre-arranged repair loans, could significantly help building owners more quickly begin the journey through repair and restoration of their buildings.

6.8 Educate Building Owners, Tenants, and Customers/Users about Building Performance Expectations and Enable Action that Will Lead to Functional Recovery

Public acceptance and input are important components of any functional recovery design and implementation. Effective public outreach requires developing and implementing appropriate educational materials, incorporating risk communication methods, and establishing ongoing engagement mechanisms. The public should be educated on the current safety-based target of the building code and its consequences on the community and its built environment in an event of an earthquake. This educational effort may help support the need for an enhanced performance target. In addition, educating building owners, tenants, and customers on the benefits of the functional recovery design may positively influence their willingness to enact functional recovery concepts. Additional work is needed to help inform the users and owners of buildings and lifeline infrastructure systems about the significant shifts required to achieve functional recovery objectives and how they are fundamentally distinct from current practice. Key components of the educational effort should include enhancing public understanding of their level of risk from seismic activity and what their buildings or lifeline infrastructure systems may or may not be able to provide given their current state. Stakeholders should also be educated on mitigation and preparedness strategies that can improve the recovery of function after an earthquake. Federal agencies could play a significant role in this effort not only by educating the public, but also by creating and promoting a nationwide seismic continuity program for all building uses to owners and tenants to address their respective unique situations. Consideration should be given to improving the continuity programs to identify effective mitigation and preparedness strategies for resuming functions post-earthquake in a timely manner.

6.9 Enhance Outreach and Continuing Education Efforts for Building Industry Professionals and their Associations

The functional recovery efforts will be more successful if adopted by many individuals, organizations, and jurisdictions. Recruiting and maintaining a workforce knowledgeable about functional recovery and implementation methods will be crucial to ensure a common understanding across the building professions and government agencies. The workforce includes engineers, architects, contractors, code officials, etc. The professional associations of the building industry are key players in moving the nation toward functional recovery because they can reach out to significant numbers of building design and construction professionals. Multiple activities can be undertaken to enhance outreach and continuing education for building industry professionals. For example, functional recovery concepts along with a discussion of the societal benefits of functional recovery could be added to the codes of ethics for different building industry associations. Similarly, the continuing education requirements for professional licensing could incorporate the functional recovery concept.

Designing buildings to functional recovery performance objectives will be a notable shift from current standards of practice for the engineering and architectural fields. Training programs will be essential to introduce skilled professionals to new concepts and to educate them on new codes, regulations, and inspection protocols.

7. Workshops

Functional recovery inherently incorporates risk tolerance, community preferences, and societal values. As a result, it is critical to gather feedback from stakeholders on developing the functional recovery framework and prioritizing options for improving functional recovery time. As part of the congressionally mandated effort, five stakeholder workshops were held across the U.S. to gather input from a broad range of community leaders and subject matter experts throughout the community on concepts that will inform the functional recovery framework and the NIST-FEMA report. The workshops were conducted in St. Louis, Salt Lake City, Seattle, San Francisco, and Los Angeles. The workshop participants represented a broad range of stakeholders and subject matter experts, including local officials, private consultants, structural engineers, social scientists, utility and lifeline system representatives, and others. The workshop collected information on three main topics: 1) the time-frame for recovery of difference components of the built environment that support various social functions, 2) attributes for evaluating and assessing options for improving functional recovery time, and 3) trade-offs among different attributes to inform evaluation of options for improving functional recovery time.

[The workshops recently concluded. Assessing results of the workshops is currently in progress. The final manuscript and presentation will include key findings from the workshops].

8. Summary

Buildings and lifeline infrastructure systems designed per current codes and standards may sustain extensive damage during an earthquake event. The widespread damage is likely to hinder the service that buildings and lifeline infrastructure systems provide to support the sociocultural and economic functions of a community [3]. The required time for regaining function of various components of the built environment is either likely to be extensive, or not well understood and difficult to estimate. A post-earthquake state in which people may not have access to their jobs, schools, housing, and other services can produce sociocultural and economic consequences that can lead to temporary or permanent displacement of a community's population. The U.S. federal government has recognized the need to extend the target of risk mitigation for the built environment from life safety to include timely recovery of function. The functional recovery design concept is proposed as a means to achieve the target performance of timely recovery of function after an earthquake. This paper summarizes the effort undertaken by NIST and FEMA in response to a Congressional mandate to recommend *"options for improving the built environment and critical infrastructure to reflect performance goals stated in terms of post-earthquake re-occupancy and functional recovery time"*. The paper provides an overview on nine recommendations across four areas of emphasis related to developing a national recovery framework, improving the built environment, improving planning and expediting response and recovery, and raising awareness and understanding of potential earthquake impacts on the built environment. Future research and consensus-based decision making are needed to prioritize these options; attributes such as costs, benefits, impact, feasibility, and timeline are likely candidates for evaluation criteria. Achieving functional recovery across a community requires a multi-faceted approach that includes parallel efforts on aspects of: design of new buildings; retrofit of existing buildings; lifeline infrastructure systems; planning, outreach, and education. Developing and implementing functional recovery objectives represents a significant shift in the design philosophy for buildings and lifeline systems that demands a multi-disciplinary perspective and engagement from a broad range of community stakeholders, but this can happen within mechanisms currently in place for codes and standards development, policy development, and community resilience planning. Achieving greater seismic resilience through functional recovery goals will benefit not only local communities; the entire nation will benefit. This work can be accomplished through the strong partnerships and interactions across traditionally disparate sectors that have already initiated efforts on functional recovery.

***Abstract*—This paper describes the generation of a quantum-based rms output voltage of 1.332 V using an ac-coupled Josephson Arbitrary Waveform Synthesizer (JAWS) without any low-frequency compensation current biases, that is, in a 'zero-compensation' (ZC) mode. Low-frequency bias currents result in unwanted error voltages that increase with frequency. The ZC technique minimizes these currents and removes the resultant error voltages.**

***Index Terms*—Digital-analog conversion, Josephson junction arrays, signal synthesis, superconducting integrated circuits, voltage measurement.**

I. Introduction and System Description

Josephson Arbitrary Waveform Synthesizers (JAWS) use current-pulse-biased arrays of Josephson junctions (JJs) to generate quantum-based voltages. When operating correctly, each current pulse causes each JJ to generate a voltage pulse with an integrated area $h/(2e)$ that is dependent only on fundamental constants: the electron charge e and the Planck constant h. By controlling the pulse-timing, JAWS systems are used to create spectrally pure low-frequency sine waves for ac voltage metrology along with other arbitrary waveforms [1].

To create large output voltages for metrology, many JJs and narrow pulses with a fast repetition rate are required. In this paper, we use a cryocooled system at 4.5 K with 204 960 JJs across two separate chips with four independent high-speed current pulse biases [2]. The JJs have critical currents between 5.9 mA and 6.5 mA and are placed in series arrays along the center-conductors of 16 coplanar waveguides.

There are a number of sources of error that can impact the JAWS output voltage, including the transfer function of the output leads, leakage resistance and capacitance, feedthrough of the bias signal, and inductive voltage errors [3]. In this paper, we have increased the maximum output voltage that can be generated using a 'zero-compensation' (ZC) technique [4] that reduces the last two sources of error. Both of these errors are caused by bias signals at low-frequencies that create undesired error voltages at the DUT. The ZC technique uses a current bias that, ideally, has negligible current at low-frequencies and thus removes the source of the error voltages. However, this technique depends on the JJ nonlinearity to convert an input current pulse stream with no low-frequency content into a quantum-based output voltage pulse stream with calculable low-frequency content.

By optimizing the algorithm used to generate the bias waveform, the microwave bias electronics, and the shape of the current bias pulses, we create a ZC waveform with an rms magnitude of 1.332 V at 10 kHz (Fig. 1).

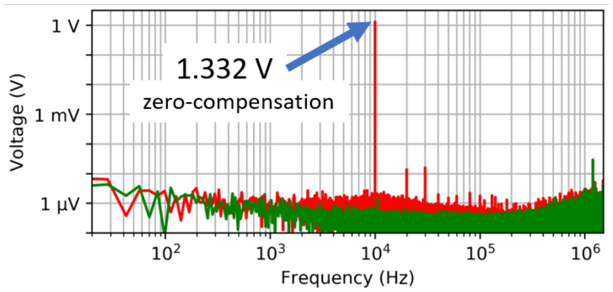

Fig. 1. Spectrum of a quantum-based 'zero-compensation' JAWS rms output voltage of 1.332 V at 10 kHz (red, harmonics are due to the digitizer nonlinearity) and background with no bias applied to the JJ arrays (green). The spectrum is sampled at 3.75 megasamples per second.

II. Current Bias Waveform

We use an 8-bit 57.6 gigasample-per-second arbitrary waveform generator (AWG) to create the current pulse bias. The waveform stored in the memory of the AWG is generated using a two-step procedure. First, a delta-sigma algorithm is used to determine the desired timing of the pulses from the JJs. The algorithm uses a three-level output corresponding to either a positive JJ pulse, a negative JJ pulse, or no JJ pulse at each clock step with a clock rate of 14.4 GHz. We also constrain the algorithm so that pulses with opposite signs are separated by at least 50 clock cycles and pulses with the same sign are separated by at least 3 clock cycles.

Second, we digitally high-pass filter the AWG waveform to remove all of the low frequency content below 100 MHz. This algorithm uses the multi-bit nature of the AWG and typically results in a reduction in the low-frequency current content below 100 MHz by at least four orders of magnitude when generating large output voltages.

The AWG is followed by a high-power, wide-bandwidth amplifier. The amplifier non-linearity when operating near saturation mixes down part of the large power components in the pulse-bias around 14.4 GHz, which creates a low-frequency signal at the synthesis frequency after the amplifier. We employ a two-pole high-pass filter between the amplifier and the cryostat to reduce this low-frequency component of the bias.

Finally, we also use the AWG finite-impulse-response (FIR) filter to optimize the shape of the current bias pulses. We start by surrounding each pulse with opposite sign half-pulses to create a composite pulse-like object which further reduces

Paper presented at 2020 Conference on Precision Electromagnetic Measurements (CPEM), Denver, CO, US. August 24, 2020 - August 28, 2020.

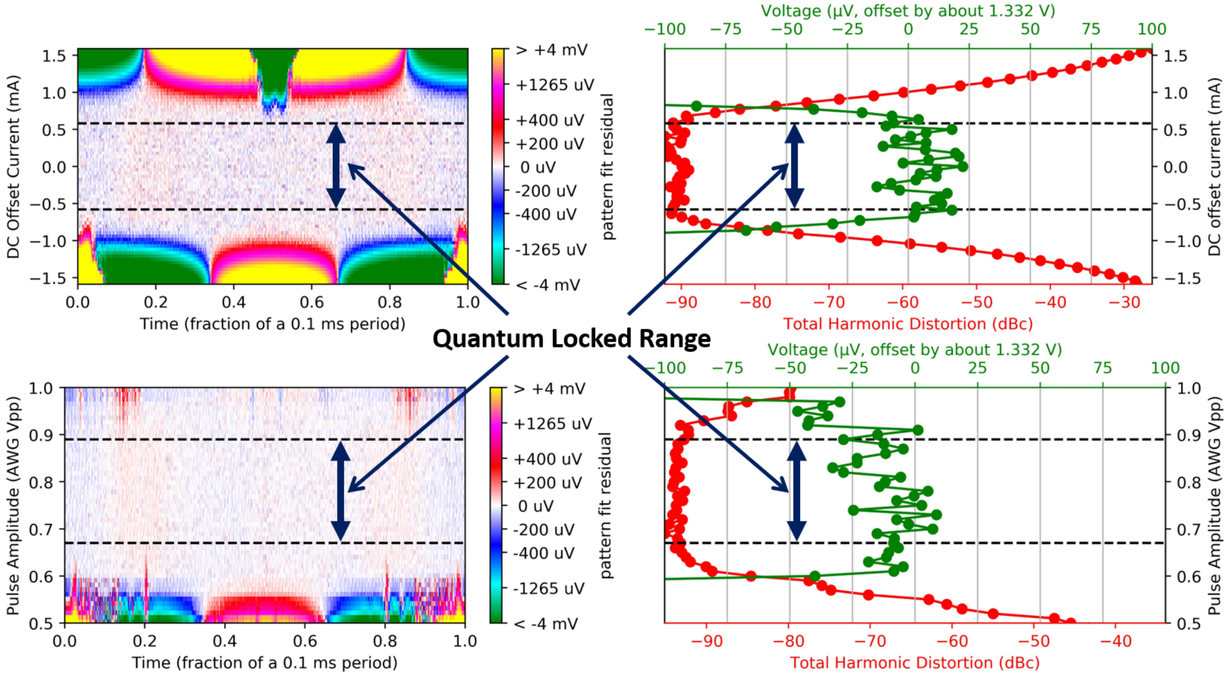

Fig. 2. Density plots showing the residual of a fit to a sinusoid as a function of time and bias dither (left) and the generated voltage (green) and THD (red) versus bias dither (right). The dithered bias is either a dc current offset on all JJ arrays (top) or the pulse amplitude applied to a quarter of the JJ arrays (bottom). The quantum locked range is between the dashed black lines.

the low-frequency content produced by the AWG, though the detailed shape of the pulse is then modified to optimize the quantum-locked range (see next section). The width of this pulse-like object sets a limit on the pulse repetition rate, which in turn places a limit on the maximum output voltage.

III. Quantum Locked Range

Using the techniques discussed in the previous section, we were able to generate a quantum-based output rms voltage without compensation of 1.332 V at 10 kHz (Fig. 1). However, a clean spectrum is not proof of quantum-based behaviour. We also need to confirm that every JJ generates a single output voltage pulse for every input current bias pulse over a range of bias parameters. We call this range the ‘quantum locked range’ (QLR) for the dithered bias parameter. For ZC waveforms, the two most relevant bias parameters are the dc current and the amplitude of the current pulses.

In Fig. 2 (left) we plot the residuals of a fit to the 10 kHz sinusoid as a function of waveform period (x-axis) and dc offset current through all of the JJs (y-axis, top) or the pulse amplitude applied to a quarter of the JJs (y-axis, bottom); the response to changing other pulse amplitudes is similar. From the same data, we also extract and plot (right) the magnitude of the fundamental and the total harmonic distortion (THD). We observe a clear dc current offset QLR with a width greater than 1.1 mA over which the magnitude and THD are constant. The similar pulse amplitude QLR is 0.2 V or 20 % of the tuning range of the AWG. In this case, the units of the QLR do not directly correspond to current through the JJ arrays.

At CPEM 2020 we intend to expand this preliminary data beyond measurements at a single frequency and present a more comprehensive comparison between the output voltages generated by the different current pulse bias channels.

IV. Conclusion

In conclusion, we were able to generate a quantum-based rms output voltage of 1.332 V without compensation using a cryo-cooled JAWS system. This ‘zero-compensation’ bias mode results in smaller voltage errors in comparison to the more typical JAWS bias mode that requires low-frequency bias currents.

STRUCTURE IGNITION MECHANISMS IN WILDLAND-URBAN INTERFACE (WUI) FIRES AND ASSOCIATED CALIFORNIA STATE FIRE MARSHAL STANDARD TEST METHODS

Samuel L. Manzello
National Institute of Standards and Technology (NIST), USA

1. INTRODUCTION

Wildland fires that spread into communities, known as wildland-urban interface (WUI) fires, are a major global problem. In the USA, a series of very destructive WUI fires have occurred over the past several decades, mainly in California. The most significant of these were the 2018 Northern California fires that destroyed more than 18,800 structures and resulted in scores of fatalities. WUI fires are not limited to the USA, as South Korea experienced significant fires in 2019. Australia, like the USA, has a long history of destructive WUI fires, and the 2020 Australian WUI fires were worldwide news for months.

More than a decade ago, the state of California in the USA identified the need to develop an approach to harden communities to WUI fires exposure. The term harden simply indicates to make infrastructure in communities more ignition resistant. The premise has its roots in the development of standards and codes developed to mitigate urban fire disasters that were observed in the USA, such as the 1871 Great Chicago Fire or 1904 Baltimore Fire. The urban fire codes and standards provide the basis for fire resistant construction in many countries throughout the world [1]. In the USA, the concept of WUI fire building codes and standards is far newer, due to the more recent WUI fire problem in this country. Developing test standards for outdoor fire exposures presents significant challenges.

The objective of this study is to provide an overview of WUI structure ignition mechanisms and the associated standard test methods developed by the State Fire Marshal (SFM) of California [2]. The paper closes with a short discussion on the need for improved WUI standard test methods.

2. WUI FIRE STRUCTURE IGNITION MECHANISMS

The main ignition mechanisms of structures from WUI fire exposures are due to direct flaming combustion contact, radiant heat, and firebrand exposure. Direct flaming combustion contact refers to the situation where a structural component is in direct contact with flaming combustion from an adjacent combusting fuel source. In WUI fires, this could be ornamental vegetation, such as mulch, shrubs, or trees, or other fuel types, such as a burning vehicle or a neighboring structure [3].

Radiant heat is a form of electromagnetic radiation that is emitted from sufficiently hot materials. Due to the combustion of vegetative and structural fuels in WUI fires, any fuel type in close proximity to these combustion processes will experience radiant heat that may lead to ignition of these adjacent fuels.

Firebrands are generated from the combustion of both vegetative and structural fuels in WUI fires. The most important hazard is if the deposited firebrands have sufficient energy to ignite these adjacent fuel sources. In most cases, the firebrands themselves are in a state of glowing combustion since it is difficult to sustain flaming combustion as they are transported through the atmospheric boundary layer. Once firebrands land on fuel beds, the initial ignition mechanism is that of smoldering combustion. If a glowing firebrand is able to provide enough energy, self-sustained smoldering combustion may occur in the fuel bed, and under the influence of an applied wind field, the smoldering combustion reaction may transition to a flaming combustion reaction. Firebrand exposure is a dominant mechanism to structure ignition in WUI fires [4].

3. CALIFORNIA STATE FIRE MARSHAL (SFM) TEST STANDARDS

Based on post-fire studies of ignition vulnerabilities in WUI fires, standard test methods were devised by the office of the State Fire Marshal (SFM) in California to address ignition vulnerabilities to exterior walls, exterior windows, horizontal projections such as eaves, decking assemblies, and the use of ignition resistant materials. It is important to note that the exposure conditions used in these test methods are best guess estimates of what exposure conditions would be in a WUI fire and were developed with the best available information at that time.

Manzello, Samuel. "Structure Ignition Mechanisms in Wildland-Urban Interface (WUI) Fire and Associated California State Fire Marshal Standard Test Methods." Paper presented at Japan Association for Fire Science and Engineering, Hirosaki, JP. May 28, 2020 - May 29, 2020.

3.1SFM-12-7A-1 EXTERIOR WALL SIDING AND SHEATHING

This standard test method makes use of a burner to expose a wall to a 10 min 150 kW fire exposure. The test attempts to simulate a scenario where an exposure of flame impingement occurs as a result of ignition of plants, trash, a deck, or other combustible materials beside the wall. The test method does not apply to a scenario where the building is exposed to a large radiation source for a long duration of time, such as burning of an adjacent structure.

3.2 SFM-12-7A-2 EXTERIOR WINDOWS

To assess the performance of windows exposed to direct flames, this test method uses a 150 kW burner under a target window. The specimen is exposed to the flame for 8 min. This test method is not representative of a radiation exposure from a WUI fire.

3.3 SFM-12-7A-3 HORIZONTAL PROJECTION UNDERSIDE (EAVES)

This standard test exposes a projection to a flame of 300 kW for 10 min. The sample is then observed for another 30 min to monitor the existence of glowing or flaming combustion on the unexposed side of the specimen.

3.4 SFM-12-7A-4 DECKING

In part A, the test method exposes decking assembly samples to direct flame exposure of 80 kW for 3 min. The sample fails if there is runaway combustion, structural collapse, or flaming dripping materials. The test procedure requires observation of the sample for 40 min after the flame exposure.

In part B, a standard burning firebrand (Class A crib from ASTM E108 [5] to represent a firebrand) is placed on the deck while a fan blows an air flow of approximately 5.4 m/s over the specimen and the sample is observed for 40 min for signs of sustained flaming or falling firebrands. In all cases, the samples need to be exposed to conditions of accelerated aging or weathering to create a more realistic representation of the actual decking assembly in the test.

3.5 SFM-12-7A-5 IGNITION RESISTANT MATERIAL

Any material designated as ignition resistant must pass a 30 min ASTM E84 [6] test. ASTM E84 was not developed by the SFM of California but is a legacy standard test method, also known as the Steiner Tunnel test method.

4. NEED FOR IMPROVED TEST METHODS

While these test methods described above attempt to harden communities to WUI fire exposures, these standards remain largely unproven to actually mitigate WUI fire spread and structure ignition processes. Post-fire investigations conducted by NIST and elsewhere have indicated that most structures in WUI fires are destroyed from firebrand exposure [4].

The development of the NIST Firebrand Generator (NIST Dragon) coupled with the Fire Research Wind Tunnel Facility (FRWTF) at the Building Research Institute (BRI) in Japan have led to improved regulations in California. As an example, a recently developed test method, ASTM E2886 [7], has been implemented to resist firebrand entry into building vents. This standard is listed as part of California’s requirements for firebrand resistant building vents in WUI hazard areas and BRI/NIST experiments form the scientific basis for this test method. While there is no special SFM test method for roofing assemblies, classification is based on the legacy ASTM E108 [5] roof test method. Based on BRI/NIST experiments that demonstrated firebrands may penetrate under roof tiles, California requires the addition of a non-combustible cap-sheet placed under roof tiles to mitigate firebrand ignition. Fencing assemblies are known to be vulnerable to firebrand exposure, but these have yet to be addressed in California [2]. Recent firebrand shower experiments have also demonstrated the deficiencies of SFM-12-7A4 part B, the decking test method.

5. SUMMARY

WUI fire structure ignition mechanisms and associated standard test methods in use by the state of California were discussed. To be able to lessen the destruction from WUI fire exposures requires the development and implementation of improved scientifically based standards and codes.

Abstract— **Magnetic random access memory (MRAM) based on perpendicular magnetic tunnel junctions (pMTJs) is one of the core building blocks for beyond-CMOS technologies. Their inherent non-volatility, rad-hardness and endurance (10^{16}) makes pMTJs extremely competitive for computation-in-memory and other DoD applications where security and ruggedness are of the utmost vitality. To deliver on the potential of MRAM for computation-in-memory, reductions in the energy- and delay characteristics of pMTJs must be demonstrated. Based on interfacial- and bulk perpendicular magnetic anisotropy materials, we demonstrate two novel perpendicular synthetic antiferromagnet (p-SAF) designs for ultra-fast and ultra-low power switching performance: one using interfacial PMA materials and one using bulk PMA materials. Our stacks are compatible with or close to the existing p-MTJ stack and fabrication process, which will make the technology transition to back-end-of-line semiconductor process practical within a 5-10 year time frame.**

Keywords—MRAM; beyond-CMOS; spintronics; rad-hard

I. Introduction (*Heading 1*)

The Magnetic Tunnel Junction (MTJ) is one of the core building blocks for beyond-CMOS technologies. Compared to other beyond-CMOS building blocks, MTJs offer several unique advantages. Two factors stand out for their ability to enable computation-in-memory and other DoD applications. The first is the inherent non-volatility of the data storage layers, yielding essential radiation hardness, instant power-on, non-destructive data read-out, and security in hardware. And the second, is endurance up to 10^{16} read/write cycles and above, which is three orders of magnitude better than any reported memory cells. This provides necessary robustness for a true computation-in-memory and computation-near-memory arrays.

Advancement of MTJs in the past decade has led to successful magnetic random-access memory (MRAM) products, including toggle-MRAM (Everspin, IBM, Honeywell) and STT-MRAM (Everspin, GLOBALFOUNDRIES). It is realized by the community that MTJs may be the most promising building block for true computation in random access memory (CRAM) because of its superior endurance performance that is needed for computation [1-3]. State of the art performance metrics for the best performing p-MTJs have been demonstrated recently: ultrahigh TMR (208%) in p-MTJs with interfacial perpendicular magnetic anisotropy (PMA) and the ultralow write delays (t_{SW} ~ 165 ps at 50% switching probability) [4-5]. To enable true CRAM, as shown in Fig. 1, industry needs higher TMR ratio (>500%) and much lower write delay (<50 ps) with reasonably low operation energy (E_{SW} ~50 aJ per write operation, read is already negligibly low) and high thermal stability (delta = 60 k_BT). These numbers are from the preliminary benchmarking effort for CRAM. In theory, the highest TMR for a MgO-barrier based MTJ could reach

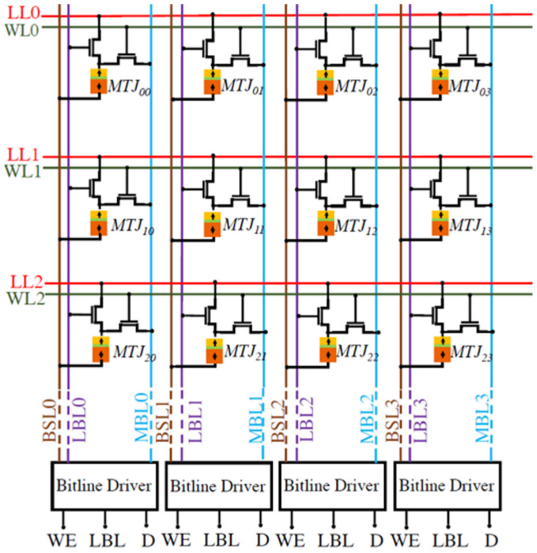

FIGURE 1: MRAM-based CRAM. LL, WL, BSL, LBL and MLM = Logic Line, Word Line, Bit Select Line, Logic Bit Line and Memory Bit Line

Gopman, Daniel; Wang, Jian-Ping; Low, Tony; Wang, Weigang; Taylor, William. "Toward Ultra-fast and Ultra-low Power Switching in Perpendicular Magnetic Tunnel Junctions." Paper presented at GomacTech 2020 Conference, San Diego, CA, US. March 16, 2020 - March 20, 2020.

35,000% with right materials and interfaces ,and the write delay could be reduced to below 10 ps with optimized materials and switching mechanisms. Our approach seeks to advance MTJs toward these performance specifications so that CRAM topology, many other new computing topologies, and future high-density MRAM products can become a reality.

An MTJ with engineered perpendicular magnetic anisotropy (PMA) relative to the planes of the layered heterostructure, or pMTJ, is an essential building block for advanced MTJs. The PMA materials are promising candidates for the development of ultra-high-density spintronic memory and logic devices due to their high thermal stability, scalability, and ultra-low power consumption. Interfacial PMA materials such as the Ta/CoFeB/MgO stack possess a PMA (K_u) of ~2-5 Merg/cm^3 and a α of ~0.015-0.027 [6-8]. Considerable progress has been made in the application of interfacial PMA materials to STT-MRAM [9-11]. Bulk PMA materials such as L1$_0$-FePd [12-16] and Mn-based perpendicular Heusler alloys [17-20] have a large K_u (1.3-1.4 MJ/m^3), a low α (0.002~0.015), and a low processing temperature (200 ºC). These properties make them ideal for ultra-high density and ultra-low power consumption memory devices. Furthermore, the write current density (J_c) for perpendicular spintronic devices is defined by the equation $J_c = 2\alpha e t_F M_s \left(H_{appl} + H_k\right) / \hbar\eta$ [21], where J_c mainly relates to the α, the saturation magnetization (M_S), and the K_u. Notably, switching time is proportional to M_S. However, for interfacial PMAs (such as the Ta/CoFeB/MgO stack) and bulk PMA FePd thin films, their M_S=1100~1300 kA/m, which is relatively high.

Synthetic antiferromagnetic (SAF) structures, comprised of two ferromagnetic layers aligned in an antiparallel arrangement and separated by a thin (<1 nm) metallic spacer, are used extensively in multilayered magnetic sensors and memories [22], which is one of promising methods to obtain the low M_s of the ferromagnetic layer for p-MTJs [23-25]. Owing to the nearly net-zero flux configuration, SAFs are generally implemented as the reference layer to compensate the deleterious offset fields from other layers. More recently, SAFs were demonstrated to show the potential for faster write operation in magnetic domain-wall memories compared with single-layer counterparts due to additional torques on the magnetization induced by the interlayer coupling field [26]. A recent simulation has made a similar argument for single-domain MRAMs in which a SAF *free layer* replaces the single magnetic layer [27]. This work, supported partially by the DARPA-sponsored STARnet research center C-SPIN, shows that the design of a SAF-MTJ using conventional interfacial PMA materials in construction of a SAF free layer can enable switching energy-delay products on the order of 100 aJ-10 ps for a 10 nm diameter free layer with a 60 k_BT thermal stability factor, where k_B is the Boltzmann constant and T is the ambient temperature (300 K). In addition, PI Jian-Ping Wang recently developed a perpendicular interfacial synthetic-ferrimagnetic structure (CoFeB/Gd/CoFeB) and realized field-free switching using spin orbit torques [28], and the bulk L1$_0$-FePd p-SAF composite free layer as well as the integration into p-MTJs and the 25% TMR ratio has been obtained at room temperature after 350 ºC post-annealing, even up to ~13% after 400 ºC post-annealing.

Ultrafast STT switching in the sub-ns regime is one of the key issues for STT-RAM development. One of the crucial limitations for ultrafast switching is the incubation delay induced by pre-switching oscillation [29]. Several approaches have been proposed to minimize pre-switching oscillations in order to improve the switching speed in spin valves such as developing all perpendicular structures [30], applying a hard axis field to set the free layer equilibrium away from the easy axis [31], and adding an extra perpendicular polarizer [32-34]. As of now, limited work has been done on sub-nanosecond STT switching in MTJs. Minimum switching times of 400–580 ps at 50% switching probability have been reported in conventional in-plane MTJs [35,36]. By adding a perpendicular polarizer, Liu et al showed 100% switching at 500 ps with external field assistance in their MTJ device [37]. Rowlands *et al* achieved 50% switching probability at 120 ps under zero bias field in a fully orthogonal MTJ [38]. For this present approach, a notable achievement is the observation of group of 165(190) ps at 50(98)% switching probabilities in the in-plane MTJs [5]. However, switching probabilities have not been studied extensively p-MTJs – with the exception being a single simulation work which showed that a SAF-MTJ using conventional interfacial PMA materials in construction of a SAF free layer can enable switching energy-delay products on the order of 100 aJ-10 ps for a 10 nm diameter free layer. With voltage controlled magnetic anisotropy (VCMA) [39,8], the switching energy of conventional pMTJs can be further reduced to sub-10 fJ level [40,41]. However, due to the precessional nature of the switching, the time of the pulse voltage has to be accurately controlled, giving rise to a write error rate (WER) of 10^{-5}, which far exceeds the tolerable limits for reliable chip-level performance [42]. We are exploring a unique Even-VCMA effect where voltages with both polarities can reduce the PMA; this is theoretically predicted when the Fermi level of the FM is precisely controlled [43]. With the advanced SAF structure developed in the proposal, STT and Even-VCMA can work together in a complimentary fashion, eventually leading to ultra-low energy (<100 aJ), ultra-low WER (< 10^{-10}) and ultra-fast (< 50 ps) switching.

The key specifications for advanced pMTJs for computational random access memory systems are: ultra-high TMR ratio (>500%); ultra-fast switching (50 ps for 50% switching probability of a 60 k_BT pMTJ); ultra-low switching energy (100 aJ); ultra-small feature size (10 nm) and low damping constant for the magnetic storage layer (<0.01). This provides necessary robustness for a true computation-in-memory and computation-near-memory arrays.

With the realization of advanced pMTJs for computational random access memory systems, significant gains can be realized over classic, near- and edge memory computing. By using memory cells to carry out computation, one gains a 1400-fold improvement over near-memory computing in execution time, and a 40-fold energy reduction [44]. Surprisingly, our team has discovered a realization of a spintronic, reconfigurable in-memory binary neural network accelerator that performs with greater energy efficiency and throughput on image classification and genomics kernel tasks than corresponding CPU-, GPU- and FPGA-based implementations [45].

II. Achieving ultrafast switching MTJs

To reach ultimate fast switching, a balanced SAF (with near zero net magnetization) is desired. However, such as balanced SAF would require an extremely large exchange coupling constant which is not practical. Therefore, aside from the gains in write speed realized by the SAF structure, additional reduction in write delay may be achieved by electric-field tuning of the PMA using the so-called even voltage control of magnetic anisotropy (even-VCMA) effect.

Indeed, a promising approach to reduce the overall switching energy (E_{SW}) in MTJs is utilizing the interfacial perpendicular magnetic anisotropy (PMA) at the FM/oxide interface and the corresponding VCMA effect [8,36-38,46-48], where the MTJ can be precessionally switched by an effective in-plane field generated by a sub-ns voltage pulse. We have achieved a low switching current at 10^8-10^9 A/m^2 with fast speed at 400 ps, corresponding to a low E_{SW} that is below 20 fJ. However, due to the precessional nature of switching, the MTJ can be only be switched in a very tight window in VCMA, giving rising to a very large write error rate in the order of 10^{-5}, much larger than STT (10^{-10}). The core structure is CoFeB (0.9 nm)/MgO (1.6 nm)/CoFeB (1.5 nm), with thicknesses reported in parentheses. However, in another device with a very similar structure, we were able to extend the switching window from 0.5 ns to more than 1 ns with external field an applied in-plane instead of at 40°.

The key to reducing switching energy and switching time with interfacial SAF free layer is to utilize the VCMA effect to lower the energy barrier during switching. The efficiency of VCMA is characterized by the change of interfacial magnetic anisotropy density per unit electric field, $\Delta K_S/\Delta E_{ext}$. With the Even-VCMA effect where the STT and VCMA can be combined, truly ultra-low energy and ultra-fast switching is possible, simultaneously with a very low WER that is comparable to STT alone.

III. Development of SAF MTJs

A. Interfacial PMA MTJ

Consistent with current state-of-the art approaches, we have designed p-MTJs with interfacial perpendicular SAF free layers for sub-100 ps switching (see Fig. 2(a)). We have already achieved above 200% TMR with Mo dusting layers inserted at the Ta/CoFeB interface [4]. Unlike thick Mo layers that exhibited a strong (110) crystalline texture, the inserted Mo layer between Ta/CoFeB had little negative influence on the crystallization of CoFe (001), thereby combining the advantages of Mo as a good thermal barrier and Ta as a good boron sink. We envision possible solutions using other heavy metal insertions, to include W and Hf, which have potential to provide higher TMR.

The high probability switching of interfacial p-MTJs has been demonstrated in 100 nm diameter nanopillars. Our p-MTJs comprising a Ta/CoFeB/MgO free layer, rapid thermal annealed for 5 minutes at 300 °C exhibit a significant VCMA effect that enables fast, reliable switching at 200 ps. We report switching probability greater than 90% for a 200 ps pulse and 40 fJ switching energy. By engineering a thicker MgO tunneling barrier (approximately 50% thicker than the previous sample), the switching energy of a 100 nm p-MTJ can be reduced to 9 fJ, with a modest reduction in switching probability.

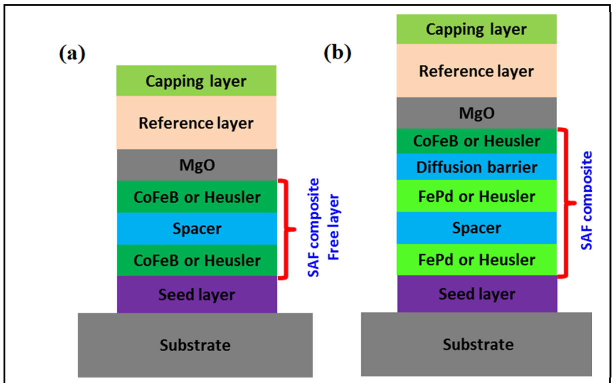

FIGURE 2: (a) The designed interfacial perpendicular SAF(p-SAF) structure, in which the CoFeB and Co-based in-plane Heusler alloys will be used as a ferromagnetic layer and Ru, Ta, Cr will be as a spacer to generate the synthetic-AFM, and Gd will be a spacer to lead to synthetic-ferrimagnetic layer. (b) The designed bulk p-SAF structure with L1$_0$-FePd and Mn-based perpendicular Heusler alloys as a ferromagnetic layer and Ru and Cr as a spacer.

B. Bulk PMA MTJ

The p-SAF structure with bulk PMA FePd thin films has been developed and integrated into p-MTJs as a free layer (see Fig. 2(b)). The p-SAF structure using bulk PMA FePd thin films through an fcc phase Ru spacer were designed and developed. It can be found that the L1$_0$-phase FePd p-SAF structure presents good PMA and antiferromagnetic coupling properties with a square shape minor M-H loop and a net remanent magnetization ~500 kA/m. The PMA constant K_u of the FePd p-SAF structure was then evaluated to be ~1.05 MJ/m^3 based on its M_s and H_K from the M-H loops, which is several times larger than that of interfacial PMA materials. The J_{iec} of the FePd p-SAF structure was calculated to be ~ -2.86 mJ/m^2, which is about one order of magnitude larger than that of the [Co/Pd]$_n$ p-SAF system with the same post-annealing temperature [50]. In addition, using magnified STEM we demonstrated that the Ru spacer follows the texture of FePd layer and forms the metastable fcc phase. In addition, most recently the p-MTJs with the [Co/Pt]$_n$ SAF layer from Japanese group showing high TMR (131% by CIPT after 350 °C post-annealing)[51], however, compared with FePd (α~0.002) [11], the [Co/Pt]$_n$ multilayer has a much larger α ~0.05~0.18 which will result in an appreciably larger switching current density which translates to higher write energy and slower write times.

Gopman, Daniel; Wang, Jian-Ping; Low, Tony; Wang, Weigang; Taylor, William. "Toward Ultra-fast and Ultra-low Power Switching in Perpendicular Magnetic Tunnel Junctions." Paper presented at GomacTech 2020 Conference, San Diego, CA, US. March 16, 2020 - March 20, 2020.

IV. Benchmarking and metrics of SAF MTJs for fast switching

The relevant metrics of SAF pMTJs for fast switching and implementation as advanced MTJs for computation in random access memory have informed the development activities described above. These include device size, switching delay, switching energy, write error rate, thermal stability, tunneling magnetoresistance and the damping constant. For the interfacial p-MTJs, these results are specific to the CoFeB/MgO/CoFeB p-MTJ system. Here we have successfully engineered 100 nm nanopillars with energy-delay product 9 fJ-200 ps, and that are thermally stable with TMR exceeding 100%. The switching probability of these devices was 80% and damping constant 0.01.

For the bulk SAF pMTJs, strategies have been developed to identify the useful buffer layers that can engineer a large perpendicular magnetic anisotropy in FePd, thereby providing thermal stability down to 10 nm diameter nanopillars. We find that these include Pt, Ru, Ir, Rh, but not Mo or Ta. This is consistent with the need for a fcc (001) buffer whose in-plane lattice parameter is comparable with the in-plane lattice parameter of FePd (0.385 nm). We have also shown the ability to engineer a bulk SAF trilayer using FePd/Ru/FePd, FePd/Ir/FePd and FePd/Rh/FePd. We find that Ru and Ir spacers are more thermally stable over the high-temperature growth and annealing treatment than the Rh spacer and can convey a net zero magnetization state at zero applied field, a prerequisite of a SAF device.

V. Conclusions

To deliver on the potential of MRAM for computation-in-memory, reductions in the energy- and delay characteristics of pMTJs must be demonstrated. Based on interfacial- and bulk perpendicular magnetic anisotropy materials, we believe there is a path to developing two novel perpendicular synthetic antiferromagnet (p-SAF) designs for ultra-fast and ultra-low power switching performance: one using interfacial PMA materials and one using bulk PMA materials. Our stacks are compatible with or close to the existing p-MTJ stack and fabrication process, which can transition to back-end-of-line semiconductor process practical within a 5-10 year time frame within our near-term roadmap shown in Fig. 3.

ABSTRACT

Interoperability across emerging visualization modalities, including augmented reality (AR) and virtual reality (VR), remains a challenge with respect to industrial applications. One critical issue relates to the lack of standard approaches for coordinating geospatial representations that are required to facilitate AR/VR scenes with domain-specific information in the form of time-series data, solid models, among other data types. In this paper, we focus on the linking of manufacturing asset data via the MTConnect standard with geospatial data via the IndoorGML standard. To this end, we demonstrate the utility of this integration through two visualization-based prototype implementations, including one focused on (i) monitoring production facilities to improve situational awareness and (ii) evaluating and delivering suggested navigation paths in production facilities. We then comment on implications of such standards-driven approaches for related domains, including AR prototype development and automatic guided vehicles.

Keywords: Geospatial modeling, standards, augmented reality, smart manufacturing

1 Introduction

The digitalization of manufacturing systems has become a core focus area to improve agility, productivity, and efficiency. This trend is especially important for introducing emerging information technologies (IT), e.g., virtual reality (VR) and augmented reality (AR), into production scenarios. The combination of advanced manufacturing with IT capabilities is referred to as *smart manufacturing* [1]. Early adopters of smart manufacturing concepts have been able to lower costs, improve worker safety, and achieve deeper situational awareness [2]. To gain broad use and dissemination of such solutions, standards are vital since the collaborative communication and integration of the underlying hardware and software is critical for success [3]. However, interoperability of such applications, methods, and devices remains challenging for the broad realization of smart manufacturing [4].

In this paper, we aim to address one of the interoperability problems faced by manufacturing organizations looking to adopt technologically advanced solutions. As an anchor to more seamless integration, we focus on the representation (i.e., computer-readable data model) of geospatial definitions. Linking real-time geospatial data across production systems is critical for the proper coordination of (i) automatic guided vehicles (AGVs) [5], (ii) interface-guided navigation for human operators [6], and (iii) perspectives for higher level situational awareness for decision makers [7]. Considering the ubiquity of on-board spatial reasoning devices, e.g., Light Detection and Ranging (LiDAR) technologies on AGVs, aligning multiple coordinate systems, facilitating multiple user perspectives, and tracking multiple moving devices is not trivial.

In response, we propose the use of standards for static

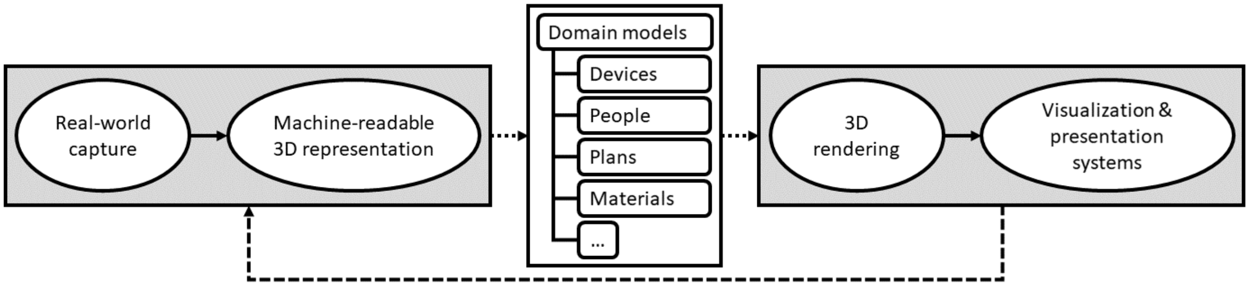

Figure 1. General pipeline for generating industrial visualization prototypes. Activities in grey and white boxes summarize standards efforts from the visualization and SMS communities, respectively. Dashed lines signal opportunities for automation.

geospatial representations that can build a bridge between such vision-based systems. As a first step, in this paper, we study the feasibility of leveraging one such standard, i.e., IndoorGML[1] released by the Open Geospatial Consortium (OGC), with an existing Smart Manufacturing Systems (SMS) standard, i.e., MTConnect[2], to facilitate the geospatial underpinnings of indoor manufacturing environments. We chose to work with these specific standards due to the publicly available tools supporting IndoorGML as well as publicly available MTConnect data via the NIST SMS Testbed (see Sec. 4).

Through this demonstration, we showcase two use cases derived from the underlying mapping between the standards. The first use case shows the quick three-dimensional (3D) rendering and presentation of a shop floor for situational awareness. The second use case presented demonstrates a tablet-based guidance for navigation from one job to another on the shop floor. Both use cases were generated by leveraging existing tools and methods already produced in accordance with the standards. In our minds, this demonstrates the power of standards in that leveraging tools that interface with standard data representation is much easier than building each component from scratch. To conclude the paper, we discuss implications of building additional bridges, i.e., mappings and toolkits, across standard interfaces to improve VR, AR, and mixed reality (XR) interoperability.

2 Motivation and Background

Industrial visualization-driven installations, e.g., AR and XR implementations, are often the production of one-off prototypes, wherein the domain models, e.g., machining performance models, digital solid models, and user manuals, are tightly coupled with domain-agnostic interfaces, e.g., rendering modules, presentation modalities, and visualization engines. After years of many organizations developing their own one-off installations, interoperability has become more of a pipe-dream. Solutions to help solve the problem are severely lacking. To address such needs, standards development organizations, such as IEEE, OGC, and the Khronos Group, have worked to contribute standard representations, modules, and languages. However, these efforts suffer from severe silo-ing and seem to fail to communicate with one another. This is especially true for domain-agnostic groups, e.g., World Wide Consortium (W3C) and Khronos Group, communicating with domain-heavy groups, e.g., American Society of Mechanical Engineers (ASME), the MTConnect Institute, and the OPC Foundation.

However, both perspectives, domain-specific thinking, e.g., for manufacturing and field maintenance, and visualization-specific concerns, e.g., real-world capture and scene rendering, are vital. SMS-specific standards, e.g., MTConnect and OPC-UA, provide the necessary semantic descriptions of concepts, such as information about devices, people, and materials. Figure 1 showcases the current state of industrial prototype development. From a high-level view, the visualization community is focused on two separate efforts, (1) digitizing real-world information (shown in the box to the left of Fig. 1) and (2) rendering and presenting scenes through the appropriate visualization modalities (see box to the right of Fig. 1). To produce successful and meaningful user experiences, it is vital to connect to domain-specific models. However, in the current state, automating these data transformations is expert-driven and requires many iterations and human hours. To this end, there is significant opportunities in automating (or self-automating) these transformations (indicated as dashed lines across Fig. 1).

In this paper, we particularly focus on the potential of standards to help contextualize geospatial information with streaming data collected form the shop floor. Below, we review relevant work related to (1) representing indoor spaces specifically for production environments and (2) leveraging those representations for navigation purposes.

[2] Available at https://www.mtconnect.org/

2.1 Indoor Space Definition for SMS

Since the majority of manufacturing processes are located inside buildings [8], modeling indoor spaces is required to fully represent production systems virtually. Often, the initial description of such environments begins with a map or layout of the workshop floor. Such maps are helpful in (1) supporting AGV tasks, (2) tracking tools, components and fixtures, as well as (3) facilitating guided navigation for operators [9, 10].

One of the core challenges of leveraging maps of production systems is the disparate nature of their source and intent. For example, AGVs, depending on brand and purpose, construct their own maps at various levels of detail [11]. In such cases, some AGVs leverage on-board LiDAR systems to build maps in order to avoid walls and other obstacles. To curate such maps, additional manual labor is required. Other AGVs have used camera systems that read optical markers on the floor or the ceiling to follow a predefined path through the workshop [12, 13]. Both solutions work for their specific use case, but the created maps cannot be interchanged easily. This example demonstrates that even in cases of similar technologies, e.g., two different types of AGVs, relating geospatial data and aligning coordinate systems represents significant redundant work.

In complex environments that are ubiquitous in SMS, the overhead of reconstructing geospatial definitions is significant. As a result, there exist standard efforts for constructing and curating data representation that define such geospatial information. Here, we specifically focus on modeling indoor spaces. Standards have been used across domains to limit redundant work. The most widely used standards for representing indoor spaces relate to Building Information Model (BIM) activities, an approach with a suite of standards built using the Industry Foundation Classes (IFC) [14, 15]. The IFC standards and developed and maintained by buildingSMART[3]. To support complex BIM modeling, there are other standard data representations that facilitate lower level modeling. In this paper, we specifically focus on two OGC standards, namely CityGML[4] and IndoorGML[5]. More information about each standard is provided below in Sec. 3.

Defining the boundaries of indoor spaces is not complete without the full expression of affixed and mobile objects in that space. This is especially true in production environments, wherein the location of objects, such as handheld tools and devices, is a practical challenge [16, 17]. Carrasco et al. [18] argues that there is a strong need for low-cost solutions for indoor localization technologies to support small and medium enterprises (SMEs). Such technologies include WiFi or Bluetooth Low Energy (BLE)-based location mapping. The downside of these technologies is that they can only deliver an accuracy of about 1-2 meters. To facilitate more precise positioning, there are systems that utilize RFID chips, Ultra Wideband (UWB), Indoor GPS, or simultaneous localization and mapping (SLAM)-based approaches. These systems are in general more expensive, but can deliver accuracy down to a few centimeters.

2.2 Indoor Space Navigation for SMS

With a geospatial definition of an indoor space, an apparent use case of such a representation is centered around navigation purposes. Referencing a formal description of indoor building entities, such as walls, structural columns, corridors, and other obstacles, finding physically viable paths can be facilitated. Navigation tasks are commonly derived in SMS across a variety of clients. For example, to accomplish their intended tasks, such as material transport [19, 8], AGVs must navigate complex manufacturing environments and avoid unforeseen obstacles, e.g., plastic barriers, ramps, and other devices.

Since maintenance costs of buildings are much higher than its construction costs [20], balancing expenses of maintenance tasks is important. Lee et al. [21] observed and analysed tradespeople in maintenance fieldwork to investigate their current practices. They showed that up to 50% of time in maintenance is spent on field navigation and object localization. In response, they developed an AR-based software application [6] that utilizes an Operations and Maintenance (O&M) information model to support O&M fieldwork. Their prototype showed a reduction of up to 51% of time needed to locate target areas. Many more examples exist for how computer-supported, often AR-based [22], maintenance tasks require indoor navigation approaches.

Figure 3. Process workflow of our implementation. In parallel, we construct a geospatial representation of the SMS Test Bed, access near-real-time data from the MTConnect data streams, and obtain auxiliary information about the connected devices. Through Unity3D, we achieve the IndoorGML-MTConnect integration to facilitate the discussed use cases.

a production system. In this section, we describe each standard's data model and considerations for their integration.

IndoorGML is a standard developed by OGC that describes indoor spatial information in an open data model within an eXtensible Modeling Language (XML) Schema Definition (XSD) [15]. The standard focuses on modeling indoor spaces including its properties and the underlying topology. Intentionally, this standard was designed to be used for indoor location-based services, such as navigation or geo-tagging. One of the core concepts of IndoorGML is the definition of rooms as cells with its properties, e.g., name, ID, and purpose of the room, as well as whether it is navigable or non-navigable. Cells are not allowed to overlap each other, but they can share a common boundary. Additionally, it is possible to define nodes (or states) which can be connected by edges (or transitions). They are mostly used for indoor navigation where the transitions operate as paths and the states as way-points. IndoorGML provides the possibility to define topological information of cells by creating a Node-Relation-Graph (NRG). The NRG describes the connectivity and adjacency of cells and simplifies the 3D representation of an indoor space to enable use by complex computational processes. To create a NRG, the Poincaré duality is used. With that a k-dimensional object can be transferred into an n-dimensional space by creating an (n-k)-dimensional object. For example a 3D cell becomes a zero-dimensional node and a two-dimensional boundary becomes a one-dimensional edge. Another feature of IndoorGML is the multi-layered description of indoor spaces. The same space can be divided in cells by rooms, corridors, and staircases; in cells defined by WiFi coverage; or in cells described as restricted and public areas. Each of these layers have their own semantics and NRG.

While IndoorGML focuses on the topological and semantic representation of indoor spaces, it is purposefully limited when modeling interior geometries of these spaces, including objects such as windows, columns, and furniture. This is due to the fact that it was designed to allow integration with other standards such as OGC's previously defined CityGML. As the name suggests, CityGML is meant to be a standard capable of modeling entire cities, at multiple levels of detail (LoD). In CityGML, there exist five LoDs, wherein LoD 0 and LoD 4 are the highest and lowest abstractions, respectively. In particular, LoD 4 allows the geometric representation of building interiors. Ryoo et al. [23] present a comprehensive comparison between the IndoorGML and CityGML LoD 4 standards and their respective strengths and weaknesses. Kim et al. [24] further discuss the integration of the two standards, along with issues and potential solutions.

Here, we study the integration of IndoorGML with SMS data, assuming to be compliant with the MTConnect standard. MTConnect is a semantic standard with controlled vocabulary, types, and relationships for data collected from manufacturing assets. This data could be used to analyze and optimize manufacturing processes or to monitor machines from a workshop floor. The data can contain information like device identity, attributes about its components, and machining parameters, e.g., maximum speeds and axes lengths. Ideally, MTConnect data is captured in near-real-time and collected by *agents*, which share the data via Hypertext Transfer Protocol (HTTP). Stored in a non-proprietary XML-format, MTconnect data streams are read-only, prohibiting command messaging to the monitored machines.

By enriching geospatial data conforming to IndoorGML with near-real-time data conforming to MTConnect, it is possible to create a static representation of a workshop supported by dynamic process data. We created a virtual scene in Unity3D[6] that is capable of leveraging both standards. We expanded the IndoorGML file with additional information, such as the HTTP-address of the MTConnect-stream and position as well as ex-

[6] Available at https://unity.com/

ternal references to the geometrical shape or further documents of objects, e.g., machining centers. The Unity3D-scene creates a 3D representation of the workshop based on the spatial data, placing the defined objects within the scene. Once the scene is rendered, connection to the MTConnect data streams is established and the received data gets processed. This data can now be used to display the current state of each machine. The scene creation is explained in detail within the use cases in Sec. 4.

4 Implementation

To show potential use cases in merging a geospatial description with near-real-time process data, we developed two virtual scenes. These scenes were developed within Unity3D, which is mostly used as a game engine but can also be leveraged for the use in visualization and simulation in other domains. For this prototype, we used the SMS Test Bed[7] as a geospatial representation of a typical workshop. Some of the machines of the SMS Test Bed are connected by the MTConnect standard, which is also used for this prototype. Figure 3 presents a workflow for our two uses cases derived from the same data integration process. As shown in the figure, we anticipate the production of additional use cases through this integration.

4.1 Testing Facility and Setup

The SMS Test Bed represents a digital architecture built on top of a real contract manufacturer at the National Institute of Standards and Technology (NIST). Academic and industrial researchers leverage the SMS Test Bed as both a reference implementation of a set of MTConnect-enabled devices with varying levels of capabilities as well as a rich data source [25]. In our demonstration, we parse near real-time MTConnect data streams from the SMS Test Bed and track the availability of the floor's resources. Note that our prototypes rely on whatever data is available from the NIST shops at the time it is run.

4.2 Use Case 1: Workshop Monitoring

The first use case demonstrates the potential benefits realized by the IndoorGML-MTConnect integration for a supervisor of a workshop. In the case, the supervisor requires a simple way to understand the current status (i.e., machine tool availability) of the floor. With the tendency to implement more automated workflows in manufacturing processes, such a prototype can help to get quick feedback about the production floor's current state.

Once the virtual scene has been initialized, the user selects and loads the modified IndoorGML file. A 3D view of the workshop floor is then rendered displaying all machines defined within the space. The models of the machines are defined by an external reference to an object file (.OBJ) as part of the IndoorGML file. The image section visible to the user is defined by a camera object inside Unity3D. This camera can be moved around freely inside the scene or set to a map-like view.

When the connection to the MTConnect stream has been successful, the machines are attributed a color according to their status, e.g., availability status and alarm codes, which in our particular case is set by the status of availability. There are three possible options: available (green), unavailable (red), and unknown (yellow). This helps to quickly get an overview over the whole workshop and identify potential problems easier. Figure 4 shows a 3D view of a workshop with its machines. Since most of the machines in the NIST Shops are not yet digitilized via the SMS Test Bed, many models are colored yellow. Based on the accessible data, it could also be helpful to add the status of current machining process and any occurring errors or unexpected events. When users want to obtain detailed information about one specific machine, they can click on it in the 3D view, which will open a window displaying all data that available through the SMS Test Bed. Another scene feature is the ability to switch the camera into first person view. Users are now able to navigate around the workshop and interact with virtual doors to enter other rooms. While activating this mode, the collision with walls and objects is enabled, so users can move around as workers would be able to in the real world. This is helpful when planning the layout of a workshop and to quickly see if the position and rotation of a machine is useful in terms of productivity, maintainability, and user friendliness.

Despite not being implemented in this prototype, it would be trivial to modify the first person view so that the virtual scene can be leveraged on a head-mounted display in a VR environment. Migrating to AR systems requires more work since synchronization between the virtual and physical spaces is required.

4.3 Use Case 2: Inspection and maintenance

The second use case focuses on aiding maintenance and inspection in production systems. After the modified IndoorGML file and the connected MTConnect data stream have been loaded (akin to the first use case), a map-like view of the workshop is presented to the user. Additionally, the states and transitions are displayed to indicate possible routes around the workshop. As discussed before, IndoorGML supports graph-based representations, wherein each state and transition represents a node and edge, respectively. This is especially useful for informing indoor navigation. To demonstrate this point, our prototype allows users to select a way-point or a machine, either by clicking on it or choosing it from a drop-down list, as a start and endpoint. Since the system of way-points, paths and their length is known, we leverage Dijkstra's algorithm to calculate the shortest path between the start and endpoint. The calculated path and its total length is displayed (see Fig. 5). This feature enables mainte-

For the purpose of maintenance and inspection, it is helpful to procure further details about the machine once the worker has reached it. Therefore, we created an additional tab labeled ”Machine” (see Fig. 6). This enables users to choose a machine from a drop-down list to obtain an overview outlining the available information according to their choice. Our prototype shows live data available via MTConnect, pictures of the machine, and additional documents akin to a handbook, programming manual, or hints for maintenance.

4.4 Limitations of Use Cases

Within the current state of our software prototype, there are limitations which can be tackled through future work. With respect to the representation of the shop floor, we currently only place machine tools into the virtual scene. In reality, there are additional objects that could be considered, including static objects, such as desks and cabinets, as well as dynamic objects, such as humans, carts and AGVs.

Considering whether an object is affixed to some coordinates or has the ability to move is handled through CityGML. Note that we have not yet fully implemented this integration aspect but plan to in the near future. As Fig 7 suggests, `MTConnectAssets` can be modeled as `BuildingFurniture` within CityGML. Movable entities are meant to be modeled using the `BuildingFurniture` element. The static objects, i.e., `MTConnectDevices`, could follow the modeling paradigm of the `BuildingInstallation` element defined within CityGML. With objects that are dynamical in position, finding the indoor location of these objects and transferring those positions to the Unity3D scene are both required. Such extensions would especially be helpful for tracking commonly misplaced objects on the floor, such as tooling and measurement devices.

Another limitation lies within the digital models themselves. First of all, the solid models of the machines are separated from the modified IndoorGML file. Even though this separation allows for modification of the models without affecting the geospatial representation, this solution is not a fully integrated one. In the future, we plan to consider embedding these models within the CityGML description of objects within the indoor space. The `lod4Geometry` element of CityGML offers native support for the description of object geometry. Additionally, the used 3D models are rigid and their geometry has been simplified, so that their shape can be described with fewer polygons, which led to a better performance of our prototype. Their purpose in our prototype was to leverage these models to recreate a quick, decently realistic layout of the existing workshop. If there exist emerging needs to display the movement of digital assemblies, the models must be split into multiple objects based on their independently

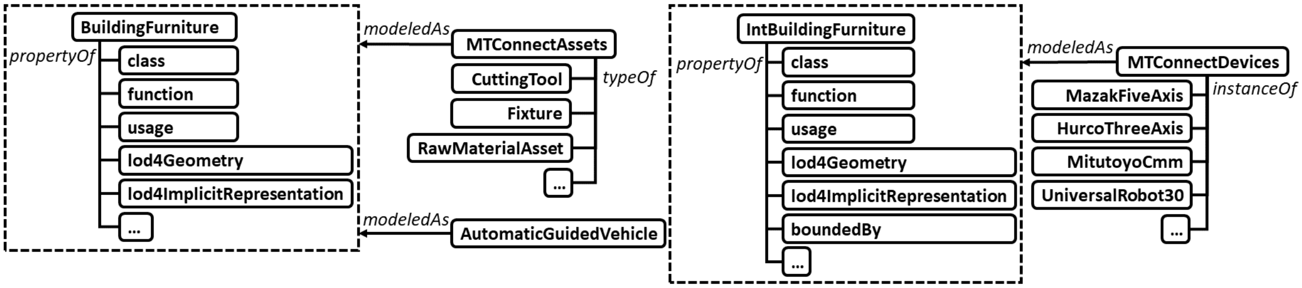

Figure 7. Elements and attributes represented in the CityGML object types critical to our integration. (A) `BuildingFurniture` can be used to model production floor tooling and other equipment that is expected to change its positional data often. (B) `IntBuildingInstallation`, traditionally used to model columns and other practically immovable objects, is used to model large production devices, e.g., CNC machining centers.

moving sub-assemblies and then realigned based on their position and kinematic properties.

When the layout of the workshop is extended over multiple floors, it is still possible to display that within our prototype since IndoorGML offers multi-floor modeling. However, in our prototype, extending to a multi-floor instance could cause user interaction and experience issues, e.g., occlusion challenges. To include machine-specific data within our modified IndoorGML file, significant manual labor is required. These activities could be (semi-)automated by either (1) formally appending the CityGML and IndoorGML with data elements designed to capture production-specific scenarios or (2) mapping similar elements that already exist in these data structures with knowledge graphs. Improving the automation of such procedures would expedite the initial process of implementing our prototype in other workshop environments. With more formal methods deployed, it would also be possible to develop an editor tool to visually construct our modified spatial representation on the fly. Additionally, a formal amendment to the schema representation would allow for proper governance and validation procedures.

5 Extensions to other technologies

Based on the research opportunities described in the previous section, we describe the technology implications for two domains: augmented reality and automated guided vehicles. Moving forward, we plan to test these geospatial representations and concepts to meet challenges faced by both domains.

5.1 Implications for Augmented Reality

Current AR systems suffer from interoperability issues caused by a lack of a shared coordinate system in which to operate. This is made obvious when trying to use different devices, e.g., tablets and head-mounted displays, AR frameworks, e.g., Vuforia, ARKit, and ARCore), or tracking techniques, e.g., marker-based tracking or marker-less tracking. Such techniques and technologies are often incompatible with each other in many ways, including the understanding of the space in which they operate. For instance, a marker-less AR application built using Apple's iOS exclusive framework ARKit[8] might place a virtual object in space relative to a feature map that would be incompatible with Google's ARCore[9] toolkit. Moreover, a marker-based AR application would not be able to make sense of the position of the virtual object since it would not track the features to which it is relatively positioned. To this end, most industrial AR installations exist as isolated use-case-specific prototypes that are only *aware* of their immediate surroundings rather then the larger context of the manufacturing floor. As a result, most AR applications are unable to share spatial information consistently.

While infeasible for many AR applications, in environments that can be easily predefined, such as manufacturing floors, standard geospatial representations can help define a shared underlying coordinate system on top of which applications can be built. This would lead to a better integration of industrial AR and virtual reality (VR) systems regardless of the devices or frameworks used. This notion has garnered attention from the standards development community. Recently, the OGC has chartered a new standards effort for representing device and camera poses with respect to global coordinates. We hope these efforts will realize a new standard representation that is already consistant with existing OGC standards, i.e., CityGML and IndoorGML.

5.2 Implications for Automated Guided Vehicles

Automatic (or automated[10]) guided vehicles (AGVs) presents another domain for which geospatial representations can

[8] Available at https://developer.apple.com/augmented-reality/arkit

[9] Available at https://developers.google.com/ar

[10] In this paper, we consider automatic guided vehicles and autonomous vehicles, e.g., mobile robots, as the same. To learn more about their distinction, refer to ASTM Committee F45. F45 addressed issues related to performance standards and guidance materials for AGVs. More information is available at https://www.astm.org/COMMITTEE/F45.htm.

help performance. Clearly, AGVs already have on-board capabilities for constructing ad-hoc maps of indoor spaces and avoiding obstacles. However, there still remain challenges related to the lack of semantically rich data available to AGVs. For example, consider a robotic arm mounted on an AGV tasked to approach a table and engage with some physical object. Without formally encoding that the AGV is allowed to get very near, the AGV could stop short of the target table in fear of collision. This simple example demonstrates the importance of formally preserving the context of the physical environments. The target area should be treated differently than walls, columns, or other hazards. We envision that the integration of point cloud-maps built by AGVs with semantically rich geospatial representations would enhance their mobility and navigation.

Additionally, relating other information standards with such geospatial representations, as we have demonstrated here with the MTConnect standard, can further increase the information available to AGVs at any given time. Looking forward, achieving this kind of integration would enhance the situational awareness of AGVs for better planning and routing purposes. For example, an AGV could move and perform tasks automatically based on machine availability and readiness captured by near-real-time MTConnect data streams. Theoretically, this could enhance the agility and flexibility of a fleet of AGVs servicing tasks related to MTConnect-enabled devices, including loading, unloading, and material transport.

6 Closing & Looking forward

The full realization of smart manufacturing systems remains a work-in-progress. We believe that standardizing spatial data representations for production systems is vital for fully describing factories digitally. To this end, we presented a prototype that makes use of existing standards to combine geospatial descriptions (via IndoorGML) and real-time process data (via MTConnect) of machines. We set up two different use cases, focusing on both monitoring and navigation, to demonstrate the usefulness of merging these two areas.

Further development should consider creating a framework that supports the the combination of multiple sources of information that already exist in modern factories. This can include positions of workers and tools, RFID-sensor readings, video feeds of surveillance cameras, or energy consumption measurements. By bundling such information, the development of applications which support the control of smart factories can be developed much easier since the acquisition of data would be standardized. In other words, from a design perspective, leveraging standards for representing geospatial and device data in production systems facilitates more flexible prototype interface development. The more consistently information is represented, the simpler development of new applications becomes.

Furthermore, we see significant research opportunities in sensor fusion for more precise geospatial alignment. One example is leveraging on-board sensors from AGVs and more contextually defined, static geospatial definitions, such as those offered by IndoorGML and CityGML. If successfully integrated, such definitions could enable safer AR installations. For example, adding context to a 2-D point cloud delivered by an AGV could help avoid dangerous occlusion problems, e.g., rendering a digital object and effectively blocking view of a safety hazard. We are currently planning a partnership with the Robotics Program at NIST to investigate these research topics.

[3]Colorado School of Mines, Metallurgical and Materials Engineering, Golden, CO, 80401, United States

Voltage-pulsed atom probe tomography is difficult or impossible to use for materials with poor electrical conductivity. Laser-pulsed atom probe tomography has been shown to overcome this limitation by triggering the field evaporation optically and enables the analysis of strongly insulating materials[1]. However, using a laser-pulse to trigger ion evaporation does not completely render the electrical insulating properties of the tip irrelevant. For example, when the electrical resistivity of the tip is high enough, the atto-amp to femto-amp ion current emitted from the tip apex can result in a significant voltage drop along the tip axis (Figure 1a)[2]. This voltage drop has the effect of giving the emitted ions an `energy deficit' – i.e. the actual accelerating voltage for the ion's is smaller than the voltage applied experimentally to the base of the sample. A static energy deficit will be resolved when a mass spectrum is calibrated, however, when the voltage drop fluctuates throughout an atom probe dataset it cannot be corrected with any standard analysis methods. This effect has been noted in the literature for infrared, visible, and ultraviolet laser wavelengths[3]. More recently it also showed up when using extreme ultraviolet (EUV) light[4] to triggered field ion evaporation of SiO_2 -- Figure 1b shows a time-of-flight history for an SiO_2 tip held at constant voltage collected using an pulsed 29.6 nm light source. Over the course of the run, the pointing and intensity of the EUV light source fluctuated resulting in a changing ion current and therefore a changing energy deficit which significantly degrades the quality of the resulting mass spectrum (Figure 1f) which would degrade subsequent analyses.

In order to correct the data for this unknown (fluctuating) acceleration voltage we have developed an empirical algorithm. The algorithm first splits the data into a large number of contiguous `chunks'. Then, the chunks are optimally aligned to a reference spectrum with a multiplicative correction factor (Figure 1c) using a histogram-based dot product optimization metric (Figure 1e). Applying a log-transform to the time-of-flight data enables the use of the FFT for the optimization step. The result is that a correction factor can be determined for every ion's flight time that minimizes the effect of the unknown (varying) voltage drop (Figure 1d). The resulting mass spectrum of the corrected data is significantly improved (Figure 1f) versus the uncorrected data. This correction algorithm ensures that the highest quality input data is supplied into the atom probe data analysis pipeline. In principle, this method can be extended to spatially heterogenous materials using a multireference approach which would be facilitated by well-known unsupervised machine learning algorithms.

ABSTRACT

Multi-scale multi-physics computational models are a promising tool to provide detailed insights to understand the process-structure-property-performance relationships in additive manufacturing (AM) processes. To take advantage of the strengths of both physics-based and data-driven models, we propose a novel hybrid modeling framework for laser powder bed fusion (L-PBF) processes. Our unbiased model integration method combines physics-based data and measurement data for approaching more accurate prediction of melt pool width. Both a high-fidelity computational fluid dynamics (CFD) model and experiments utilizing optical images are used to generate a combined dataset of melt pool widths. From this aggregated dataset, a hybrid model is developed using data-driven modeling techniques, including polynomial regression and Kriging methods. The performance of the hybrid model is evaluated by computing the average relative error and compared with the results of the simulations and surrogate models constructed from the original CFD model and experimental measurements. It is found that the proposed hybrid model performs better in terms of prediction accuracy and computational time. Future work includes a conceptual introduction on the use of an AM ontology to support improved model and data selection when constructing hybrid models. This study can be viewed as a significant step towards the use of hybrid models as predictive models with improves accuracy without the sacrifice of speed.

Keywords: Additive manufacturing, Laser powder bed fusion, Hybrid model, Melt pool width, Gaussian process/Kriging, Data-driven surrogate model, Ontology

1. INTRODUCTION

Metal additive manufacturing (AM) produces metallic parts by fusing materials in a layer-by-layer fashion directly from a 3D CAD model [1]. Laser powder bed fusion (L-PBF) is the most common AM process used for the fabrication of metallic components. In the L-PBF process, a thin powder layer is spread on a substrate and a laser beam selectively melts and fuses powder with neighboring particles and previous layer. This process is repeated until the final part is formed. L-PBF has tremendous potential of producing metallic parts with complex geometry, internal structures, and conformal heating/cooling channels for a wide range of applications including aerospace, automotive, and biomedical implants [2–4]. Compared to conventional manufacturing techniques, L-PBF has many advantages as it allows to locally control microstructures by varying process parameters so that parts with desirable mechanical properties can be produced [5,6]. It also minimizes material wastes and reduces lead time [7]. While offering many advantages, the L-PBF process also faces challenges such as inconsistent part quality and defects in terms of porosity, poor surface finish, delamination, crack formation, and residual stress [8]. Without proper control mechanisms, these challenges can lead to unstable mechanical properties and poor dimensional accuracy on produced parts.

To overcome these challenges and help develop process control mechanisms, there have been many research efforts that have aimed to understand the influence of different process parameters and material properties on part quality [9,10]. The research efforts can be broadly categorized as experimental-based and physics-based investigations. The experimental-based investigation is more realistic as it directly captures observed physical phenomena occurring during the process. However, this

Moges, Tesfaye; Yang, Zhuo; Jones, Kevontrez; Feng, Shaw C.; Witherell, Paul; Lu, Yan. "Hybrid Modeling Approach for Melt Pool Prediction in Laser Powder Bed Fusion Additive Manufacturing." Paper presented at ASME 2020 International Design Engineering Technical Conferences and Computers and Information in Engineering Conference (IDETC/CIE 2020), St. Louis, MO, US. August 16, 2020 - August 19, 2020.

approach can be time consuming and costly while lending itself to inherent process variabilities and sensor calibration errors that cause large measurement uncertainty [11]. Additionally, not every process parameter can be measured. For these reasons, amongst others, interest in computational models for AM continues to rise.

For the L-PBF process, computational models have been widely used to simulate the heat transfer, fluid flow, and phase transformations in L-PBF process and estimate the temperature fields, flow velocities, melt pool characteristics, solidification rate, and residual stress [12,13]. Although these computational models are promising tools to understand the physics of the process, their prediction accuracy can be potentially affected by the assumptions used during model formulation [14]. In addition to modeling assumptions, inaccurate selection of model parameters, such as absorption coefficient and material properties, also leads to significant discrepancy between computationally predicted and experimental results [15]. Furthermore, even though high fidelity physics-based models describe the L-PBF process in detail, solving these models is time consuming due to the complex physics.

Overall, physics-based models suffer from prediction accuracy caused by uncertainties that are associated with the modeling assumptions made about the L-PBF process. The prediction accuracy of the experimental-based investigations is highly affected by sensor noise and measurement uncertainties due to the inherent complexity and stochastic nature of the process. Alterations to each approach have sought to compensate for their drawbacks. For instance, reduced-order physics-based models have been sought to reduce computational demands, though the tradeoff is they can be less accurate. Highly complex, multi-variable experiments of processes like L-PBF are also difficult to implement due to their high cost and time requirements. We propose that the most effective way to overcome the challenges associated with each approach is to develop a model that embraces the advantages of each approach.

In this study, we propose a hybrid model by intertwining physics-based simulation data and experiment-based empirical data for the prediction of output quantities of interest (QoIs) in L-PBF process. To develop an unbiased model which integrates computational and experimental data, data-driven modeling techniques including polynomial regression and Gaussian process/Kriging methods, which are suitable for multi-dimensional problems having limited data, are employed. Melt pool width is chosen as our primary output QoI since the melt pool plays a significant role in determining the microstructure, residual stresses, and mechanical properties of a part fabricated by L-PBF process [16]. A CFD model is used to predict melt pool widths for various combinations of laser power and scan speed. Empirical data is obtained from ex-situ melt pool width measurement data taken from single-track experiments with similar process parameters.

In developing the hybrid model, a polynomial regression method is first applied to construct the initial simulation-based surrogate model using data from a CFD model. Then, the Kriging method is applied to model the residual error between experimental and computational results. An adaptive modeling method is used to iteratively update the Kriging model to improve the predictive errors of the surrogate model. to improve the model, measurement data are iteratively selected by updating sample points using the maximum average relative error as a determining factor. The performance of the hybrid model is evaluated by comparing the relative error to the individual simulation-based and experiment-based surrogate models. It is found that the hybrid model performs better in terms of prediction accuracy and computational time. Once the hybrid model is developed, making predictions on a new set of input variables is straightforward.

This paper is organized as follows: in Section 2, we briefly review the prior research efforts on the physics-based computational models focusing on thermal models and data-driven modeling approaches used in L-PBF AM. Then we provide an overview of the CFD model, the data-driven modeling techniques used in this study, and the hybrid model development methodology in Section 3. In Section 4, we demonstrate the proposed methodology to develop a hybrid model for melt pool width prediction and analyze its performance using CFD simulation data and measurement data. A conceptual use of AM ontology for model selection is introduced in Section 5. Section 6 presents the concluding remarks of the current study and future work. We view this work to be an essential step to developing fast and accurate hybrid models that compliment both physics-based and experimental approaches to improve L-PBF part quality.

2. BACKGROUND

Though L-PBF has shown to be a capable technology for producing complex parts, challenges remain, e.g., inconsistent part properties with defects. Part defects are often attributes to porosity in the fabricated parts, surface roughness, anisotropy in microstructure, residual stresses, delamination, and cracks [17]. Physics-based modeling techniques are based on cause-effect principles in physics, such as fluid dynamics, thermodynamics, heat transfer, and kinetics. While such techniques provide invaluable insight into the general behavior of a process, fall short in predicting defect generation and propagation and final part quality for a specific process implementation. There are at least three reasons for that: (a) a complete set of process variables may not be obtainable due to a lack of knowledge regarding the process, (b) unknown complex energy and material behaviors in the process, such as non-linear interactions, and (c) the physics-based models have not been validated due to limitation in available measurement techniques.

AM data analytics includes measured data, data fusion, data analysis, statistical methods, and machine learning [18]. Real data are acquired from in-situ or ex-situ sensors. To model the process, the relations between inputs and outputs are created by data-driven modeling techniques. Data-driven models can be employed to model the non-linear relationship between sensor outputs with process parameters and predict output quantities of interest for different sets of input variables. However, as stated previously, the measurement data used to build the data-driven models are affected by uncertainties related to error in sensor calibration and noise, imprecise measurement methods, and variations in the measurements. The following subsections review relevant works associated with each of these modeling approaches.

2.1. Physics-based thermal models

There have been tremendous efforts in the last decade in developing computational models to simulate powder layer deposition, powder-laser interactions, melt pool formation, solidification and grain growth, and residual stress and deformation with different levels of fidelity in the L-PBF process [12–14,19]. The term fidelity used in this context is based on the different physical phenomena captured by the computational models. For instance, a model that captures a larger number of phenomena refers as high-fidelity, whereas, low fidelity is the one with least number of phenomena.

Physics-based computational modeling has been crucial to understanding process-structure-property relations in metal AM [20], and these models have come in different varieties. With regard to the transient manufacturing process, thermal models based on the semi-analytical, the finite element, and finite volume methods have been developed. The semi-analytical Rosenthal-based low-fidelity thermal models can solve the heat conduction equation for temperature profile and melt pool geometry [21,22]. However, they neglect physical phenomena such as the effective powder layer, laser spot diameter, and other phenomena related to heat transfer and fluid flow. Typically, the finite element medium-fidelity models can provide a thermal history of an entire part being built [23–26], but they do so by purely considering heat conduction and neglecting the fluid flow behavior within the melt pool. This simplification can lead to predictions of inaccurate temperature fields. For example, Manvatkar et al [27] showed that by ignoring Marangoni convection in the molten melt pool, cooling rates in laser assisted AM may be overestimated by as much as double the correct values. Conversely, Gan et al [28] demonstrated that incorporation of fluid-flow and vaporization can significantly enhance a model ability to accurately predict melt pool geometry, peak temperature and surface topology. For these reasons, several high-fidelity models based on the finite volume method and CFD have been developed to account for additional physics within the melt pool [29–34].

Ensuring the accuracy of high-fidelity models requires an extensive use of well-designed and highly controlled experiments for validation. Due to extremely high temperatures, violent metallic powder spattering, and highly complex physics occurring at multiple length scales within very short time scales, it is difficult to conduct in-situ measurements in the L-PBF process. Typically, as is the case for Ghosh et al [35], ex-situ measurements are used for numerical validation. It is apparent that assumptions and simplifications made about the process can significantly affect a computational model's predictive capabilities.

2.2. Data-driven models

Data-driven modeling methods, as a more stochastic approach, have been deployed to analyze AM data. Different data-driven approaches have been implemented to construct surrogate models from experiment-based empirical data and physics-based simulation data. Data-driven surrogate models that rely on empirical data can help estimate data points in a new design space and evaluate correlations between input parameters and output QoIs [36,37]. In addition, simulation-based data-driven surrogate models aim support a black-box approach to reduce the high computational cost of high-fidelity simulations [38]. Data-driven machine learning techniques have been used in AM for different applications throughout the AM lifecycle [39].

Using experiment-based empirical data, Fathi and Mozaffari [40] developed a data-driven framework to relate process parameters including laser power, scan speed, and powder flow rate to melt pool depth and deposition height for the laser-based direct energy deposition (DED) process. Similarly, Lu et al. [41] used a neural network to map process parameters to deposition height for the DED process. Since obtaining measurement data for such complex processes is difficult and time consuming, in lieu of empirical data, researchers have used physics-based simulation data to develop data-driven surrogate models. From the semi-analytical Rosenthal-based thermal model, Yang et al. [42] developed a Dynamic Variance-Covariance Matrix (DVCM) method to investigate the influence of input parameters such as laser power, scan speed, absorption coefficient, and thermal diffusivity on melt pool width for L-PBF process. Kamath [43] built data-driven surrogate models from the Eagar-Tsai thermal model using regression trees and Gaussian process regression to predict melt pool depth for the L-PBF process. Recently, Tran and Lo [44] developed an approach to optimize process parameters such as laser power, scan speed, and layer thickness using artificial neural network (ANN) for L-PBF process.

The previous works focused on developing data-driven surrogate models based on either experiment-based empirical data or physics-based simulation data to predict output QoIs. As measurement data contain errors and uncertainties associated with sensor calibration and noise, imprecise measurement methods, and variation in the process; and physics-based simulation data have uncertainty associated with modeling assumptions, numerical approximation, and variability in input parameters, data-driven surrogate models that are developed solely from empirical data or simulation data may exhibit variable predictive capabilities. Therefore, hybrid models that embraces the advantages of experiment-based and simulation-based approaches are needed.

In general, physics-based models typically do an acceptable job at predicting output QoIs in a wide range of input variables. However, there are multiple sources of uncertainty in these computational models that can cause significant prediction errors [15]. On the other hand, data-driven modeling techniques often rely on a specific system to help find the relationships between inputs and outputs, and without the explicit knowledge of the physical behavior of the system [45]. In such scenarios,

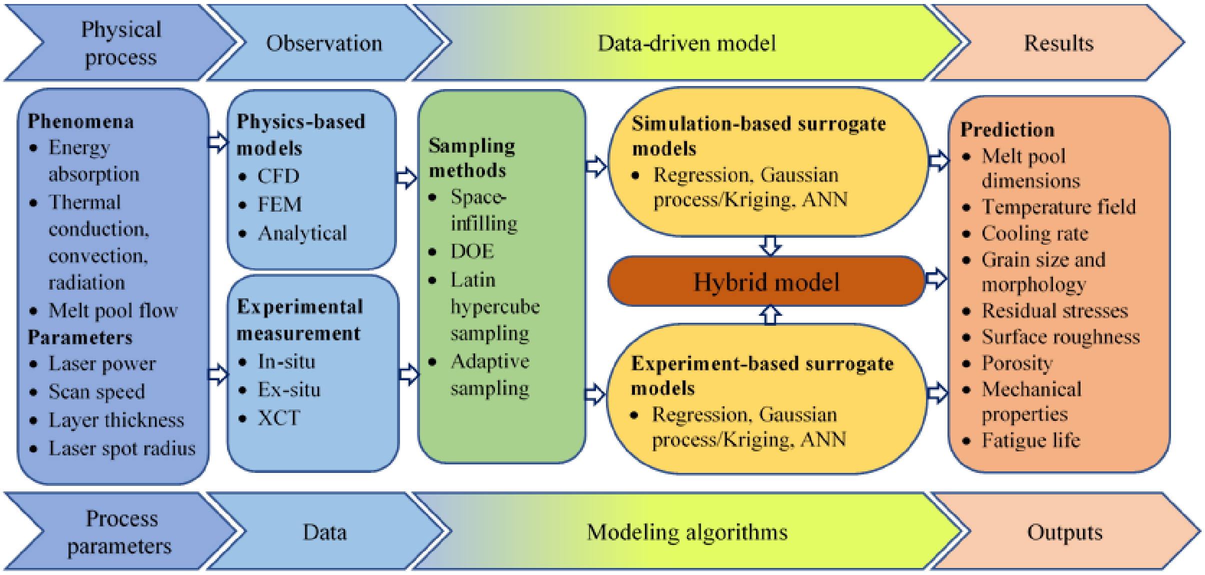

Figure 1. Hybrid modeling framework

due to data sparsity, extrapolation is limited and careful selection of training data, training algorithm, and model complexity is required [46]. The proposed hybrid model offers an approach where extrapolation can be done for a wide input of parameter ranges while capturing the complex and highly non-linear behavior of the L-PBF process [46].

3. HYBRID MODEL DEVELOPMENT

As mentioned above, researchers have developed various approaches by utilizing different scales, disciplines, and perspectives to overcome the complexity of AM processes. All these efforts can significantly improve knowledge mining in AM. However, these efforts also raise more challenges in data filtering, algorithm selection, and model integration. Different simulations, for example, may only work under specific conditions if they were developed based on different physical phenomena. It is also hard to guarantee consistency between different datasets from various sources. Another typical issue is the stochastic error observed between computational and experimental data. This error may initiate from the fundamental hypothesis or numerical approach of the simulation. However, physical experiments cannot benefit from selective simplifying assumptions like simulations. Hence, experimental results tend to include more complicated physical phenomena than those obtained from a simulation. Thus, even high-fidelity simulations cannot truly match the real experimental data based on different AM machines, labs, and material.

Modifications applied to physics-based models can potentially address the above issues. This section presents the development of an unbiased model integration method to combine computational and experimental data to provide accurate predictions regardless of the sample size and fidelity of the data. The high-fidelity physics-based model, though requires higher computational cost, has the freedom to generate a vast amount of data. On the other hand, the experimental data is assumed to be ground truth but usually limited and expensive to sample.

Figure 1 shows the proposed hybrid modeling framework for the L-PBF process. Various combinations of process parameters, physics-based models and experimental measurement techniques provide datasets with inherent uncertainties [47–49]. Then, multiple sampling methods filter through each dataset to systematically create subsets of the data to be used for training and validation. Once these data subsets are determined, they are used in conjunction with data-driven models to build simulation-based and experiment-based surrogate models. To improve the accuracy of these surrogate models, a hybrid model that combines the physics-based data and experimentally measured data using an unbiased model integration method is created. With this framework in mind, a brief overview of the physics-based CFD model and data-driven approaches used in the current study is provided, and the workflow and algorithm of the proposed hybrid model are discussed in detail in this section.

3.1. Brief details on CFD model

A well tested, three dimensional, transient, thermal-fluid flow model for L-PBF [28,29] is adapted to compute temperature and velocity fields to generate the data referenced in this work. The thermal-fluid flow model solves for conservation of mass (Eqn. 1), momentum (Eqn. 2), and energy (Eqn. 3) to consider liquid flow within the melt pool driven by Marangoni convection.

$$\frac{\partial \rho}{\partial t} + \frac{\partial \rho u_i}{\partial x_i} = 0 \tag{1}$$

Moges, Tesfaye; Yang, Zhuo; Jones, Kevontrez; Feng, Shaw C.; Witherell, Paul; Lu, Yan. "Hybrid Modeling Approach for Melt Pool Prediction in Laser Powder Bed Fusion Additive Manufacturing." Paper presented at ASME 2020 International Design Engineering Technical Conferences and Computers and Information in Engineering Conference (IDETC/CIE 2020), St. Louis, MO, US. August 16, 2020 - August 19, 2020.

$$\frac{\partial \rho u_i}{\partial t}+\frac{\partial \rho u_i u_j}{\partial x_j}=\frac{\partial}{\partial x_j}\left(\mu\left(\frac{\partial u_i}{\partial x_j}\right)\right)-\frac{\partial p}{\partial x_i} -\frac{180\mu}{\delta^2}\frac{(1-f_l)^2}{f_l^3+B}u_i + \rho_{ref}g_i\beta\left(T-T_{ref}\right) \quad (2)$$

$$\frac{\partial \rho \mathrm{h}}{\partial t}+\frac{\partial \rho \mathrm{u_i h}}{\partial \mathrm{x_i}}=\frac{\partial}{\partial \mathrm{x_i}}\left(\mathrm{k}\frac{\partial \mathrm{T}}{\partial \mathrm{x_i}}\right) \quad (3)$$

where t is the time, u_i is the ith component of the velocity, μ is the viscosity, p is the pressure, h is the enthalpy, T is the temperature, ρ is the density, k is the thermal conductivity, and β is the thermal expansion coefficient. In this work, B is a small parameter with a value of 10^{-3} to avoid division by zero and δ is the approximate primary dendritic spacing, which was set to 1μm. Additionally, enthalpy is related to temperature according to the following:

$$\rho \mathrm{h}=\int_0^{\mathrm{T}} \rho \mathrm{c_p dT}+\rho \mathrm{Lf_l} \quad (4)$$

where $\mathrm{c_p}$ is the specific heat capacity, L is the latent enthalpy of fusion, and $\mathrm{f_l}$ is the volume fraction of liquid phase.

The thermal boundary condition including the heat source model at the metal-gas interface is specified as:

$$\mathrm{q_{ener}}=\frac{2\mathrm{Q}\eta}{\pi \mathrm{r_b^2}}\exp\left(\frac{-2((\mathrm{x}-\mathrm{V_s t})^2+\mathrm{y}^2)}{\mathrm{r_b^2}}\right) - \mathrm{h_c(T-T_\infty)}-\sigma_s\varepsilon(\mathrm{T^4}-\mathrm{T_{ref}^4}) \quad (5)$$

where Q is the laser power, η is the absorptivity, r_b is the laser beam radius, $\mathrm{V_s}$ is the scanning speed, $\mathrm{h_c}$ is the convective heat transfer coefficient, $\mathrm{T_\infty}$ is the ambient temperature, σ_s is the Stefan-Boltzmann constant, ε is the emissivity, and T_{ref} is the reference temperature.

The momentum boundary condition at the liquid-gas interface is:

$$F_{L/G}=\gamma n\kappa+\nabla_S T\frac{d\gamma}{dT} \quad (6)$$

where γ is the surface tension coefficient, n is the outward pointing normal of the surface, and κ is the curvature of the surface. The thermophysical properties of Inconel 625 and approximated processing conditions used in the simulations are summarized in Table 1. Densities taken from [50] for ambient and liquidus temperatures are used for the solid and liquid densities, respectively. Additionally, viscosity at the liquidus temperature taken from [51] was assumed to maintain a constant value within the melt pool. Temperature-dependent polynomial functions were fitted to experimental measurements [52] of thermal conductivity and specific heat capacity for the solid phase.

Table 1: Thermophysical properties and processing conditions used for the thermal-fluid flow model

Physical Property	Value	Reference
Solid density ($\mathrm{kg \cdot m^3}$)	8440	[50]
Liquid density ($\mathrm{kg \cdot m^3}$)	7640	[50]
Solidus temperature (K)	1563	[51]
Liquidus temperature (K)	1623	[51]
Solid specific heat capacity ($\mathrm{J \cdot kg^{-1} \cdot K^{-1}}$)	$0.2437T + 338.39$	[52]
Liquid specific heat capacity ($\mathrm{J \cdot kg^{-1} \cdot K^{-1}}$)	709.25	[50]
Solid thermal conductivity ($\mathrm{W \cdot m^{-1} \cdot K^{-1}}$)	$0.01530T + 5.2366$	[52]
Liquid thermal conductivity ($\mathrm{W \cdot m^{-1} \cdot K^{-1}}$)	30.078	[50]
Latent heat of fusion ($\mathrm{KJ \cdot kg^{-1} \cdot K^{-1}}$)	29.0	[50]
Dynamic viscosity (Pa · s)	7×10^{-3}	[51]
Coefficient of Thermal expansion ($\mathrm{K^{-1}}$)	5×10^{-5}	[51]
Preheat temperature (K)	353	-
Laser spot radius (μm)	45	-

3.2. Data-driven modeling techniques

This section aims to introduce the data-driven modeling techniques used in this study, namely the polynomial regression (PR) and Kriging methods. In general, the PR model uses the training data to estimate the optimal parameters of the polynomial formulation. On the other hand, the Kriging method offers an interpolation approach from which the prediction is derived based on correlations to existing data. The mathematical formulation of the predictive model can be expressed as:

$$y(\tilde{x})=f(\tilde{x})+\varepsilon \quad (7)$$

where $\mathrm{y}(\tilde{\mathrm{x}})$ represents the exact solution for new point $\tilde{\mathrm{x}}$, $\mathrm{f}(\tilde{\mathrm{x}})$ is a hypothetical function derived statistically from data that produces the model estimate, ε is error, and $\tilde{\mathrm{x}}$ represents a set of input variables. For different modeling approaches, the composition of each of these elements could be different.

3.2.1. Polynomial regression (PR) method

Similar to linear regression, PR formulates the relationship between the input variables x and the outcome y with higher-order variation [53]. The efficiency and accuracy of PR make it popular in various engineering domains. The quadratic polynomial function can be presented as:

$$\hat{y}=\beta_0+\sum_{i=1}^{k}\beta_i x_i+\sum_{i=1}^{k}\beta_{ii}x_i^2+\sum_i\sum_j\beta_{ij}x_i x_j \quad (8)$$

where β_0, β_i, β_{ii}, and β_{ij} are regression coefficients, and k is the number of design variables.

Moges, Tesfaye; Yang, Zhuo; Jones, Kevontrez; Feng, Shaw C.; Witherell, Paul; Lu, Yan. "Hybrid Modeling Approach for Melt Pool Prediction in Laser Powder Bed Fusion Additive Manufacturing." Paper presented at ASME 2020 International Design Engineering Technical Conferences and Computers and Information in Engineering Conference (IDETC/CIE 2020), St. Louis, MO, US. August 16, 2020 - August 19, 2020.

3.2.2. Kriging method

Unlike traditional parametric modeling methods that can derive specific formulations, the Kriging method predicts a result based on the spatial correlation between an estimated data point and existing data points [54,55]. The general form of the Kriging approach can be presented as:

$$Z_E = \bar{Z} + \sum_{i=1}^{n} \lambda_i (Z_i - \bar{Z}) \tag{9}$$

where $\bar{Z}$ represents the regional mean value of the response and λ_i is the distance-correlated weight value, which is determined by computing the spatial correlation.

To calculate the weight factor, λ_i, one should first compute the spatial correlation R between data points. The value of the spatial correlation can be derived from:

$$R(\theta, x_i, x_j) = \prod_{l=1}^{n} exp(-\theta_i (x_{i,l} - x_{j,l})^2) \tag{10}$$

where $x_{i,l}$ is the l^{th} component of the i^{th} vector x_i [56]. $R(\theta, x_i, x_j)$ depends on the location of points x_i and x_j and the correlation parameter, θ.

3.3. Hybrid modeling approach

This section discusses development of the hybrid model based on a combination of computational and experimental data. The hybrid model applies a polynomial regression method to construct the initial simulation-based surrogate model using computational data obtained from the aforementioned CFD model (Section 3.1.). The Kriging method is then applied to model the residual error between computational and experimental results, using an adaptive modeling method to iteratively update the model and reduce the predictive errors of the hybrid model. Figure 2 outlines our workflow for the hybrid AM model construction.

3.3.1. Workflow of hybrid modeling approach

The proposed method uses physics-based computational data from a CFD model to construct the initial surrogate model by applying the polynomial regression method. This model can generally represent trends, but may include significant error when compared to the experimental data. The next step is to model the residual error between computational and experiment results. An adaptive modeling method can iteratively update the Kriging model to reduce the predictive errors of the hybrid model [57,58,59]. The process adaptively adjusts the training and validation datasets to approach higher predictive accuracy. To evaluate the hybrid model performance, the Average Relative Error Magnitude (AREM) is deployed for individual and global validation [58]. The formulation of AREM can be expressed as:

$$AREM = \frac{1}{m}\left(\frac{\sum_{i=1}^{m}|y_i - \hat{y}_i|}{y_i}\right) \quad (y_i \neq 0) \tag{11}$$

where y_i is the observed value from given data, $\hat{y}$ is the value predicted by the surrogate model of the data points that were not selected to construct the surrogate model, and m is the number of data points.

3.3.2. Algorithm for hybrid model development

This section provides the algorithmic approach to build the proposed AM hybrid model. We first generate N_{sim} simulation data to construct the initial surrogate model. Similarly, M_{meas} experimental data are measured to improve and validate the hybrid model. The adaptive Kriging model starts with M_{in} initial experimental data points and M_{up} additional points for updating. To validate the final hybrid model, M_{val} experimental data points are used. Therefore, the training-validation data ratio is $(M_{in} + M_{up}) : M_{val}$. The case study in Section 4 uses a total of 72 simulation data points and 21 experimental data points. Here, it is important to note that, in the limited number of experimental data, the predetermined number of validation data can be reached before the error value is less than the threshold. In this case, all

4. CASE STUDY: HYBRID MODELING OF MELT POOL WIDTH

This section demonstrates the proposed hybrid model presented in Section 3.3 and discusses its performance by comparing it against computational and experimental data. As previously stated, melt pool widths obtained from CFD model and measurement data are used as output QoIs to demonstrate the hybrid model's capabilities. The primary input variables used for the simulations and experiments are laser power and scan speed. The range of laser power used for the simulations and experiments is from 49W – 285W and 100W – 195W, respectively. Whereas, the scan speed used for both the simulations and experiments ranges from 100mm/s – 1400mm/s.

4.1. Data for hybrid model

The experiments were performed on Inconel 625 bare plates and ex-situ measurements were conducted to record melt pool widths using optical microscope [60]. The melt pool widths were measured from the optical image of a 1mm long scan track by manually tracing the edges of the track and averaging the distance between the traces at different locations as shown in Figure 3(a). The average and standard deviation of the measured melt pool widths at different combinations of laser power and scan speed are given in Table 2. Similarly, the thermal CFD model is simulated as shown in Figure 3(b), and melt pool widths are extracted for a given input variables. The simulation results for the corresponding experimental data along with the relative percentage error are also given in Table 2.

The average relative percentage error of the simulations against measurement results is 20.78%. This highlights that the physics-based computational model by itself induces major discrepancy against the experimental data. This discrepancy may be due to the different assumptions taken during model formulation including powder particle distribution, spattering of molten metal, gas-liquid-solid interaction, mass loss due to chemical reactions, and others. This discrepancy is due to model uncertainty and also the uncertainty associated with measurements, including sensor error and imprecise measurement methods [15,22].

20	195	1000	107.17 (4.55)	113	5.44
21	195	1200	90.15 (4.97)	110	22.02

4.2. Implementation of the proposed hybrid model

Figure 4 shows the schematic framework for the case study implementation of the hybrid model for melt pool width prediction. First, the CFD model is simulated and 72 data points of melt pool widths were extracted for the given combinations of laser power and scan speed, as shown in PV map (left) in Figure 4. Similarly, experimental data provided 21 data points of melt pool widths are measured for the given combinations of laser power and scan speed, as shown in the PV map (right). All simulation data are used to construct the initial surrogate model using a polynomial regression method. The adaptive Kriging model starts with 5 initial data points and 10 additional points for updating. As a result, 6 experimental data points are excluded from the model construction and are used to validate the model. The training-validation data ratio is 15:6. The hybrid model is then used to predict melt pool widths for other possible combinations of laser power and scan speed in the design space with good accuracy and computational time.

The accuracy of the proposed hybrid model mainly depends on the accuracies and the number of computational and experimental data used and the data-driven techniques applied. Obtaining more experimental data used for training, updating, and validating the proposed hybrid model is crucial for improving the accuracy.

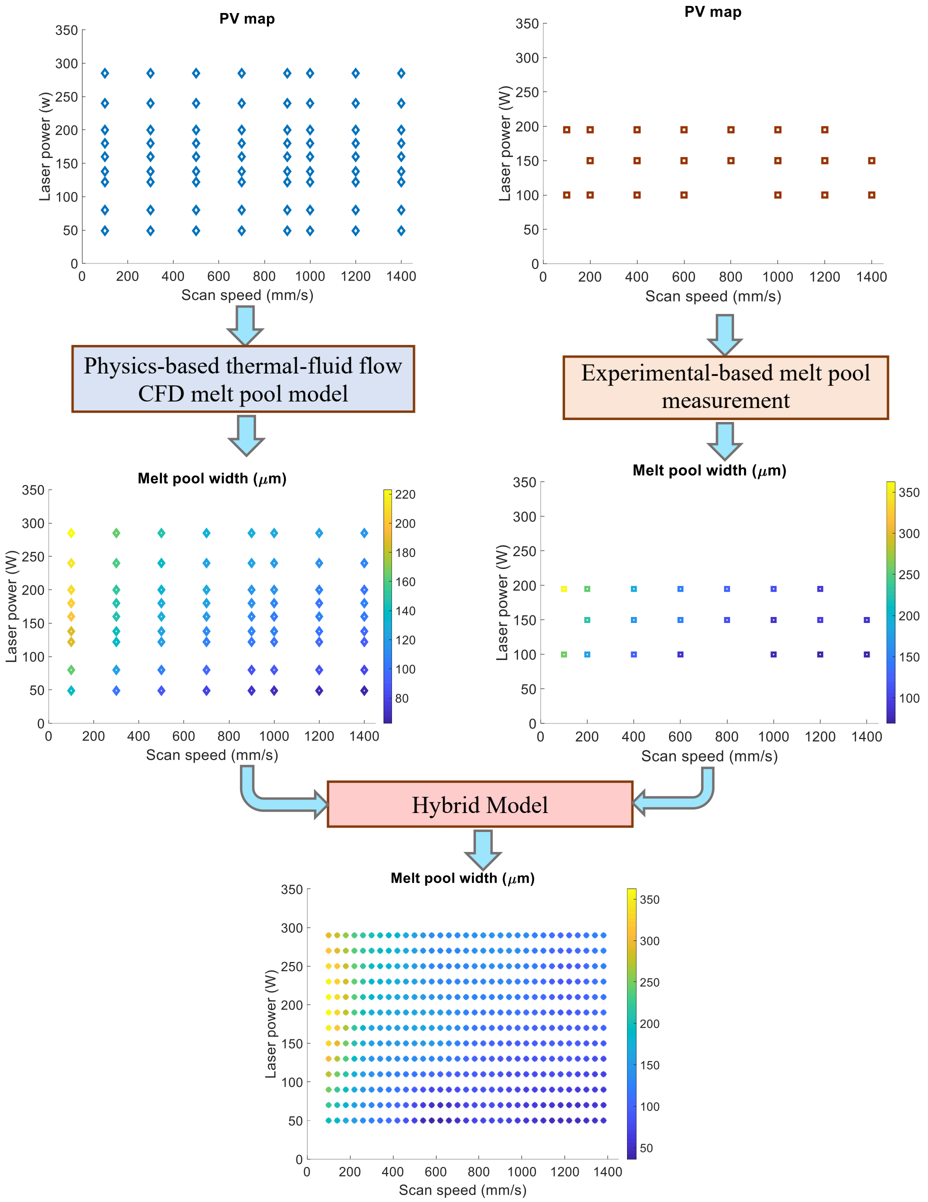

Figure 4 Schematic implementation framework of hybrid model of melt pool width

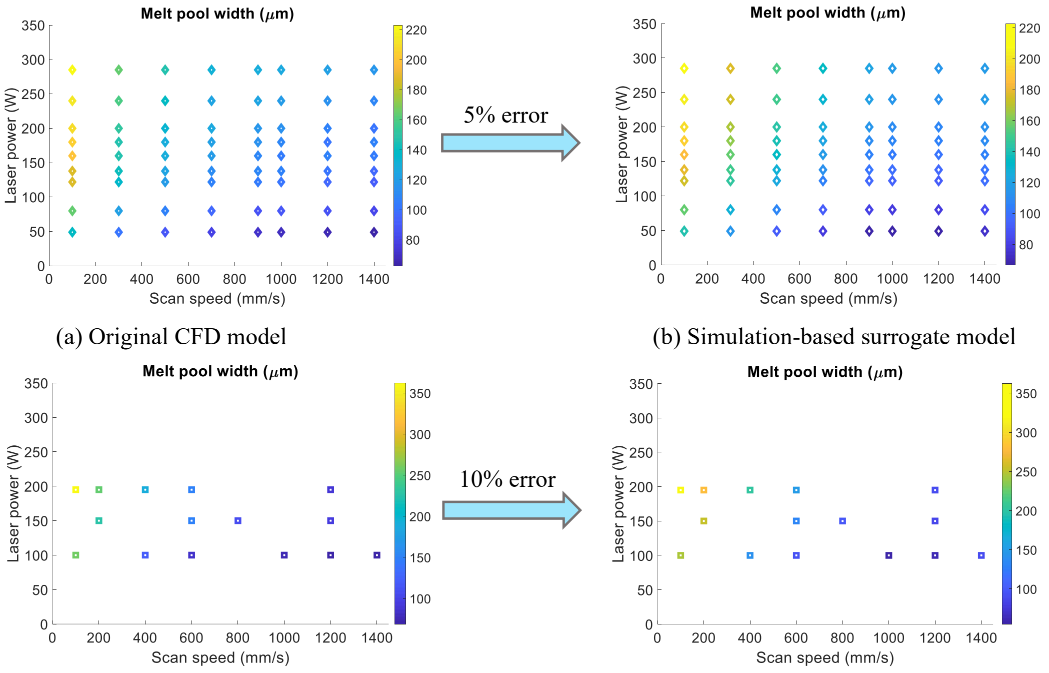
4.3. Verification of Surrogate models

To develop and evaluate the hybrid model, both computational-based and experimental-based surrogate models are constructed using corresponding data. To evaluate the accuracy of these surrogate models and compare them with the original simulation and measured data, model verification is conducted for the same processing parameters. The computational-based surrogate model is compared to the original CFD model as shown in Figure 5(a) and (b), and the average error is about 5%. The cause of this discrepancy may be due to the variabilities in data-driven modeling approaches. Similarly, the experimental-based surrogate model has around 10% difference when compared to the original measurement data as shown in Figure 5(c) and (c). This error is mainly attributed to the limited number of measurement data points (only 15) used to build the surrogate model.



(a) Original CFD model

(b) Simulation-based surrogate model

(c) Original measurement data

(d) Experimental-based surrogate model

Figure 5. Comparison of original simulation model and measurement data with surrogate models

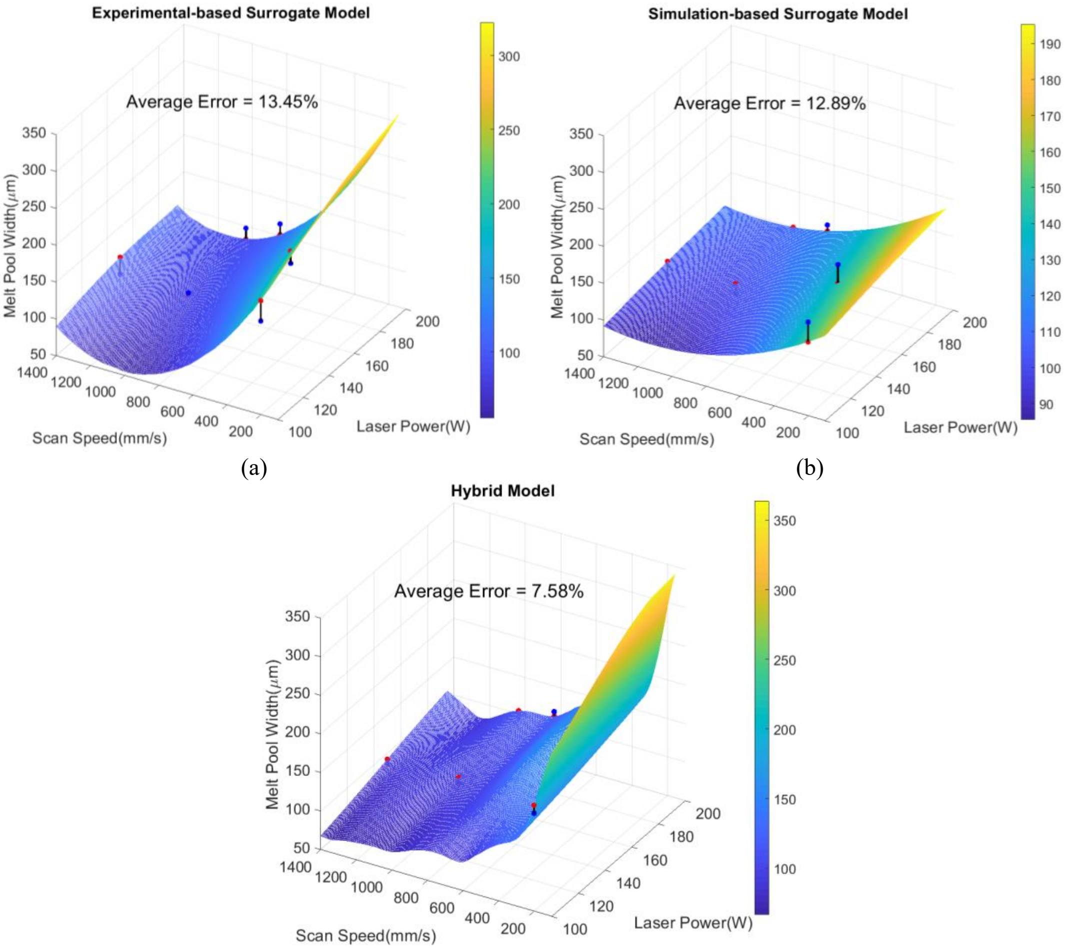
4.4. Performance evaluation of hybrid model

In order to evaluate the performance of the proposed model, we compared the average relative error of hybrid model to the experimental-based surrogate model and computational-based surrogate model as shown in Figure 6 and Table 3. The blue and red dots in the graph represent the measured and predicted results with the validation parameters, respectively.

The results of melt pool widths predicted at the 6 validation data points (that are not used in the model construction) using the experimental-based surrogate model has an average relative error of 13.45%, as shown in Figure 6(a). Similarly, the melt pool widths predicted using the simulation-based surrogate model has an average error of 12.89% as shown in Figure 6(b). Figure 6(c) depicts the prediction of melt pool widths using the proposed hybrid model. The hybrid model has an average error of 7.58%. Table 3 provides the input parameters used for validation, the measured results, simulated results, predictive results from experimental-based and simulation-based surrogate models, and their deviations from the measured results using percentage relative error in parentheses. It can be observed that the hybrid model predicted melt pool width with better accuracy than both simulation-based and experimental-based surrogate models.

Table 3. Comparing the proposed hybrid model to the experimental validation data points

No. of Run	Laser power (W)	Scan speed (mm/s)	Measurement results	CFD simulation results	Experiment-based surrogate model	Simulation-based surrogate model	Hybrid model
1	100	200	177.26	146 (17.64%)	204.92 (15.60%)	150.24 (15.24%)	187.71 (5.90%)
2	150	400	166.96	132 (20.94%)	183.63 (9.98%)	141.91 (15.00%)	148.26 (11.20%)
3	150	1000	86.922	110 (26.55%)	84.13 (3.21%)	100.94 (16.13%)	95.21 (9.54%)
4	150	1400	85.735	101 (17.80%)	108.64 (26.72%)	104.52 (21.92%)	92.20 (7.54%)
5	195	800	126.3	120 (4.99%)	111.82 (11.46%)	118.23 (6.39%)	120.34 (4.72%)
6	195	1000	107.17	110 (2.64%)	92.53 (13.66%)	110.05 (2.69%)	114.23 (6.59%)
	Average % relative error			**(15.09%)**	**(13.45%)**	**(12.89%)**	**(7.58%)**



(a)

(b)

(c)

Figure 6. Melt pool width prediction using (a) experimental-based surrogate model, (b) simulation-based surrogate model, (c) proposed hybrid model

Therefore, by integrating the physics-based and experimentally obtained data using the proposed hybrid modeling approach, melt pool widths can be predicted with better accuracy. It can be concluded that with a few experimental data, the overall prediction accuracy of physics-based numerical models can be improved through the proposed approach. Since the hybrid model is a data-driven approach, for new sets of input parameters, the melt pool widths can be predicted in a few seconds. Thus, the hybrid model is computationally efficient compared to pure physics-based models. Due to improved accuracy and computational efficient, the proposed hybrid model better suited for real-time monitoring, control and optimization.

5. FUTURE WORK: AM ONTOLOGY FOR MODEL SELECTION

Our case study demonstrated the ability to create a hybrid model for a specific application, with comparable parameter sets. However, the context under which models are run and experiments are conducted is not always as straight forward. To help resolve potential discrepancies in the data sources, we propose there is a role for ontologies. Ontology can be used to capture the rapidly evolving knowledge of the AM process, computational models, uncertainty sources, and design for AM in an organized structure to help users to interoperate and reuse information [47,49,61]. As stated previously, there are numerous physics-based models ranging from low-fidelity to medium-fidelity to high-fidelity. A well-founded AM ontology can be used to capture the complex interconnections between these models as well as data-driven models and provide useful information for model composition towards developing a more accurate and reliable predictive metamodel [62,63]. In this section, we introduce the conceptual use of AM ontology for providing structured information of the different AM models to help develop a more accurate hybrid model.

An ontology consists of various concepts and correlations among entities. The AM ontology offered in Moges et al. [47]

captures the different features of AM models including assumptions, considered and neglected phenomena, model inputs and outputs, and uncertainty sources. The ontology attempted to capture these features at the five stages of the process: powder layer formation, laser-heat source interaction, melt pool formation, solidification, and residual stress formation. Different physics-based models have been developed to simulate each of these stages of the process. For instance, to simulate the melt pool behavior in L-PBF, there are Rosenthal-based analytical models, FEM thermal models, path-level thermal simulation model [64], CFD models, and Lattice Boltzmann method (LBM) models [14]. Similarly, to determine the amount of absorbed energy by the powder particles, there are different methods including radiation transfer, ray tracing, and Beer-Lambert approach [14]. Since these models are developed based on different methods and formulations, they have different pros and cons in terms of prediction accuracy and computational time. Even some models predict more accurately at a specific region of a PV map than the other regions.

The hybrid model developed in this paper uses computationally predicted data obtained from one physics-based model namely CFD model. It was shown in Section 4 that this hybrid model improves the predictive accuracy of the melt pool width compared to the original physics-based model. However, in order to further improve the accuracy, instead of using simulation data obtained from a single physics-based model, a hybrid model that uses different simulation data obtained from different physics-based models could be more reliable. For this, a systematic approach that leverages the AM ontology is needed to select the simulation data obtained from different physics-based models and integrate them with experimental data to build a more precise hybrid model.

In the future, a more reliable approach need to be developed for (a) investigating the capability of different physics-based models and data-driven techniques, (b) developing strategic approaches to select the different simulation data, (c) integrating the different simulation data with the experimental data using various data-driven methods. Hence, ontology can be an essential tool for strategically selecting models based on their inherent key features. Furthermore, incorporating different data-driven techniques into the existing AM ontology will enable us to select and apply a more suitable technique for developing a hybrid model to predict other output QoIs.

6. CONCLUSION

In this study we proposed a methodology to integrate physics-based data and experimentally measured data into a hybrid model that enables fast and accurate predictions in the L-PBF process. We proposed a hybrid model which comprised of data generated from both numerically predicted and experimentally recorded melt pool widths for various combinations of laser power and scan speed. The numerical results were obtained from a thermal CFD model and ex-situ cross-sectioning was used to gather the experimental results.

In our hybrid modeling approach, we first constructed an initial simulation-based surrogate model using simulation data by applying the polynomial regression method. Then, we applied the Kriging method to model the residual error between the simulated and experimental results using an adaptive modeling method to reduce predictive errors of the hybrid model. The performance of the proposed model is evaluated by comparing predicted results of melt pool widths from a CFD model, a simulation-based surrogate model, an experimental-based surrogate model, and the hybrid model against experimentally measured data. The results showed that on average, the hybrid model had the highest accuracy out of all the models. Additionally, due to improved accuracy and computational efficiency, the proposed hybrid model better suited for real-time process control.

In order to further improve the accuracy of the hybrid model, instead of using data obtained from a single physics-based model, integrating data obtained from multiple physics-based models with experimentally measured data could be more reliable. To address this, AM ontology can be used as an essential tool to help understand the capability of the different physics-based models and data-driven techniques and select the most accurate model at a specific region in the PV map. In the future, the knowledge captured in AM ontology can be leveraged for developing a more accurate hybrid modeling approach by providing predictive capabilities of multiple models. We view this work as a step towards effectively and efficiently utilizing physics-based models, data-driven approaches, experimental-based measurement data, and AM ontology to build reliable and robust predictive models that can be applied for L-PBF process control.

Abstract – **A virtualization platform is responsible for allocation and aggregation of radio resources from different access technologies as well as the distribution of the total capacity among Virtual Network Operators (VNOs). The Radio Resource Management (RRM) employed by each VNO should comply with the requirements specified in the Service Level Agreements (SLAs) of each user. A joint admission control and resource management scheme based on proportionally fair rate allocation among different users was proposed in our previous publication. Although, all SLAs are satisfied in that scheme, users with vastly different QoS requirements might not necessary be treated fairly in terms of the allocated rates. This is especially the case when the available capacities of the VNOs cannot support the maximum requested rates for all such users. This paper attempts to overcome this weakness by replacing the proportional fairness strategy with a more general concept of utility-proportional fairness. The proposed approach is evaluated by simulations under increasing congestion scenarios and the results show improved fairness in the allocated rates.**

Keywords – Virtualization, distributed resource allocation, utility-proportional fairness, Service Level Agreements (SLA), admission control.

I. Introduction

S*ervice-oriented* architecture is expected to enable flexibility in sharing and utilization of network resources, wider range of customized services, along with a reduction in the capital and operational expenditures [1]. *Virtualization* supports service-oriented architecture through decoupling of the services and functionalities from the underlying Radio Access Networks (RANs) [2]. It enables the transformation of the physical infrastructure into multiple logical networks that can be shared among different Virtual Network Operators (VNOs). As such, VNOs do not need to own the infrastructure. Instead, they obtain the resources from a centralized virtualization platform and enforce their own service requirements and policies through the process of Radio Resource Management (RRM) [3].

The diversity in users' Quality of Service (QoS) requirements drives the emergence of resource slicing along with virtualization [4]. Performance optimization in virtualized Heterogeneous Networks (Het-Nets) not only optimizes the performance of various slices but also maximizes the utilization of the overall shared resources [5]. Scalability limitations of centralized RRM necessitate decentralized resource management [6], [7]. Authors in [8] have proposed a distributed RRM model for dense 5G networks based on non-cooperative game theory. While their approach achieves energy efficiency, it does not incorporate customized specifications and requirements of different services. An adaptive two-layer decentralized RRM with slow and fast timescales has also been presented in [9]; however, the methodology does not include network virtualization and slicing concepts. Authors in [10] propose another distributed RRM with a focus on multi-connectivity in 5G networks. Their approach aims at reducing the processing costs and signalling overhead; but does not consider the notion of RAN slicing, isolation, as well as service orientation.

In our previous publication, we proposed a joint admission control and RRM for virtualized RANs [1]. Here, we extend the proportionally fair rate allocation scheme in [11] to a more general utility-proportional rate allocation [12]. The intention is to address some of the observed shortcomings of proportionally fair allocation such as giving advantage to users with low bandwidth requirements [12]. Similar to [1], our proposed scheme maximizes the aggregate system utility using a two-stage distributed optimization on a *fast* and *slow* time scale and overcomes the scalability issues of the centralized RRM [13], [14]. At the faster time scale, and given the capacities of each VNO, users adjust their rates based on the congestion pricing. At the slower time scale, each VNO adjusts its own capacity according to its assigned congestion price subject to the total aggregate capacity of the system. The admission strategy, which requires limited degree of centralization, ensures system ability to guarantee minimum bandwidth requirements to the newly admitted user as well as to all users already present in the system.

The rest of this paper is organized as follows. Section II describes the system architecture and quantifies user preferences. Section III formulates system performance model. Section IV outlines the resource management scheme. Section V describes simulation scenarios and results. Finally, conclusion and plans for future research are discussed in section VI.

II. System Model

System architecture and quantification of user preferences by their corresponding utilities are described in the following subsections.

Marbukh, Vladimir; Sayrafian, Kamran; Rouzbehani, Behnam. "Utility Proportional Resource Allocation for Users with Diverse SLAs in Virtualized Radio Access Networks." Paper presented at IEEE International Black Sea Conference on Communications and Networking, Odesa, MD, US. May 26, 2020 - May 29, 2020.

A. System Architecture

Figure 1 shows the mechanism of service-oriented RAN slicing and resource management along with interaction of different entities in the system. The Virtual-RRM (VRRM) module is a centralized virtualization platform which is responsible for configuring the RAN protocol stack and QoS metrics according to the slice requirements. Those requirements are enforced by different VNOs based on their specific policies. As an example, assume that VNOs A and B provide two types of services with different requirements. For *slice* A with high throughput requirements, radio flow A is configured to support multi-connectivity. Therefore, slice A is using the resources from 2 different radio access points. On the other hand, the network *slice B* is configured with only one connection according to the provided policy.

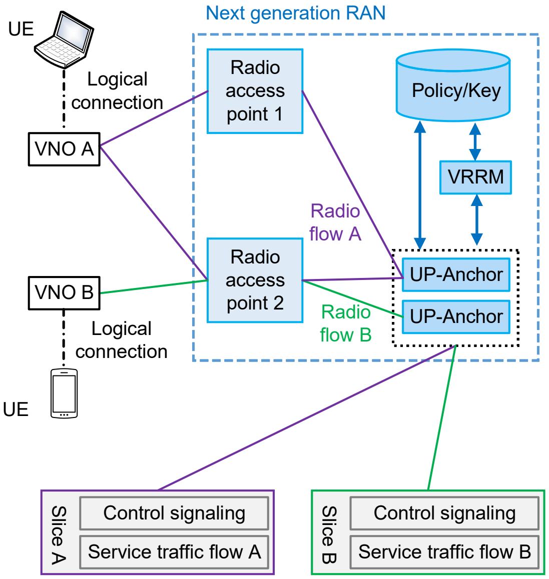

Figure 1. Service-oriented RAN slicing

The User Plane Anchor (UP-Anchor) is responsible for distributing the traffic flow in each slice. A RAN slice is composed of a control plane and a separate data plane. The required capacity allocation is subject to the SLA agreements between the VNOs and users. In this paper, we consider the following three categories of SLA contracts:

- Guaranteed Bitrate (GB): This is the highest priority category where a minimum threshold for data rate assignment must always be guaranteed regardless of the traffic load variation and network status. In addition, the assigned data rate need not exceed a maximum threshold for this SLA category.
- Best effort with minimum Guaranteed (BG): This is the second highest priority category for which a minimum level of data rate is guaranteed. Higher data rates are served in a best effort manner if available.
- Best Effort (BE): This is the lowest priority category for which there is no level of service guarantees and users are served in a pure best effort manner.

B. User Preferences

We assume that preference of each user for rate R can be quantified by the utility function $U(R)$, $R>0$. In [1], we assumed the following logarithmic utility:

$$U(R)=\lambda\log(\alpha R)\,, \tag{1}$$

However, logarithmic utility is typically inadequate for users with diverse QoS requirements which is the main driver of emerging resource slicing technology [12]. This utility function basically favors users with low bandwidth requirements, as observed in [12]. Logarithmic utility may also lead to negative utility values which could potentially cause undesirable oscillations during the rate allocation process. Some of these issues including negative utility values can be avoided by replacing utility (1) with the following utility function, shown in Fig.2.

$$U(R)=\lambda\log(1+\alpha R)\,. \tag{2}$$

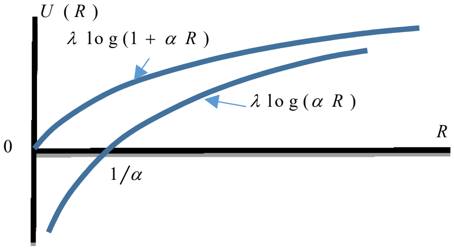

Figure 2. Logarithmic utilities

Fig. 3 exhibits the general utility of a user which requires certain minimum rate $R^{\min}$ and does not significantly benefit from rates above $R^{\max}$.

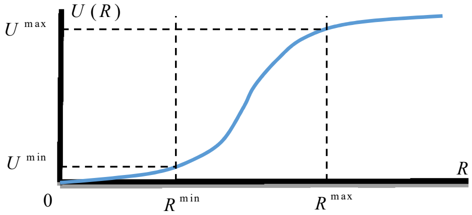

Figure 3. Utility of user with min/max rate guarantee

For example, GB users can be described by sigmoid utility $u(R)$ which is near zero for $R<R^{\min}$, quickly increases for $R^{\min}<R<R^{\max}$, and levels off for $R>R^{\max}$. A natural SLA for user with this utility is $R^{\min}<R<R^{\max}$. Sigmoid utility is often represented by the following function:

$$U(R)=\frac{k}{1+\exp[-\alpha(R-r)]}\,, \tag{3}$$

where parameters $k,\alpha,r>0$ can be expressed in terms of $R^{\min}$, $R^{\max}$, and $U^{\max}=U(R^{\max})$ [15]. Similarly, BG users are described by an utility which is near zero for $R<R^{\min}$, quickly increases for $R^{\min}<R<R^{\max}$, and then logarithmically increases for $R>R^{\max}$.

III. System Performance Optimization

The concept of utility proportional fairness and the class of utility functions which describes the SLAs considered in this paper are briefly discussed in the following subsections.

A. Utility Proportional Fairness

Let I_{sv} be the set of users obtaining service from the slice $s = 1,..,S$ of VNO $v = 1,..,V$, where sets I_{sv} with different (s,v) do not overlap, e.g., $I_{km} \cap I_{ln} = \emptyset$ if $(k,m) \neq (l,n)$, $k,l \in \{1,..,S\}$ and $m,n \in \{1,..,V\}$. Following Network Utility Maximization (NUM) framework [12], we assume that the goal of system management is maximization of the aggregate utility

$$U_\Sigma(R_i) = \sum\nolimits_{s=1}^{S} \sum\nolimits_{v=1}^{V} \sum\nolimits_{i \in I_{sv}} U_i(R_i) \tag{4}$$

over vector of rates (R_i) allocated to users $i \in I_{sv}$, $s = 1,..,S$; $v = 1,..,V$. This maximization is a subject to the following capacity and contractual constraints. The total capacity allocated to all users serviced by VNO v, $i \in I_{sv}$, $s = 1,..,S$ cannot exceed the VNO v capacity C_v:

$$\textstyle\sum_{s=1}^{S} \sum_{i \in I_{sv}} R_i \leq C_v, v = 1,..,V. \tag{5}$$

Also, the aggregate capacity allocated to all VNOs cannot exceed the total system capacity C^{VNNO}:

$$\textstyle\sum_{v=1}^{V} C_v \leq C^{VNNO}. \tag{6}$$

The above constraints are due to data rate guarantees to a user $i \in I_{sv}$ in slice s, i.e. R_s^{min} and R_s^{max} respectively:

$$0 \leq R_s^{min} \leq R_{svi} \leq R_s^{max},\ \ s = 1,..,S,\ \ v = 1,..,V \tag{7}$$

The second set of constraints is due to guarantees on the minimum capacity of each VNO v, $C_v^{min} \geq 0$:

$$C_v \geq C_v^{min}, v = 1,..,V. \tag{8}$$

Here, we consider a distributed solution to the aggregate utility (2) maximization:

$$\max_{(C_v)} \max_{(R_i)} \sum\nolimits_{s=1}^{S} \sum\nolimits_{v=1}^{V} \sum\nolimits_{i \in I_{sv}} U_i(R_i) \tag{9}$$

subject to constraints (5)-(8). Note that due to lower bounds in (7) and (8), optimization problem (5)-(9) may not have a feasible solution. This possibility necessitates an admission control similar to the process described in [1].

For concave user utilities, including logarithmic utilities (1) and (2), optimization problem (5)-(9) is convex; and therefore, the local maximum is also a global maximum (R_i^*). This is assuming that feasible sets (5)-(8) are non-empty. In the particular case of logarithmic utility (1), solution (R_i^*) is proportionally fair for any feasible allocation (R_i), i.e.

$$\sum\nolimits_{i \in I_{sv}} \lambda_i (R_i - R_i^*) / R_i^* \leq 0. \tag{10}$$

For non-concave user utilities (e.g., sigmoid utility (3)), optimization problem (5)-(9) is non-convex; and therefore, not generally tractable.

To resolve problems with proportional fairness, utility proportional fairness has been proposed in [12]. Rate allocation (R_i^*) is utility $u_i(R_i)$ proportional if

$$\sum\nolimits_{i \in I_{sv}} [(R_i - R_i^*) / u_i(R_i^*)] \leq 0 \tag{11}$$

for any feasible allocation (R_i). Proportional fairness (10) is a particular case of utility $u_i(R) = \lambda_i^{-1} R$ proportional fairness. It is known that utility $u_i(R)$ proportional fairness is equivalent to NUM with modified utility [12]

$$U_i(R) = \int_{R_i^{\min}}^{R} dr / u_i(r),\ R_i^{\min} \leq R \leq R_i^{\max}, \tag{12}$$

i.e., equivalent to aggregate utility maximization

$$\max_{(C_v)} \max_{(R_i)} \sum\nolimits_{s=1}^{S} \sum\nolimits_{v=1}^{V} \sum\nolimits_{i \in I_{sv}} U_i(R_i). \tag{13}$$

subject to constraints (5)-(8).

Note that the NUM problem should be solved every time the set of users changes due to user arrivals/departures. Assuming that resource optimization occurs on a faster time scale changes in the number of users, distributed solution to NUM (5)-(8), (12)-(13) is discussed in the next section. As an example, consider the following utility function,

$$u(R) = [u^{\min} + \lambda^{-1}(R - R^{\min})]_{u^{\min}}^{u^{\max}}, \tag{14}$$

where $\lambda = (R^{\max} - R^{\min}) / (u^{\max} - u^{\min})$, and $[z]_a^b = \max\{a, \min\{z,b\}\}$. Using utility (14) in equation (12) will lead to the following $U(R)$, and the comparison is shown in Figure 4.

$$U(R) = \left[\lambda \log\left(1 + \left(\frac{u^{\max}}{u^{\min}} - 1 \right) \frac{R - R^{\min}}{R^{\max} - R^{\min}} \right) \right]_0^{U^{\max}}, \tag{15}$$

where $U^{\max} = \lambda \log(u^{\max} / u^{\min})$.

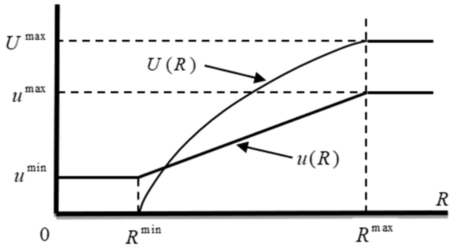

Figure 4. Piece-wise linear utility fairness

Our selection of utility (14) is due to its ability to describe BE users as well as users with rate guarantees.

IV. Resource Management

User rate and VNO capacity adaptation algorithms, given that the optimization problem (5)-(8), (12)-(13) has a feasible solution for the set of users, i.e., system has sufficient capacity to satisfy minimum rate requirements for all users in the system is presented in the following. The admission control strategy which basically ensures compliance with SLA for newly accepted as well as remaining users in the system is identical to the process described in [1].

User $i \in I_{sv}$ requests data rate by solving its individual optimization problem:

$$R_i(p_v) = \arg \max_{R_i^{\min} \le R \le R_i^{\max}} [U_i(R) - p_v R], \qquad (16)$$

where p_v is the price of a unit of data rate offered by the VNO v. Since function $U_i(R)$ is increasing and strictly concave for $R_i^{\min} \le R \le R_i^{\max}$,

$$R_i(p_v) = (1/k_i)\left([1/p_v]_{u_i^{\min}}^{u_i^{\max}} + k_i R_i^{\min} - u_i^{\min}\right). \qquad (17)$$

Figure 5 shows rate (17) versus price.

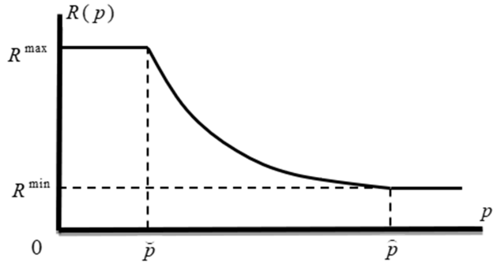

Figure 5. User rate vs. price

Due to the lower bound constraints in (7)-(8) optimization problem (5)-(8), (12)-(13) may not have a feasible solution. In this case, VNO v capacity deficit

$$\textstyle\sum_{s=1}^{S} \sum_{i \in I_{sv}} R_i^{min} - C_v > 0 \ \ , v = 1, .., V \qquad (18)$$

is arbitrarily allocated to currently present users in this VNO.

The optimal prices p_v^{opt} that maximize the utilization of the VNOs' available bandwidth are determined by the following distributed adaptive algorithm. The algorithm proceeds in discrete steps $k = \{1,2, \ldots\}$. At each step k, users solve the individual optimization problems (16) resulting in rate (17). If constraints (7)-(8) are satisfied, i.e., the aggregate data rate of the users does not exceed the total capacity of the associated VNO, then in step $k+1$ the price $p_{v,k+1}$ is reduced in order to motivate users to request higher rate. However, if the constraints (7)-(8) are not satisfied, $p_{v,k+1}$ is increased, resulting in a decrease of users' data rates. The main idea here is to maximize utilization of the available capacity in an efficient way. The price adaptation model can be expressed as [16]:

$$p_{v,k+1} = \left[p_{v,k} + h(\tilde{R}_{vk} - C_{vk})\right]^{+} \qquad (19)$$

where

$$\tilde{R}_{vk} = max\left(C_v^{min}, \textstyle\sum_{i \in I_{sv}} R_{ik}\right) \qquad (20)$$

$[x]^{+} = \max(0, x)$, and $h > 0$ is a small positive constant which regulates the tradeoff between optimality under stationary scenario and adaptability under non-stationary scenario, e.g., due to changing set of users. The main advantage of this approach is that VNOs do not have to know users' utilities which are considered private information.

In a slower time-scale each VNO adjusts its own capacity by negotiating the price with the VRRM. The adaptation of capacities among the tenant VNOs (C_v) is subject to the total available capacity of VRRM is C^{VRRM} (6). The average price of a unit of data rate in the entire system at step $k = \{1,2, \ldots\}$ is as follows:

$$P_k^{ave} = \frac{1}{C^{VRRM}} \sum_{v=1}^{V} C_v P_{v,k} \qquad (21)$$

where $P_{v,k}$ is the price of a unit of rate assigned to VNO v from VRRM at step k.

We propose the following capacity adaptation algorithm for the VNOs according to [16]:

$$C_{v,k+1} = C_{v,k} + H(P_{v,k} - P_k^{ave}), \qquad (22)$$

where $H > 0$ is a small constant.

Algorithm (21)-(22) increases (decreases) the capacity of a VNO if its corresponding price is higher (lower) than the average price (21). However, VNO capacity cannot fall below the lower bound in (8) due to equation (20).

V. Simulation Scenario & Results

To evaluate our proposed resource management strategy, the simple traffic distribution scenario with VRRM capacity of 510 Mbps has been considered in this section. Network parameters are defined in Table 1. It is assumed that 3 VNOs with different SLA types (i.e., GB, BG and BE) are providing services from 4 service classes: *Conversational* (Con), *Streaming* (Str), *Interactive* (Int.) and *Background* (Bac.) according to the class-of-service definition in UMTS. VNO GB delivers Voice (Voi), Video calling (Vic), Video streaming (Vis) and Music streaming (Mus). VNO BG serves File sharing (Fil), Web browsing (Web) and Social Networking (Soc) services, while VNO BE provides Internet of Things (IoT) and Email (Ema). It is further assumed that at each time step k, forty new users arrive and submit their requests for service to their associated VNOs. Simultaneously, twenty users depart from the system. For simplicity, the traffic type percentages of both arrivals and departures, defined as $U_{[\%]}^{srv}$, remain the same.

Table 1 – Network Parameters

VNO	**Service**	**Class**	$\boldsymbol{R_{svi}}$ in Mbps	$U_{[\%]}^{srv}$	$\boldsymbol{\lambda_s}$	C_v^{min} in Mbps
1 (GB)	Voi	Con.	[0.032, 0.064]	10	5	0.4 C^{VRRM}
	Vic		[1, 4]	10	4	
	Vis	Str.	[2, 13]	25	3	
	Mus		[0.064, 0.32]	15	1	
2 (BG)	Fil	Int.	[1, C^{VRRM}]	15	4	0.3 C^{VRRM}
	Web		[0.2, C^{VRRM}]	5	3	
	Soc		[0.4, C^{VRRM}]	10	2	
3 (BE)	Ema	Bac.	[0, C^{VRRM}]	5	4	0
	IoT		[0, 0.1]	5	4	

To evaluate the performance of user rate and VNO capacity adaptations, we consider stress scenario with proportionally increasing numbers of users of different services specified in Table 1. We assume user utility (2) as a particular case of utility-proportional rate allocation scheme. Benefits of utility-proportional fairness as compared to the previously used proportionally-fair strategy is demonstrated through extensive simulations. Figure 6 shows evolution of the system aggregate utility for utility proportionally rate allocation algorithm. The results show convergence of the users' rate adaptation and also highlights our assumption on separation of time scales, i.e., rate allocation should occurs much faster than changes in the set of users. The performance for the case where this assumption does not apply requires further investigation.

Figures 7 shows the converged system aggregate utility for utility proportional and proportionally fair resource allocation schemes. The advantage of utility-proportional scheme is clearly noticeable since admission of new users is inconsistent with decreasing aggregate utility. Figures 8 and 9 display another drawback of proportionally-fair rate allocation which gives advantage to users with lower rate SLA rate requirements. As the number of users increase at VNO GB, Voi users that have the lowest rate SLA requirements maintain their maximum requested rate of 0.064 Mbps long after Vis users rate drops to their minimum requested 2 Mbps. In general, under the proportionally fair resource allocation, users with highest SLA rate requirements will encounter reduced assigned rates well before users with lower SLA rates. Under a "fair" rate allocation scheme, all users should experience rate reduction from their maximum assigned rates approximately around the same time. As observed, this situation is better achieved using the utility-proportional strategy through proper adjustment of the parameter α in (2). Further results confirming this advantage have been omitted due to brevity.

VI. Conclusion and Future Research

The proposed radio resource management scheme in this research overcomes the shortcomings of the proportionally fair rate allocation by exploiting the general concept of utility proportional fairness. Simulation results clearly demonstrate advantages of using this strategy. In general, a customized SLA-based utility proportional fairness could lead to even better overall performance. The authors plan to further investigate this issue in future research. Viability of the time scale separation and convergence assumption in practical situations should also be studied. That will include mechanisms to mitigate performance loss in situations of comparable time scales in rate/capacity adaptation and users' arrivals/departures process. A requirement for this study is realistic models of users' arrival and departure processes. Finally, employing artificial intelligence (AI) techniques as a part of the network management could be a major focus of future research.

ABSTRACT

The number and types of measurement devices used for monitoring and controlling laser powder bed fusion (LPBF) processes and inspecting the resulting AM metal parts have increased rapidly in recent years. The variety of the data collected by such devices has increased, and the veracity of the data has decreased simultaneously. Each measurement device generates data in a unique coordinate system and in a unique data type. Data alignment, however, is required before 1) monitoring and controlling LPBF processes, 2) predicting the material properties of the final part, and 3) qualifying the resulting AM parts can be done. Aligned means all data must be transformed into a single coordinate system. In this paper, we describe a new, general data-alignment procedure and an example based on LPBF processes. The specific data objects used in this example include in-situ photogrammetry, thermography, and ex-situ X-ray computed tomography (XCT), coordinate metrology, and computer-aided design (CAD) models. We use the data-alignment procedure to align the data from melt pool images, scan paths, layer images, XCT three-dimensional (3D) model, coordinate measurements, and the 3D CAD model.

Keywords: additive manufacturing, data alignment, data fusion, manufacturing system integration

1. INTRODUCTION

For three main measurement needs, accurately qualifying complex, laser powder bed fusion (LPBF)-built, metal parts is still extremely difficult. First, there are LPBF process instabilities, which can cause significant variations in built parts. Second, there are not well-understood quantitative relationships among the CAD geometry, the raw-material properties, the fabrication process, which are needed to predict final-part properties. Third, there are the current, LPBF-system states, which are needed for control. Meeting those three needs required the extensive use of a wide range of measurement devices, including sensors and measuring machines, to understand relationships before making decisions throughout the entire additively manufactured product life cycle.

High-quality parts require 1) understanding the physical phenomena, 2) developing the correct models of the different phenomenon, 3) linking those models through data, and, finally, 4) making the best life-cycle decisions possible. Meeting those four requirements were based on the measurement, the principle of physics, and associated mathematical models.

Metal additive manufacturing (MAM), is a completely new kind of fabrication technology. The life cycle of AM parts includes designing, engineering, controlling, and inspecting. Nevertheless, the required data links needed to perform those life-cycle functions optimally do not exist. Instead, LPBF MAM process users are building new kinds of data-driven models and information links, based on new kinds of data collected by new kinds of sensors. In addition to traditional numerical types of data, many AM sensors collect a myriad of different types and quantities of in-situ and ex-situ image data. For example, there are sensors for photogrammetry and thermography and machines for X-ray computed tomography (XCT) and coordinate measurement, such as coordinate measuring machines (CMMs) [9]. Unfortunately, different sensors collect data in different, physical, local, coordinate systems. Moreover, the data from sensors in those systems must be "fused" to create the links that provide input to the models needed to make all AM-part, life-cycle decisions.

Feng, Shaw C.; Lu, Yan; Jones, Albert T. "Measured Data Alignments for Monitoring Metal Additive Manufacturing Processes Using Laser Powder Bed Fusion Methods." Paper presented at the ASME 2020 International Design Engineering Technical Conferences & Computers & Information in Engineering Conference, St. Louis, MO, US. August 16, 2020 - August 19, 2020.

Today, aligning data is not possible because there are no procedures for both spatially and temporally aligning data from different coordinate systems. The scope of this work is on alignment of data. Data can come from scan commands, laser-spot locations, melt-pool images, layer-wise images, XCT model, CMM model, and CAD model. Our approach to aligning these different data types is to find and use the reference locations and orientations required to transform a local coordinate system into the reference coordinate system. The authors have identified the meta data needed to align related data sets, which can be used for data registration. Registered data can then be used for analyzing the quality of part.

This rest of paper has the following sections. Section 2 reviews related publications in data collected from both in-situ and ex-situ monitoring. Section 3 proposes a procedure for data alignment. Section 4 gives examples of data alignment. Section 5 discusses the proposed procedure. Section 6 concludes the paper and identify the future work.

2. REVIEW OF SENSOR DATA TYPES AND ALIGNMENT METHODS

Recently, researchers have been integrating LPBF sensors and developing techniques to apply sensor data as input to various applications, such as data analytics. The section provides a review of types of data, data fusion, and research needs.

2.1 Sensor Data Types

In-situ process monitoring is necessary for real-time control and is enabled by sensors that monitor in-process phenomena. Scime et al. [20] used a common, staring cameras with a k-Mean unsupervised classification algorithm to detect anomalies on freshly coated powder bed for laser PBF. The images are used to detect anomalies on a freshly coated powder bed surface: waviness from blade hopping, streaks, debris, voids, and incomplete spreading. Many researchers [11][12][3] have reported the use of multiple monitoring methods, including high-speed coaxial cameras, off-axis thermal detectors and/or staring cameras to collect data for monitoring melt-pool characteristics, including melt pool geometry, energy intensity, spatter, and residual heat.

Reutzel et al. [19] described measurements of melt-pool geometry and temperature with images taken by a single-color camera in the infrared (IR) range. Temperature measurements, however, were based on images taken from a dual-color camera. The authors aligned the images with built-in reference marks in addition to the part design. Everton et al. [5] described in-situ sensors and sensing techniques for monitoring part buildup, layer-by-layer, in LPBF processes. Purtonen et al. [17] applied optical sensors included photodiodes, spectrometers, Charged Coupled Device (CCD) and Complementary Metal Oxide Semiconductor (CMOS) imaging sensors, pyrometers, and infrared cameras to monitor the LPBF process.

Commonly used off-axis sensors are Digital Single Lens Reflex (DSLR) cameras. A DSLR camera can take images of the powder bed each time it is triggered. A combination of flashlights from different angles of illuminations can detect anomalies on each scanned layer [1]. Bartletta et al. [2] explored using a high-speed camera to record the laser-scanning process including melting, solidifying, and track formations. Foster et al. [6] used staring-video cameras and coaxial cameras to collect data for monitoring melt-pool characteristics with other types of sensors for data fusion to monitor the progress of melting and track formation.

2.2 Sensor Data Alignment

For the background, data alignment is part of the data registration process, as shown in Figure 1. Data registration is necessary to fuse different data correctly. Data alignment includes both temporal alignment and spatial alignment. Temporal alignment requires a synchronized clock, which usually is a prerequisite of spatial alignment. Spatial alignment is a process that converts sensor data from its original, local coordinate system to another coordinate system so that the data can be compared and fused with the data generated in the new coordinate system. AM data alignment as a research topic continues to expand. Nevertheless, the current limitations of that research are still impeding the use of advanced data analytics, which can accelerate the understanding and control of AM processes and improve decision-making across the AM part lifecycle. Specifically, data-correlation limitations include 1) a limited understanding of how to characterize the new types of sensor data and 2) there is no information to link the data correctly in space and time.

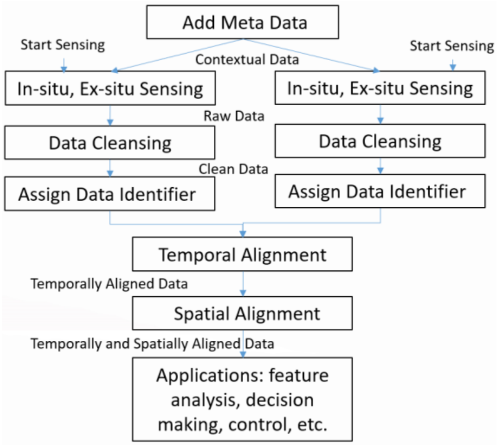

Figure 1 General Data Registration Procedure

2.3 State of Research in Sensor Data Alignment

Morgan et al. [13][14] used the direct-image-alignment approach, where no well-defined edges or corners in the build imagery can be used for alignment. This approach uses a filtered, built image and a synthetic image derived from the laser scan directions. These images are constructed so that they have high intensities where there is solidified materials and low intensities where there is unfused powder. The images must look as similar as possible so that they can be aligned by minimizing the differences. This requirement is almost impossible to be achieved due to measurement uncertainties associated with the sensor data.

Witherell [21] investigated data curation, fusion, and analytics techniques and showed an abstract data-alignment model for additive manufacturing. Bartlett et al. [2] correlated the measured surface temperature with layer-wise, scanned surface images to identify potential anomalies on the layer. The authors then correlated layer-wise measurements with the part measurements using ex-situ, scanning electron microscopy to validate the identified defects. Since the part used in the experiment is a regular shape, the data alignment is relatively simple.

Everton et al. [5] described specific sensors and sensing techniques for monitoring layer-by-layer builds in L-PBF processes. The purposes were to see 1) defects, such as pores, balling, unfused powder, and 2) cracks on a scanned surface with a correlation to the thermal images of that layer. Abdelrahman et al. [1] used a binary template created from the sliced 3D model of the part, as the reference geometry to do data alignment layer by layer. The aligned data then is used to create a 3D model to detect anomalies visually both before laser scanning and in the solidified material after laser scanning. Foster et al. [7] used angle illuminations to collect layer-wise images, which were then fused with pre-placed powder layers. Three-dimensional reconstruction of the images identifies potential flaws in the part.

Petrich et al. [16] used reference marks that were built into the part to align layer-by-layer images with an XCT model for defect location in the scanned part. Roehling et al. [18] modulated the heating and cooling profiles for visualizing the correlation between heating, cooling, and grain growth. Finally, Hirsch et al. [8] proposed a method to align 1) the design model, 2) the part slices, and 3) layer-by-layer images to create a 3D composite model for defect analysis.

2.4 Gaps and Research Needs

Clearly, there is an issue to properly relate a variety of sensors used for in-situ and ex-situ monitoring of LPBF AM processes. Those sensors provide a plethora of data, including gray-scale images and thermal data. While the data from individual sensors are important, correlations among those data can be extremely valuable. Sensor data must be aligned before the data can be applied for analysis to extract new knowledge. Data alignment is necessary to determine the state of the powder-fusion process, the material microstructure, and the fabricated part. For example, without correctly aligning measurements in the spatial domain, conflicting predictions can be made on the process performance and part quality. Lastly, there is no contextual information for data alignment. This is one of major barriers for part qualification and verification to ensure AM product quality

3. PROCEDURE FOR DATA ALIGNMENT

For in-situ monitoring, there are three sensor data types: photographic images, video clips, and time-series data. Photographic images include gray-scale images and thermographic images. Gray-scale images are commonly used to monitor melt pool shape, including its area and dimensions. Thermographic images are used to monitor temperature as well as energy intensity of a recently scanned layer. Video clips are used to monitor the dynamic behaviors in the scanning process, such as spattering and pluming. Time-series, acoustic data is collected from sonic sensors. Sonic sensor data is commonly used to monitor sparking or cracking during laser scanning.

For ex-situ monitoring, the following types of data are in the scope of this paper: XCT 3D model and points collected using CMM. CMM points should be properly associated with the corresponding features. An XCT 3D model can be used to identify pores and other defects. CMM points can be used to establish a datum reference frame and evaluate a feature's geometry again its tolerance specifications. These two types of data are commonly used in AM and are from nondestructive evaluations of additively manufactured parts.

Another type of data is scanning paths and speed, related to in-situ monitoring data. Scan paths are series of laser spot locations that are used to guide the laser to scan the powder layer. Lastly, chamber monitoring data, such as environmental temperature, gas pressure, and CO_2 levels. Note that chamber monitoring data is out of the scope of this work.

The above-mentioned data types are related, but in different coordinate systems. Examples of different coordinate systems include 1) the CAD-modeling coordinate system, 2) an in-situ sensor coordinate system, 3) a laser coordinate system, and 4) a staring camera coordinate system. Developing a procedure to geometrically align related data types and tie them all to a common coordinate system is the main purpose of our research work. The basis of our proposed, geometric, data-alignment procedure is coordinate transformation. The same point in the space is transferred from one coordinate system to another one. In this paper, the local coordinate system is referred as the "from" coordinate system, and the new coordinate system to which the point is transferred is referred as the "to" coordinate system. For example, a melt-pool image, which is collected by a coaxial camera, can be transformed from the camera coordinate system to the laser-scanning path coordinate system.

Scanning paths can be further related to the layer images taken by a staring camera. Layer images can be related to the 3D model generated by XCT. XCT 3D model can be related to the CMM model generated by the measured points (a point cloud). The CMM model can be related to the geometric model generated by a CAD system. In that sequence of relationships, melt pool images, scan paths, layer images, XCT model, CMM model, and CAD model can be sequentially related in data alignment.

In summary, the procedure includes the following steps:

(1) Group all the related data sets for data alignment. Specifically, two related data sets must have a common reference point and known difference in orientations, see Section 4 for examples.
(2) Identify every two related data sets and pair them for coordinate transformation. Also, identify the "from" coordinate systems and the "to" coordinate system in every pair.
(3) Sequence (chain) all the pairs according to spatial and/or temporal relations. For examples of spatial relations, see Section 4.
(4) Perform coordinate transformations so that all the data sets are in one single coordinate system.
(5) The chained data sets can be assigned an identifier (ID) for indexing and searching. The chained data sets can be used, such as data analysis.

4. EXAMPLES OF DATA ALIGNMENT

This section provides some data alignment examples. The sequence of align related data sets are as follows: (1) align melt-pool images to scan path, (2) align scan paths to the layer image, (3) align layer images to the XCT 3-D model, (4) align the XCT 3-D model to the CMM model, and (5) align the CMM model to the CAD model. After alignment, melt pool images, scanning paths, layer images, the XCT 3-D model, the CMM model, and the CAD model are all in the same coordinate system. This coordinate system will be the CAD coordinate system.

4.1 Melt pool image to scan path alignment

Melt pool is generated by laser melting. As shown in Figure 2, the center of the laser spot is used as the reference point in the alignment. The point in the coaxial camera coordinate system can be estimated using the shape of the melt pool shown in the image. The center of the laser spot on the scan path is in the scanning laser coordinate system. There are at least three ways to describe a scan path: (1) the command position in the XY2-100 or G-code file [10] (Note that the command position and the true laser spot center are different), (2) the intercepted encoder position of the two galvanometers [4], and (3) using an interpretation method to predict the true laser position based on the scanning speed, laser on/off timing, and camera-triggered times. When the time that the melt pool image is taken by the camera, the true laser spot moves away from the original position. If the off-distance is very small, then it is negligible.

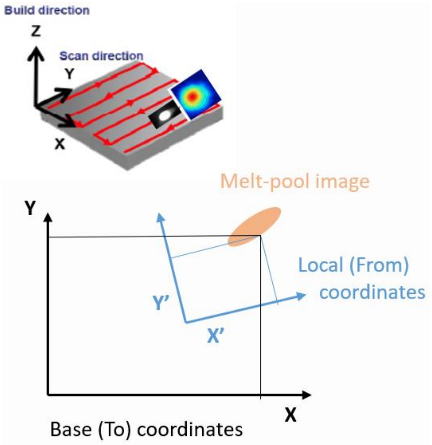

Figure 2 Melt pool images to scan path alignment

The relative orientation between the image ("from") and the layer ("To") can be computed using an appropriate image-calibration method. An image-calibration artifact with black and white grids may be used to measure the relative orientation difference between the orientation in the coaxial camera coordinate system and the orientation in the laser scanning coordinate system. The relations between the laser spot center and orientations in both coaxial camera and scanning laser coordinate systems are thus obtained for coordinate transformation. At this point, the melt-pool image is transformed to the scan path (layer) coordinate system.

4.2 Scan paths to layer image alignment

Scan paths should be aligned with the image of the layer that laser scanned. Scan paths are generated with the laser

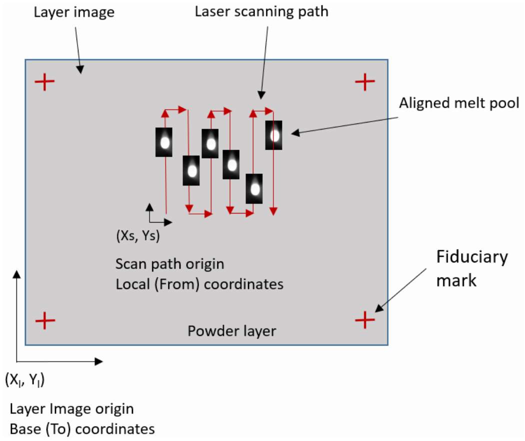

Figure 3 Scan path to layer image alignment

scanning coordinate system. Since it is not always possible to identify features on the scanned layer, fiduciary marks must be created. A fiduciary mark is created on the layer but outside the designed part during or after the laser scanning process. Four fiduciary marks can be used, minimally three. These four marks are the same artifacts in both scanning paths and the layer image. Figure 3 show an example of four fiduciary marks relative to the scan paths. With this aligning, coordinate transformation becomes possible. The "from" coordinate system is the laser scanning coordinate system. The "to" coordinate system is the layer image coordinate system. After the coordinate transformation, melt pool images, scan paths, and the layer image are all in the same coordinate system. Since there are multiple layers in an additively manufactured part, the fiduciary marks can also be used to align layers, from Layer 1 (the bottom layer) to the last Layer (the top layer), as shown in Figure 4.

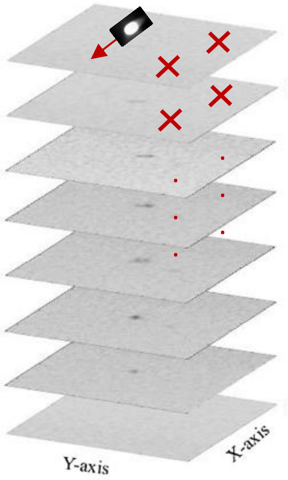

Figure 4 Layer images alignment

4.3 Layer images to the XCT model alignment

Aligned layer images should be aligned with the XCT 3-D model of the additively manufactured part. The purpose is to relate defects found in the XCT 3-D model to the defects found in the scanned layers to identify possible causes for those defects. There are some means for alignment: (1) create or specify reference datum features (e.g., plane, point, or line) in the part for alignment, (2) create fiduciary marks on last layer of the workpiece as the reference positions and align the fiduciary marks on the last layer image with the fiduciary marks shown in the XCT 3-D Model (note: the fiduciary marks has to be on the part, not outside the part so that XCT can detect them.), and (3) use mathematical algorithms to best fit layer images to the XCT 3-D model. The first method is based on geometric dimensioning and tolerancing standards, such as ANSI Y14.5. Figure 5 shows the fiduciary marks must be on the top of the part. The bottom few layers are not part of the part and are separated from the part when it is removed from the built plate.

4.4 XCT 3-D model to CMM model alignment

The XCT 3-D model should be aligned with the CMM model of the AM part. The purpose is to relate the part geometry found in the XCT model to the part geometry found in the CMM model to measure functional features, such as internal holes and thin walls, to verify if they are within the tolerances to ensure the manufactured part meets the functional requirements. The steps in the procedure includes (1) define a datum reference frame on the part for establishing a coordinate system, as defined in ANSI/ASME Y14.5, (2) align the XCT 3-D Model with the CMM model using the datum reference frame. Note that (1) a datum reference frame consists of primary, secondary, and tertiary reference planes (or equivalent geometries), (2) if datum

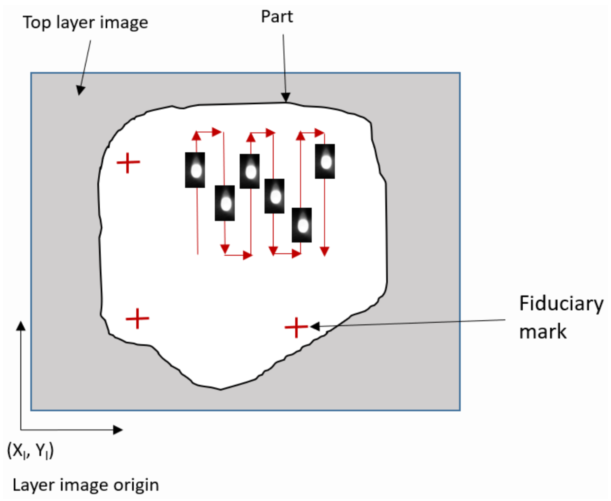

Figure 5 Layer image to XCT 3-D model alignment

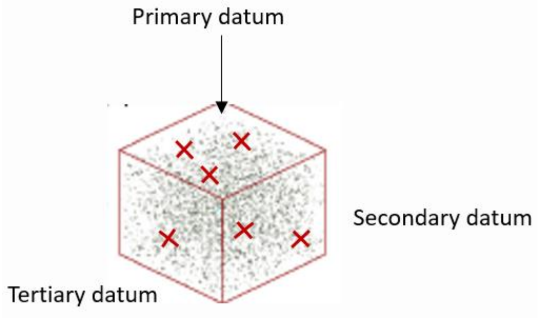

Figure 6 XCT 3-D model to CMM model alignment

reference frame is not possible to define, then other methods, such as fitting with point cloud, can be used for the alignment, and (3) CMM can be substituted with other dimensional measurement methods, such as laser scanners. Figure 6 shows an example of primary, secondary, and tertiary datums to form a datum reference frame, as specified in ANSI/ASME Y14.5.

4.5 The CMM model to the CAD model alignment

The CMM model should be aligned with the CAD model of the AM part. The purpose is to relate the part geometry found in the CMM model to the part geometry found in the CAD model to verify whether features with the specified tolerances, such as cylindricity of an internal hole, to verify if the features meet the tolerance requirements. The step in the procedure is to use the defined datum reference frame align the CMM model with the CAD model of the part for establishing a coordinate system, as defined in ANSI Y14.5. Figure 7 shows the use of primary, secondary, and tertiary datums to align CMM model to the CAD model. CMM model coordinate systems is the “from” coordinate system and the CAD coordinate system is the “to” coordinate system. With the alignment, the dimensions and tolerances of all the feature can be evaluated.

5. DISCUSSIONS

The primary challenge for AM is to control the fabrication process well enough to provide the reliability and repeatability necessary for commercial applications. For example, control is not a standalone process; control is connected to design/engineering processes upstream and inspection/qualification processes downstream. The key to the execution of all these AM processes is sensor data.

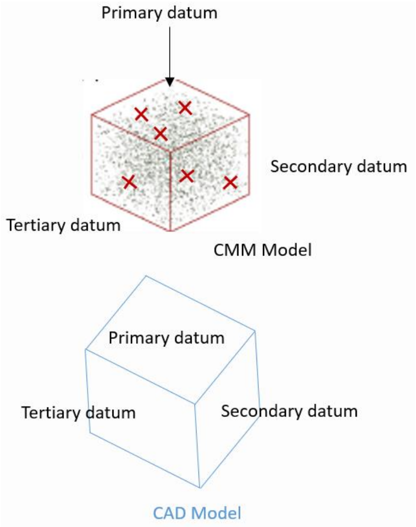

Figure 7 CMM model to CAD model alignment

In pursuit of overcoming the challenges, methods and standards of data gathering, registration, and fusion are the critical needs [15]. First, data should be collected and curated with rich meta information, e.g., sensor meta data, installation information, and configuration information. Additionally, best practices should be developed to calibrate the measurement apparatus and document the results appropriately. In addition, the data captured should be structured and represented to support interoperability among various computer information systems owned by various stakeholders, including material suppliers, machine manufacturers, measurement devices providers as well as testing labs. Both lexicon and semantic standards are required to enable seamless integrations of data generated from AM lifecycle and value chain activities. With established common data dictionary and common data exchange format, data collected during AM processes can be aligned and fused for better process monitoring and process control. In addition, data of thousands of builds conducted distributed can be aggregated into a common data virtual repository in the form of a federated data repository which will be available for the AM community to conduct advance data analytics including data alignment and data fusion and adaptive learning to accelerate AM part development lifecycle. This research establishes a good foundation on identification of the information for data fusion and provides a initial guidance on how to align the data. The remaining challenges include 1) data alignment for unsynchronized data, 2) data alignment uncertainty qualification, and 3) geometric feature alignment.

The data alignment procedure proposed in this paper is still a conceptual exploration. Real cases of additively manufacturing part using LPBF with in-situ and ex-situ measurements using appropriate sensors should take place to validate the procedure. Furthermore, defect-detection and cause analyses should also be done using the aligned data sets.

6. CONCLUSIONS

The use of laser powder bed fusion, LPBF, additive manufacturing technology to fabricate complex, metal parts in aerospace and medical industries has been increasing steadily. As a result, the demands on the quality and reliability of those parts has also increased. To respond to these demands, researchers have started to implement in-situ sensors and ex-situ measurement machines to monitor LPBF processes and to detect potential anomalies in the part. Types of in-situ data include melt-pool images, movies, and acoustic signals. Types of ex-situ data include XCT 3-D models and CMM data clouds. Correlation among related datasets are critical to detect anomalies and the causes. Correlated data set can also be used to verify the quality of AM parts. Since data alignment means all data is transformed into a single coordinate system, to compute the correlation is then possible for data analytics.

The proposed data alignment procedure in this paper addresses the long standard issue of how to align images taken by a coaxial camera, laser scanning commands, and a staring camera that are related to in-situ monitoring. The proposed procedure also addresses the need of aligning in-situ monitoring data with ex-situ monitoring data from XCT, coordinate measurement, and the design model. Examples in the paper show how to relate in-situ and ex-situ data into a suite of correlated datasets that can be used for downstream applications, such as defect analysis, feature analysis, and decision making.

Future work will be in two areas. One is to provide more examples of aligning time series data, such as acoustic signals, with geometric data. Second is to develop data registration procedure to include sensor meta-data with the sensor data for AM data analytics. The procedure will lead to standardization. We expect that these standards will lead to better implementations in the L-PBF user community. Furthermore, a case study that includes design, build, measurement, test should show that data alignment can enable defect detection in AM parts.

DISCLAIMER AND ACKNOWLEDGEMENT

Certain commercial equipment, instruments, or materials identified in this paper are not intended to imply recommendation or endorsement by the National Institute of Standards and Technology, nor is it intended to imply that the materials or equipment identified are necessarily the best available for the purpose.

We also feel thankful for the support and the insightful discussions provided by Dr. Paul Witherell and Dr. Vijay Srinivasan at NIST.

***Abstract*—We demonstrate the applicability of the reverberation chamber for over-the-air testing of power-based metrics for cellular-enabled wireless internet-of-things devices. A recent industry-sponsored round robin illustrates agreement between labs to within the industry specified limits of ± 2 dB for radiated power and ± 2.3 dB for receiver sensitivity.**

***Index Terms* — cellular device testing; internet of things; over-the-air measurement; wireless system.**

I. Introduction

Over-the-air (OTA) testing is an important facet in the design and performance verification of wireless devices with integrated antennas [1]. We illustrate the applicability of the reverberation chamber for OTA testing with results from an international round robin focused on large-form-factor cellular-enabled internet-of-things wireless devices. Organized by the cellular industry association CTIA Certification™, the round robin concluded in January 2020 with measured data from six laboratories: United States (3), Europe (2), and Asia (1).

The round robin compared measurements performed in eight different reverberation chambers and three anechoic chambers of Total Radiated Power (TRP) and Total Isotropic Sensitivity (TIS). Tests of these "power-based" metrics are required for cellular industry certification. Measurements were carried out according to newly standardized procedures outlined in [2].

Two cellular devices were tested in four cellular bands with center frequencies ranging from 710 MHz to 2132 MHz and two radio-access technologies (Wideband-Code-Division Multiple Access W-CDMA, and Long-Term Evolution, LTE).

Results show agreement between measurements to within CTIA Certification's specified limits of ± 2 dB for TRP and ± 2.3 dB for TIS. Agreement was observed for all bands and radio-access technologies from physically diverse reverberation chambers. Agreement was also observed with the anechoic chambers. Such agreement between labs allows the CTIA Certification to move forward with authorization of OTA test laboratories who desire to utilize reverberation chambers.

II. OTA Testing of Cellular Wireless Devices

OTA testing in anechoic chambers has been standardized for many years [3]. In these tests, a three-dimensional characterization of the DUT's radiated performance is pieced together by analyzing data from spatially distributed measurements on a virtual sphere surrounding the device under test (DUT). Samples are spaced equidistantly along the theta (θ) and phi (ϕ) axes (15° for TRP, 30° for TIS) for each of two orthogonal polarizations [3].

To correct for test system effects such as chamber path loss, gain of the measurement antenna, cable losses, and so forth, a reference measurement is performed. A reference antenna is mounted at the center of the anechoic chamber as a substitute for the DUT. A vector-network-analyzer (VNA)-based reference measurement is performed for each possible signal path to the measurement equipment. When combined with the gain of the reference antenna, this measurement relates the measured quantity to that from an isotropic radiator.

During OTA testing, a base-station emulator (BSE) controls the DUT. Connected to a measurement antenna located within the chamber, the BSE, requests that the DUT transmit at full power. For LTE systems, resource-block allocations are specified. For the tests in this study, the transmitter and receiver operate at different frequencies within the selected band. In addition to control, the BSE may also measure the power received from the DUT (for TRP measurements) or the DUT's reported error rate for base-station power levels that are incrementally reduced until a target error rate is observed (for TIS). When averaged in post processing, the data provide an estimate of the metric of interest.

A reverberation chamber may be used instead of an anechoic chamber for isotropic OTA tests. The reverberation chamber is an electrically large, reflective cavity that supports many modes. The fields corresponding to these modes add constructively and destructively at the receive antenna. The received power can vary significantly as a function of frequency and location of the receive antenna within the chamber. To perform a measurement, the modes are intentionally randomized by altering the metallic boundary conditions within the chamber or by probing the fields at different locations and/or polarizations within the chamber. The former is often accomplished by use of a mechanical mode-stirrer such as a rotating paddle, while the latter by use of a rotating platform or the use of multiple measurement antennas having different physical locations and polarizations.

(a)

(b)

Fig. 1: Typical measurement set-up in a reverberation chamber for (a) characterizing the chamber's power transfer function and (b) measuring a DUT's ("EUT") total radiated power and total isotropic sensitivity. RF absorber ("RF abs") has been included to broaden the chamber's coherence bandwidth (from [2], used with permission).

For OTA tests of cellular devices in reverberation chambers, the power (for TRP) or error rate (for TIS) is sampled under a number of static, ideally uncorrelated "mode-stirring states." Statistical analysis is performed to determine whether a sufficient number of mode-stirring states have been obtained to provide an estimate of the quantity of interest to within a desired level of uncertainty.

When it is necessary to demodulate a received signal in order to estimate the error rate, as for TIS, "loading" of the chamber with RF absorber is typically required to flatten the frequency response of the chamber. This creates an RF environment in which the equalizers of the DUT were designed to operate, allowing the device to be tested without the chamber environment itself introducing errors into the measurement. A metric to evaluate the flatness of the channel response is the coherence bandwidth (CBW) [4], which, in [2], is increased through loading with RF absorber until it exceeds the channel bandwidth of the signal being measured.

In [2], identification of the proper loading and its impact on uncertainty due to the reduced spatial uniformity of the average power measured within the chamber is carried out in a precharacterization step. This is discussed further in the next section. Other precharacterization steps in [2] ensure that the antenna placement is free from significant coupling to the RF absorber and that the frequency step used to assess the chamber set-up is adequate. As shown in Section III, the agreement between participating labs in the round robin indicates that the development and standardization of the precharacterization steps within the CTIA Certification Program Wireless-Internet-of-Things Subgroup's Reverberation Chamber Ad Hoc Group, are sufficiently rigorous and general to allow diverse reverberation chambers to be used in device assessment.

As with the anechoic-chamber method, a reference measurement is made to calibrate out system effects. The reference measurement provides an estimate of the "power transfer function" G_{ref} of the chamber set-up. A typical configuration for the measurement of G_{ref} is illustrated in Fig. 1(a). A reference antenna, whose radiation pattern characteristics are similar to those of the DUT [5], is used. The power transfer function is then estimated from VNA measurements averaged over a mode-stirring sequence as

$$G_{\text{ref},t} = \frac{\frac{1}{NF}\sum_{n=1}^{N}\sum_{f=1}^{F}|s_{21}(f,n)|^2}{\Gamma_{\text{meas}}\Gamma_{\text{ref}}\eta_{\text{meas}}\eta_{\text{ref}}}, \qquad (1)$$

where the averages are taken over N mode-stirring samples and F frequencies across the channel bandwidth to be tested. The variables Γ_x and η_x refer to the mismatch and radiation efficiency of antenna x, where x corresponds to the measurement or reference antenna. For this precharacterization step, measurements are averaged over T_{pre} = 12 "independent realizations" of the mode-stirring sequence, in which the same number of stirring-sequence samples is used (for example, 20 paddle steps and 10 turntable positions), but each measurement is spatially uncorrelated with those from the other 11 independent realizations. Correlation is checked by use of a cross-correlation method. The use of 12 spatially-uncorrelated calibration samples allows the user to estimate the uncertainty due to lack of spatial uniformity for a given chamber set-up and mode-stirring sequence. More details on this and the other precharacterization steps may be found in [2].

When DUT measurements are performed, a single reference measurement is made with the DUT in the chamber to account for a potential increase in the chamber loss due to the device. The DUT measurements are then conducted by replacing the VNA with a base station emulator, as shown in Fig. 1(b). The DUT is measured over the same mode-stirring sequence as was used in the precharacterization process, but typically for one independent realization only. The TRP is then computed as

$$P_{\text{TRP}} = \frac{1}{N}\frac{\sum_{n=1}^{N}P_{\text{meas}}(n)}{G_{\text{ref}}\Gamma_{\text{meas}}\eta_{\text{meas}}G_{\text{cable}}}, \qquad (2)$$

where G_{cable} refers to the VNA-measured loss (written here as a negative gain) associated with the cable between the base station emulator and the measurement antenna reference plane, as shown in Fig. 1(b). The TIS is found as

$$P_{\text{TIS}} = G_{\text{ref}}\Gamma_{\text{meas}}\eta_{\text{meas}}G_{\text{cable}}\left(\frac{1}{N}\sum_{n=1}^{N}\frac{1}{P_{\text{BSE}}(n)}\right)^{-1}, \qquad (3)$$

where the device's TIS is assessed at a base station emulator power P_{BSE} that induces a specified error rate, as defined in [3]. The round-robin tests discussed below incorporate the procedures outlined above.

III. The Round Robin Tests

A. Overview

Tests were conducted between June 2017 and May 2019. Two devices were tested by each lab: a smart phone supporting single-input, multiple-output (SIMO) operation, and a simulated large-form-factor IoT device consisting of the smart phone mounted on a lossy, large-form-factor polymer shipping case filled with RF absorber. Large, lossy DUTs are the most challenging for reverberation-chamber measurements as they increase the lack of spatial uniformity beyond that of the chamber loading. A representative set-up is shown in Fig. 2.

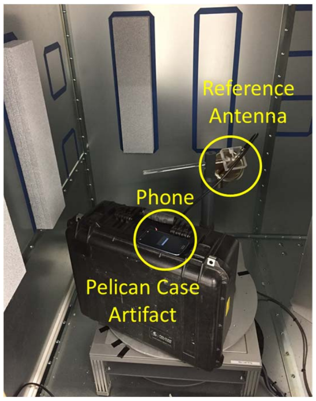

Fig. 2: The test artifact on a rotating turntable in a reverberation chamber. RF absorber (light gray) is magnetically mounted to the walls to broaden the coherence bandwidth. Display of product name does not imply endorsement by NIST. Other products may work as well or better.

The devices were measured in four licensed bands and two radio-access technologies, as specified in Table I. Per [3], TRP in Band 4 was measured over 12 resource blocks (RBs), while TIS was measured over both 50 and 100 RBs, with the latter under consideration for future versions of the CTIA test plan [3]. Labs conducted the entire set of measurements three days in a row. The smart-phone device exhibited unstable behavior in Band 17, which caused a delay until August 2017 when a second device was identified for use in that band.

Three of the eight reverberation chambers used in the round robin were deemed "small chambers," having precharacterized working volume dimensions less than 3 m on a side, while the other five were considered "large chambers." Testing was also carried out in three anechoic chambers although, as stated in Section II, a test methodology utilizing anechoic chambers for large-form-factor device tests is currently undefined in the CTIA Certification test plan. The lossy artifact with a single radiator in a known location presented little challenge for the anechoic chambers.

Table I: OTA tests conducted as part of the CTIA Certification round robin.

Band	Test	Mode	Channel	Frequency (MHz)	Bandwidth (MHz)
17	TRP	LTE	23790	710	2.4
17	TIS	LTE	5800	741	10
5	TRP	W-CDMA	4132	826.4	4
5	TIS	W-CDMA	4357	871.4	4
2	TRP	W-CDMA	9262	1852.4	4
2	TIS	W-CDMA	9662	1932.4	4
4	TRP	LTE	20175	1732.5	2.4
4	TIS	LTE	2175	2132.5	10
4	TIS	LTE	2175	2132.5	20

B. Precharacterization Results

Agreement between labs in this study is better than an initial round robin conducted by the same organization in the 2015-2016 timeframe. This is due to the extensive, newly finalized chamber precharacterization that is specified in the test plan [2]. The ability of each lab to meet the precharacterization specifications was checked.

As mentioned in Section II, the lack of spatial uniformity due to loading of the chamber can have a significant impact on the uncertainty in the measurement. In the test plan, this effect is quantified by taking the standard deviation of the T_{pre} = 12 reference power transfer function measurements from (1) as

$$\sigma_{G_{\mathrm{ref}}} = \sqrt{\frac{1}{T_{\mathrm{pre}}-1}\sum_{t=1}^{T_{\mathrm{pre}}}\left(G_{\mathrm{ref},t} - G_{\mathrm{ref}}\right)^2}. \quad (4)$$

Assuming a Gaussian distribution by the Central Limit Theorem, the standard uncertainty for the reference and DUT measurements is then calculated as

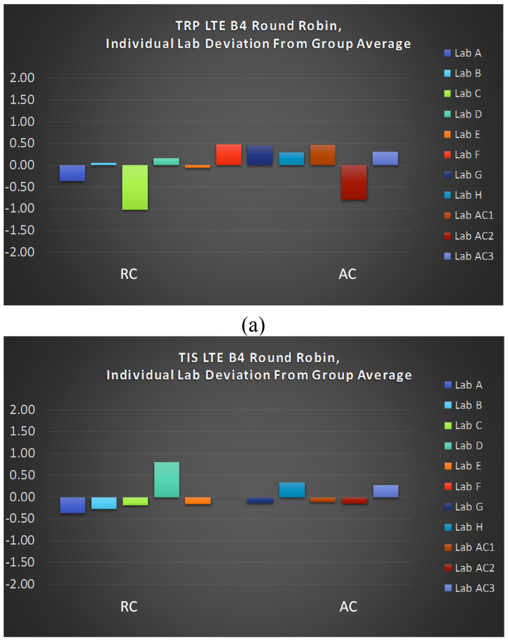
$$u_{G_{\mathrm{ref}}} = \frac{\sigma_{G_{\mathrm{ref}}}}{\sqrt{T_{\mathrm{cal}}}}, \quad (5)$$

where T_{cal} is the number of independent realizations of the reference power transfer function measured during the DUT measurement. Note that T_{cal} is often equal to one.

Laboratories generally need to keep the value of $\sigma_{G_{\mathrm{ref}}}$ as small as possible in order to meet the CTIA Certification combined uncertainty requirements of ± 2 dB for TRP and ± 2.3 dB for TIS. Minimizing this reverberation-chamber-specific component may generally be accomplished with the use of additional position and polarization stirring. While combined measurement uncertainty is not reported here, values of $\sigma_{G_{\mathrm{ref}}}$ ranged from 0.2 dB to 1.0 dB with typical values on the order of 0.5 dB to 0.6 dB.

C. DUT Results

CTIA Certification requires that the mean-normalized difference between labs falls below the uncertainty threshold in [3]. We first present results for the round-robin measurements of TRP and TIS from both the cellular smart phone alone in the chamber (Fig. 3) and the simulated large-form-factor IoT test artifact (Fig. 4). Results from Band 4 had the largest variation of any that was tested and, thus represent the worst case. In each



(a)

(b)

Fig. 3: Results for Band 4 LTE for the smart phone only: (a) TRP; (b) TIS. The highest standard deviation of any lab for three repeat measurements was 0.4 dB.

figure, the top graph shows TRP with f_c = 1.7313 GHz and a bandwidth of 2.4 MHz, while the bottom graphs show TIS with f_c = 2.1375 GHz and a bandwidth of 10 MHz. The three anechoic-chamber results are included at the right of each plot.

In each graph, the mean value (in decibels) of the respective chamber type (reverberation chamber or anechoic chamber) has been subtracted from the results. When the mean of both chamber types (anechoic-plus-reverberation chamber) is subtracted, results are typically within 0.2 dB of the reverberation-chamber-only mean, and always within 0.5 dB, indicating close agreement between chamber types.

For the smart-phone-only results in Fig. 3, no lab exceeds a 1.0 dB difference from another, and differences are typically less than 0.5 dB. This is because the DUT is small and does not significantly perturb the fields within the chamber. The results with the artifact in Fig. 4 exhibit a greater variation, with a maximum difference of 1.9 dB (the greatest difference in any band for the round robin), but differences are typically less than 1.0 dB. Some labs reported reduced repeatability for this DUT in Band 4, with Lab F unable to complete the TIS measurement possibly due to heating during prolonged testing.

IV. Conclusion

Round-robin agreement to within the CTIA Certification-specified limits between labs indicates that the newly standardized reverberation-chamber precharacterization and device measurement procedures are adequate to allow use of reverberation chambers for OTA testing of IoT devices incorporating the radio access technologies noted here.

INVESTIGATING COUPLED EFFECT OF RADIATIVE HEAT FLUX AND FIREBRAND SHOWERS ON IGNITION OF FUEL BEDS – STRUCTURE vs VEGETATIVE FIREBRANDS-

Sayaka Suzuki[1] and Samuel L. Manzello[2]
[1]National Research Institute of Fire and Disaster, Japan
[2]National Institute of Standards and Technology, USA

1. INTRODUCTION

Large outdoor fires pose problems for societies across the world. Perhaps the most often in the news are wildland fires that approach urban areas. These are more simply referred to as Wildland-Urban Interface (WUI) fires. In Asia and North America, some recent examples are the 2019 WUI fires that occurred in South Korea and those in 2018 in Northern California in the United States. In African countries, there have been large fires that have occurred in informal settlements. For centuries there have also been large urban fires in Japan, a country with no large wildland fire problem or informal settlement situation [**1**].

In all of these large outdoor fires, firebrands are produced and lead to enhanced fire spread processes. Often referred to as spotting processes, firebrands are liberated from the combustion of various fuel types and then induce ignition of fuel sources away from the initial fire source. A potentially important aspect of the physics of ignition induced by firebrands is the coupled influence of firebrand showers and radiant heat from burning houses. To this end, a new experimental protocol was developed to study the coupled effect of radiation and firebrand showers on ignition processes of fuel beds [**2**]. Experiments were performed under an applied wind field, as the wind is a key parameter in large outdoor fire spread processes.

In this study, the type of firebrands was changed to study the effect of firebrand differences.

2. EXPERIMENTS

Details of experimental protocols are described in [**2**] hence only a short description is provided. To generate firebrand showers, the reduced-scale continuous-feed firebrand generator was used and installed inside NRIFD's wind facility. The device consisted of two parts: the main body and continuous feeding component.

A conveyer was used to feed wood chips continuously into the device. The conveyer belt was operated at 1.0 cm/s, and wood chips were put on the conveyer belt at 12.5 cm intervals. For all tests, Japanese Cypress wood chips were used to produce firebrands compared to Douglas-fir wood pieces used in [**2**]. These same size wood pieces have been shown to produce firebrands similar to the projected area/mass of firebrands produced by burning structures [**3**]. Here we call firebrands from Japanese Cypress wood chips structure firebrands, and firebrands from Douglas-fir wood pieces vegetative firebrands. The wood feed rate used here was 80 g/min, which is near the upper limit for this reduced-scale firebrand generator.

The blower was set to provide an average velocity below 4.0 m/s measured at the exit of the firebrand generator when no wood pieces were loaded. Above 4.0 m/s, smoke production was mitigated, but then many firebrands produced were in a state of flaming combustion as opposed to glowing combustion. In these experiments, glowing firebrands were desired.

The fuel beds used for ignition were 300 mm by 300 mm in size and consisted of Douglas-fir wood pieces with the dimensions of 7.9 mm x 7.9 mm x 12.5 mm. These were installed inside a mock-up corner assembly lined with calcium silicate board since the ignition of the corner assembly itself was not the goal here; only ignition induced in the wood pieces was of interest.

To provide uniform radiant heat flux to fuel beds, an electrically operated quartz radiant panel was used. Dimensions of the radiant panel were also 300 mm by 300 mm (**Fig. 1**). It was mounted at a height of 440 mm from the fuel bed surface. A custom calibration rig was designed and fabricated to quantify the radiant heat flux that the radiant panel provided at the fuel bed surface. The radiant heat flux at the fuel bed surface was 8.5 kW/m^2 with no wind. Pre-heating time was determined as the duration from the time when the radiant panel was turned on to the time to start the firebrand generator. Selected pre-heating time was 10 min. Baseline experiments were also performed to examine the ignitions by firebrands without applied radiant heat flux. The wind speed in this study was 6 m/s.

Manzello, Samuel; Suzuki, Sayaka. "Investigating Coupled Effect of Radiative Heat Flux and Firebrand Showers on Ignition of Fuel Beds - Structure vs Vegetative Firebrands." Paper presented at Japan Association for Fire Science and Engineering, Hirosaki, JP. May 28, 2020 - May 29, 2020.

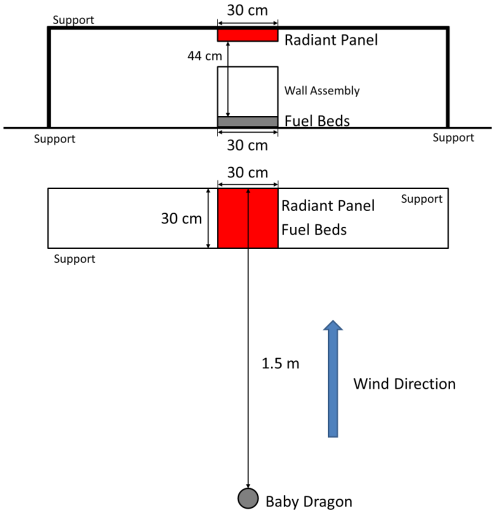

Figure 1 Schematic of the experimental settings. Front view (top) and Top view (bottom) are shown. Firebrand showers were produced using the reduced-scale firebrand generator installed in NIRFD's wind facility. Fuel beds consisted of Douglas-fir pieces of uniform size.

3. RESULTS AND DISCUSSION

Figure 2 shows the time to ignition (smoldering ignition, SI, and flaming ignition, FI) by structure firebrands compared with those by vegetative firebrands. For both type of firebrands, it required less time to ignite a fuel bed when radiate heat assistance was provided. Shorter times were needed to ignite a fuel bed by structure firebrands than by vegetative firebrands, regardless of external radiation. This is due to the fact that the contact area with a fuel bed is larger for structure firebrands than for vegetative firebrands. With 10 min pre-heating by radiative heat assistance, the time to ignition for both SI and FI reduced by 80 % for structure firebrands, while for vegetative firebrands, reduction was 65 % and 97 % for SI and FI respectively.

Figure 3 shows the mass required for ignition (unit area). The arrival firebrand mass flux of structure firebrands was 0.36 g/m^2 s and those of vegetative firebrand was 0.32 g/m^2 s, under 6 m/s wind condition. With firebrand mass flux considered, **Fig. 3** displays little difference from **Fig. 2**.

4. CONCLUSIONS

The coupled effect of radiative heat flux and firebrand showers on ignition processes of fuel beds was studied, focusing on the difference of firebrands. Structure firebrands ignited a fuel bed quicker than vegetative firebrands, regardless of radiative heat assistance. With 10 min pre-heating, the time to ignition for both SI and FI decreased dramatically for both structure and vegetative firebrands.

ABSTRACT

In this paper we propose a new evaluation challenge and direction in the area of High-level Video Understanding. The challenge we are proposing is designed to test automatic video analysis and understanding, and how accurately systems can comprehend a movie in terms of actors, entities, events and their relationship to each other. A pilot High-Level Video Understanding (HLVU) dataset of open source movies were collected for human assessors to build a knowledge graph representing each of them. A set of queries will be derived from the knowledge graph to test systems on retrieving relationships among actors, as well as reasoning and retrieving non-visual concepts. The objective is to benchmark if a computer system can "understand" non-explicit but obvious relationships the same way humans do when they watch the same movies. This is long-standing problem that is being addressed in the text domain and this project moves similar research to the video domain. Work of this nature is foundational to future video analytics and video understanding technologies. This work can be of interest to streaming services and broadcasters hoping to provide more intuitive ways for their customers to interact with and consume video content.

1 INTRODUCTION

Video understanding is a very difficult problem to solve. All current video analysis technology relies on detection, recognition and analysis of certain specific visual concepts such as people, objects, actions, activities or events. All these visual concepts recognition are usually done in isolation from the context of the video and only focusing on visual clues. This is one of the reasons why the current state of the art is lacking high level video understanding capabilities that connect the entities of a video with different events or relations. For example, given a two hour movie the current computer vision systems are not able to understand the relationship between different characters and develop a deep understanding of the video context. There has been efforts to encourage research in high level video understanding such as the "MovieQA" and "The Large Scale Movie Description Challenge" [9]. However these tasks revolve around isolated visual concepts retrieval and not about testing systems for their overall understanding of entities, relations and events within the video/movie. Early visions of this kind of work [7] proposed to use visual and audio descriptors, in addition to employing semantic analysis and linking with external knowledge sources in order to populate a knowledge graph.

The goal of our proposed research is to design and build datasets and evaluation benchmarks to foster the interest of the research community to develop systems which can extract available information from a video (e.g. a movie characters, their story lines, and relationships), and to use this information to reason about other, more hidden background information, and eventually to populate a knowledge graph with all extracted and reasoned information. In the next section we present an overview to related work in this area followed by more technical details discussing a pilot dataset collection of open source movies, the human annotation framework, query design and preprocessing, and our proposed evaluation roadmap and future directions. This is an ambitious new area of research which is to be run initially as a Grand Challenge at ACM Multimedia 2020 and as a workshop at ACM ICMI 2020 respectively. TRECVID workshop participants will be invited to participate in this new task.

2 RELATED WORK

Integrating vision and language research has recently gained a lot of attention to promote image and video understanding. Most

Curtis, Keith; Awad, George; Rajput, Shahzad; Soboroff, Ian. "HLVU: A new challenge to test deep understanding of movies the way humans do." Paper presented at ACM International Conference on Multimedia Retrieval (ICMR), Dublin, IE. June 08, 2020 - June 11, 2020.

approaches adopt the question answering paradigm as their evaluation framework. For example in [2] the authors propose the task of visual question answering for images. They provide a dataset containing 0.25M images, 0.76M question and 10M answers. However, most question types target very specific visual facets in the image such as what, where, number of objects, and what is the attributes or relation of an object to others.

MovieQA [11] is a dataset which aims to evaluate automatic story comprehension from video and text. It consists of 14,944 multiple choice questions, each with 5 multiple-choice answers, only one of which is correct, from about 408 movies with high semantic diversity. The movies have been segmented into video clips of maximum 200s durations where participants have to answer a question related to this video clip. The dataset itself comes with multiple answering sources for the questions such as plot synopses, scripts, subtitles, and audio descriptions. Annotators essentially used the plot synopses to come up with the set of questions and answers instead of watching the whole movie.

Following from this, [8] explored the biases in the MovieQA dataset and found that by using an appropriately trained word embedding, about half of the Question-Answers can be answered by looking at the questions and answers alone, completely ignoring the narrative context from video clips, subtitles, and movie scripts.

A large-scale dataset of corresponding movie trailers, plots, posters, and metadata was developed by [5] who study the effectiveness of visual, audio, text, and metadata-based features for predicting high-level information about movies such as their genre or estimated budget.

The large-scale movie description challenge [9] was first held as a workshop at the International Conference on Computer Vision (ICCV) 2015. This was held as a unified challenge on Text generation using single video clip, and Text generation using single video clip as well as its surrounding context. This challenge was later also held at ICCV 2017. It was held as two challenges: The large scale movie description and understanding challenge [LSMDC] and [MovieQA]. The LSMDC task included Movie description, Movie annotation and retrieval, and Movie fill-in-the-blank task. The MovieQA task included Question-answering in movies and video retrieval based on plot synopses sentences. A follow-up challenge was also held at ICCV 2019.

Early visions of the proposed work [7] explored the usage of visual and audio descriptors, in addition to employing semantic analysis and linking with external knowledge sources in order to populate a knowledge graph. Under this approach, time-stamped multi-modal signals of the video would be uplifted into a format that could be utilised by the applications semantic model and the resulting knowledge graph could be searchable in a newly meaningful way.

ActivityNet [4] is a large scale video benchmark for human activity understanding. ActivityNet provides samples from 203 activity classes with an average of 137 untrimmed videos per class and 1.41 activity instances per video, for a total of 849 video hours. All ActivityNet videos are obtained from online video sharing websites. Amazon Mechanical Turk (AMT) workers are used to determine if videos contain the intended activity class. AMT workers also label the beginning and end points of each activity.

The How2 dataset [10] was introduced by Sanabria et al. This is a large scale multimodal language understanding dataset to aid in the development human like language understanding capabilities, where machines should be able to jointly process multimodal data, and not just text, images, or speech in isolation.

The TRECVID Instance Search (INS) [3] task is a benchmarking task run at NIST (U.S. National Institute of Standards and Technology) to measure systems performance on the retrieval of specific instances of either persons, locations, or objects. In the last three years the task targeted pairs of instances such as the retrieval of video shots of specific people in given locations within the British Broadcasting Corporation (BBC) Eastenders TV series. While recently the task targeted video shots of specific people doing specific actions in the Eastenders world.

TRECVID Video to Text (VTT) [3] is a benchmarking task also run at NIST to evaluate the performance of systems that automatically generate a single sentence description for short videos. Videos are typically shorter than 10 seconds in length and are taken from social media to represent real world situations. Although ActivityNet, INS and VTT benchmarks are all important efforts to encourage research in recognition and video semantics, they are still considered component tasks and not targeting the real holistic problem of high-level video understanding the way humans do.

3 TECHNICAL DETAILS

3.1 Dataset

The procurement of suitable datasets is vital for the undertaking of this new research area. The authors have spent time identifying Movies with a Creative Commons (CC) license [6] which can be disseminated to participating researchers for the purpose of this research. The most important criteria in selecting the movies were reasonable video quality, duration of more than 15 min at least, and self contained story lines with clear actors, relations, events and entities. In total, a pilot dataset of about 11 hrs has been collected from public websites such as Vimeo[1] and the Internet Archive[2].

Table 1 shows the current set of collected movies, their genre and durations. All movies have been deemed by the authors to be suitable for this research, and will be disseminated to participants as appropriate. The main challenge in this new task is related to the methods and techniques teams use and not the size of data set, We consider this data set to be large enough for the Grand Challenge and workshop in the first year of this task. The authors have also been in deliberations with the BBC regarding the licensing of the TV show *Land Girls* for use in this data set, and the licensing of this series has been approved and will be available for subsequent years of this task. This is a 3-season / 15-episode series set in World War 2 about the lives of a group of women doing their part for Britain in the *Women's Land Army* during the war.

Due to the limited number of movies available for this task, the above list will be split 50-50 between a development set and test set. Final ground truths for movies selected as the development set will be made available to participants. Participating researchers will

also be encouraged to procure their own suitable development sets and to share among other participating researchers.

3.2 Human Annotation Framework

A group of human assessors will be recruited to provide manual annotations to the above HLVU dataset. These annotations will be the basis from which queries and ground-truth are generated. Each of the movies listed above will be watched at least twice by annotators. The first time is to familiarize themselves with the movie story line and the main actors. In the second time watching the movie they will be asked to use the yEd [1] graphing tool to develop a knowledge graph encompassing all of the actors, entities, relationships, and events. An example knowledge graph developed using this software, modelled on *The Simpsons*, is shown in Figure 1. In this example Knowledge Graph we map out the relations between the main characters of the show, in the way that generated Knowledge Graph's should map out the relations between main characters of the movie used in the dataset for this task.

Annotators will be provided with a primary list of possible relations between characters from which they must choose the most accurate relationship. Table 2 provides some examples of the possible relations between characters and their inverse. If needed, they will be allowed to introduce new relationships as well.

In addition to the yEd graphing tool, a specially developed in-house annotation tool will also be used by annotators to save image captions of each of the actors and entities. This should also be used to list all the different actions which take place in the relationship between two people. Additionally this should be used to list key actions and events an individual has been involved in. These actions and events referred to here are not meant to be an exhaustive list and will be those actions and events that human annotators consider to be the key actions or events which may define the relationship between two individuals. In addition, the tool can be used to enable the annotators to document all the different events that happened during the movie and eventually enabling the development of a global ontology of events and actions relevant to the whole HLVU dataset. An example screen shot from using this annotation tool is shown in figure 2.

3.3 Query Development

The yEd graphing tool described in the previous section has the capability of exporting all entities and relationships to xgml or tgf format which can be used in the query development process to read all entities and relationships and develop different types of queries for evaluation purposes. The actions and events which may define the relationship between people may be derived from the in-house annotation tool described in the previous section as well. The following are a set of proposed query types which may be used to evaluate participating systems. Each query type tries to capture and test the systems for their comprehension of the tested movies from different points of view and levels of difficulty:

3.3.1 A- Fill in the graph space: Fill in spaces in the Knowledge Graph (KG). Given the listed relationships, events or actions for certain nodes, where some nodes are replaced by variables X, Y, etc., solve for X, Y etc. Example: **X** Married To Marge. **X** Friend Of Lenny. **Y** Volunteers at Church. **Y** Neighbor Of **X**. Solution for **X** and **Y** in that case would be: **X** = Homer, **Y** = Ned Flanders. A more formal query example may look like the following xml block (asking who is the spouse of "Marge"):

```
<Q.A>
  <Q.Id.1>
    <Subject>Person:Unknown_1</Subject>
    <Pred>Relation:Spouse_of</Pred>
    <Object>Person:Marge</Object>
  </Q.Id.1>
</Q.A>
```

3.3.2 B- Question Answering: This query type represents questions on the resulting KG, including actions and events, of the movies in the described dataset. For example, based on the Simpsons KG below, how many children does Marge have? By counting the 'Parent Of' edges from Marge to other nodes, we can see that Marge has two children, Bart and Lisa. Other possible questions may be for example: What does Ms. Krabappel do for a living? and the answer

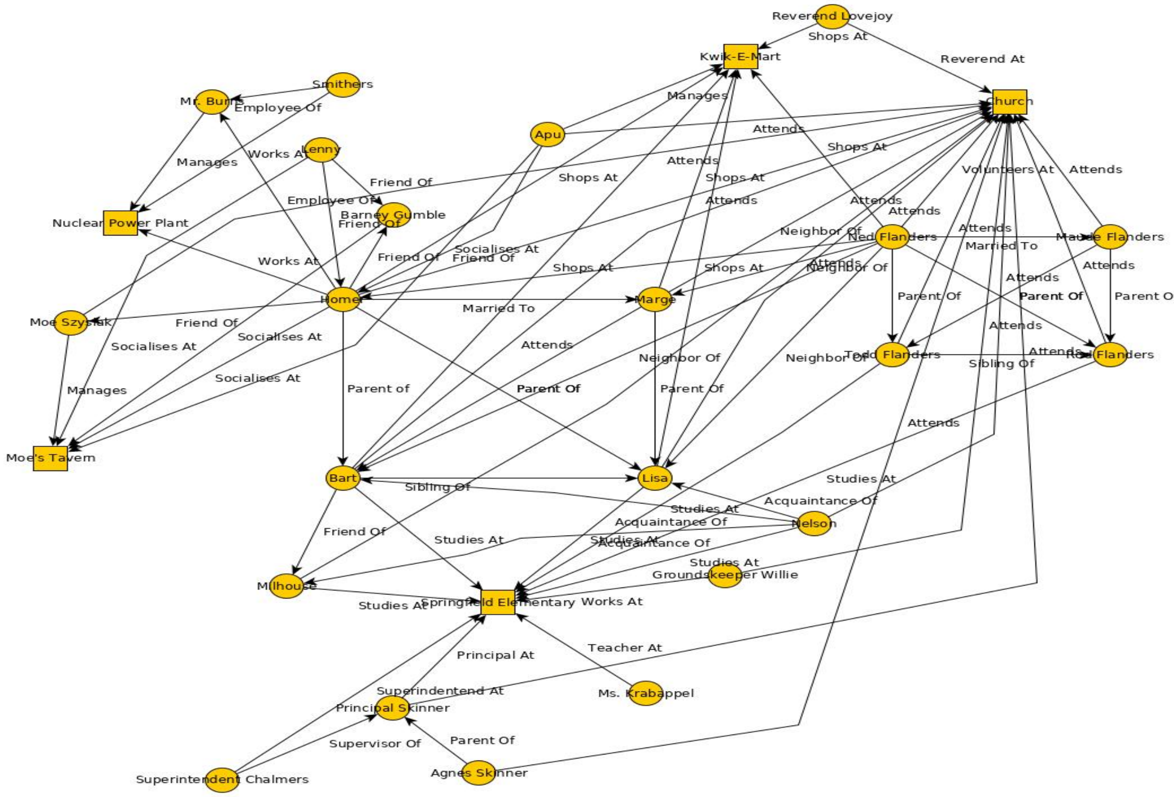

Figure 1: A sample knowledge graph depicting the world of *The Simpsons*

can be a multiple choice from the set of provided entity relationships. A query of this type may look like the following xml block:

```
<Q.B>
  <Q.Id.1>
    <Subject>Person:Ms. Krabappel</Subject>
    <Pred>Relation:Unknown_1</Pred>
    <Object>Location:Springfield Elementary</
        /Object>
    <Ans_1>Relation: X</Ans_1>
    <Ans_2>Relation: Y</Ans_2>
     .
     .
    <Ans_n>Relation: Z</Ans_n>
  </Q.Id.1>
</Q.B>
```

3.3.3 C- Relations between characters: How is character X related to character Y ? This query type question asks participants about all routes through the KG from one person to another. The main objective of this query type is to test the quality of the established KG. If the system managed to build a representative KG reflecting the real story line of the movie, then it should be able to return back all valid paths, including the shortest, between characters (i.e. how they are related to each other). For an example, looking at the Simpsons KG in figure 1, what would be the shortest route for Superintendent Chalmers, the left-bottom most node, to deliver a message to Lenny, in the top left hand corner of the knowledge graph? To answer this question we would follow the edges connecting each node and trace all possible paths from Superintendent Chalmers to Lenny, settling on the three shortest routes: (1) Superintendent Chalmers is supervisor to Principal Skinner, Principal Skinner attends Church, Church is also attended by Homer, Homer is in turn Lenny's friend. (2) Superintendent Chalmers is Superintendent at Springfield Elementary. Springfield Elementary is studied at by Bart. Bart is Child of Homer. Homer is friend of Lenny. (3) Superintendent Chalmers is Superintendent at Springfield Elementary. Springfield Elementary is studied at by Lisa. Lisa is Child of Homer. Homer is friend of Lenny. The below is the formal query representation for the above example:

```
<Q.C>
  <Q.Id.1>
    <Source>Person:Superintendent Chalmers</
        Source>
```

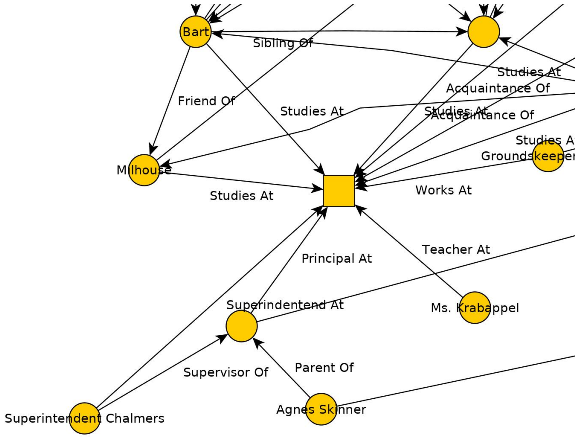

Figure 3: Visible region of graph with three blank nodes to be filled in.

```
    <Target>Person:Lenny</Target>
  </Q.Id.1>
</Q.C>
```

3.4 Evaluation Framework

Using the annotation and graphing tools described above, we can develop evaluation software to read as inputs the ground truth provided by these annotation and graphing tools, in addition to reading as input the submissions of participating teams, automatically evaluating each team's submissions, scoring and ranking results based on the selected evaluation metric. We should note here that systems will be given a set of image and/or video examples for the different actors and entities including important locations, each with a name Id. In addition, the final ontology of relationships, events, and actions will also be given so that systems can align the different query mentions of people, relations, entities, etc and return results from the given ontology classes as well. For illustration purposes, the following is a system response for each of the three query types and a proposed metric to score submissions:

3.4.1 A- Fill in the graph space: Given the partial graph query illustrated in figure 3, systems are asked to fill in the three blank spaces in the KG. The query itself will be given in xml format as illustrated in the query development section above. The ground truth for this example is: Lisa is sibling of Bart. Springfield Elementary is where Milhouse and Bart study at, and Principal Skinner is the principal. An example response by a system is shown below giving a set of answers for each unknown graph node being asked about in addition to a confidence score. Results will be treated as ranked list of result items per each unknown variable and the Reciprocal Rank score will be calculated per unknown variable and Mean Reciprocal Rank (MRR) per query [13].

```
<Q.A>
  <Q.Id.1>
    <Person:Unknown_1><Ans_1><Confidence>
    <Person:Unknown_1><Ans_2><Confidence>
     ...
     ...
    <Person:Unknown_2><Ans_n><Confidence>
  </Q.Id.1>
</Q.A>
```

The MRR measurement (Eq. 1) evaluates systems which return a ranked list of answers to questions. For this reason we consider it the most appropriate evaluation measurement for use in this query type. It is the average of the reciprocal ranks of results for a group of queries. For example, in three ranked lists submitted to answer three unknown variables in a query, if the answer to the first query is ranked second in the list, the answer to the second query is ranked first in the list and the answer to the third is ranked fourth, this gives $\frac{1}{2}$, 1, and $\frac{1}{4}$. This averages to give an MRR score of $\frac{7}{12}$.

$$MRR = \frac{1}{Q} \sum_{i=1}^{Q} \frac{1}{RANKi} \tag{1}$$

3.4.2 B- Question Answering: Multiple choice questions will be provided for participants to answer which will be based on the KG. For an example on the format and types of questions asked to participants please see the Query Development section above. The below is an example of a system response and the evaluation metric (Eq. 2) proposed for this query type.

```
<Q.B>
  <Q.Id.1>
    <Answer>Relation: Z</Answer>
  </Q.Id.1>
</Q.B>
```

$$Score = \frac{CorrectAnswers}{TotalQuestions} \tag{2}$$

3.4.3 C- Relations between characters: In this query type, systems are asked to submit all valid paths form a source node to another target node with the goal of maximizing recall and precision. NIST will first evaluate whether each path is a valid path (i.e the submitted order of nodes and edges leads to a path from the source person to the target person of the query) and report the recall, precision and F1 measures [12]:

$$Recall = \frac{NumberofSubmittedValidPaths}{NumberofValidGTPaths} \tag{3}$$

$$Precision = \frac{NumberofSubmittedValidPaths}{NumberofSubmittedPaths} \tag{4}$$

$$F1\_Score = 2 * \frac{Precision * Recall}{Precision + Recall} \tag{5}$$

Below is an example of a system response to a query asking for all paths from the Simpsons characters Superintendent Chalmers to Lenny:

```
<Q.C>
  <Q.Id.1>
    <path=1>
    <Source>Person:Superintendent Chalmers</
        Source>
    <edge>Relation:Superintendent_At</edge>
    <node>Entity:Springfield Elementary</
        node>
    <edge>Relation:Studied_At_By</edge>
    <node>Person:Bart</node>
    .
    .
    <Target>Person:Lenny</Target>
    </path>
    <path=2>
    <Source>Person:Superintendent Chalmers</
        Source>
    .
    .
    </path>
    <path=3>
    .
    .
    </path>
  </Q.Id.1>
</Q.C>
```

The evaluation framework described above will provide a way to accurately and automatically evaluate the Knowledge Graphs produced by participating researchers. This allows for consistent scoring methods to be applied to this task which increases confidence in results and allows for easy expansion of the task and number of participants.

4 CONCLUSIONS AND FUTURE DIRECTIONS

In this paper we discussed a proposed new evaluation benchmark and associated pilot dataset (HLVU) to promote research in holistic and deep video understanding. The evaluation paradigm aims for long duration self contained story lines in movies and targets automatic systems to eventually build complete knowledge graphs representing the movie characters, relationships, and key actions and events associated with them. The different query types presented aim to test the current automatic computer vision systems' capabilities and measure if they can "understand" video story lines the way humans do. The future plans for this evaluation benchmark is to organize an ACM Multimedia Grand Challenge and a workshop at ACM ICMI to host the evaluation campaign encouraging researchers to explore the dataset, discuss challenges and lessons

Curtis, Keith; Awad, George; Rajput, Shahzad; Soboroff, Ian. "HLVU: A new challenge to test deep understanding of movies the way humans do." Paper presented at ACM International Conference on Multimedia Retrieval (ICMR), Dublin, IE. June 08, 2020 - June 11, 2020.

learned trying to solve the associated problems with deep video understanding of the small world of movies. Also, securing more long term stable and large-scale dataset of licensed or open source movies including soap opera series of closed world story lines is a major future plan to continue measuring progress and the state of the art in this new domain.

Stress and Strain Heuristics for a Layered Elastomeric Foam at Impact Rates

Alexander K. Landauer, Jared Van Blitterswyk, Michael Riley, Aaron M. Forster

Materials Measurement Laboratory

National Institute of Standards and Technology

100 Bureau Drive, Gaithersburg, MD 20899

ABSTRACT

Impact mitigating materials (IMMs) are used to reduce injury or damage due to a blunt impact, which often occurs at high rates or energies. Innovation in IMMs and designs strategies are required for the development of safer protective equipment. A key challenge is translating between idealized experiments (e.g. quasistatic uniaxial stress or high rate Kolsky bar uniaxial strain measurements), fine-grain computational simulations, and real-world performance. To address this challenge, we have coupled high fidelity digital image correlation measurements with drop tower testing, based on our previous work presented to the SEM community. By using digital image correlation, an instrumented drop mass, and an instrumented load plate we obtain spatially and temporally resolved data for a realistic impact scenario. This represents an experimental framework that may be used to guide and validate design criteria applicable to the impact behavior of monolithic and layered IMMs.

Keywords: Impact protection, elastic foam, drop tower testing, digital image correlation, high-speed imaging

INTRODUCTION

Impact mitigating materials (IMMs) are designed and fabricated to minimize the effect of a mechanical insult or hit upon an object to be protected. Typical design targets include, e.g., minimizing linear and rotational accelerations, shock loading, energy transfer, specific or total mass, volume and/or cost, or maximizing energy dissipation [1, 2]. Two design paradigms exist: multi-use and single use. Single use applications can include plasticity or fracture-based solutions, whereas multi-hit applications are constrained to elastic or viscoelastic deformations that are recoverable over the expected time between impacts. Polymer foams, which consist of a crosslinked polymer matrix and gas or fluid filled negative space, are common in both paradigms due to the attractive and tailorable material properties, ease of manufacture and low cost, and adaptability due to the numerous chemistries and foaming processes available [1]. For example, rigid expanded polystyrene foams are ubiquitous for single-impact protection, whereas viscoelastic vinyl-nitrile foams are widely used for multi-impact protection. The uniaxial material response of a typical foam is represented in Fig. 1a, where the large compressive strain domain at relatively constant stress leads to a roughly constant load, i.e., an approximately constant linear acceleration of a protected mass, and the possibility for large energy dissipation if hysteretic mechanisms are active.

Here, we focus on specimens and test techniques for impact mitigation in personal protection, i.e., helmets, pads, or playing surfaces, in which multiple impacts over an O(1 s) time are expected. Typical examples include helmets and padding for contact sports (e.g., football, ice hockey, or lacrosse) and military and police armor and helmets, where impact are O(10 J) and O(10 ms) with strain rates in the padding material reaching 10^1 to 10^2 1/s. In practice, embodiments of protective systems across disciplines often have similar constructions that include a hard shell for penetration or fracture protection and one or more viscoelastic foam (or elastomeric) layers [3]. Foams are often arranged in series to provide both protection and comfort, e.g. a stiff foam adjacent to the exterior shell with an inner soft layer to interface with the head or body during normal use, see the schematic in Fig. 1b. A combination of material and structure are sought that minimize injury risk, either via top-down design, e.g., via models of discrete material layers that minimize stress wave propagation [4, 5] or promote dissipative mechanisms [3] or limit rotational (i.e., shear) loads [6], or via computational topology optimization of lattice-like architected structures [7, 8] which can then be fabricated through additive manufacturing techniques [9]. In this abstract, we discuss a combined instrumented drop tower and digital image correlation (DIC) system to interrogate the response of these structures in real-world impact-like conditions and show an example result for a layered foam.

Landauer, Alexander; Van Blitterswyk, Jared; Riley, Michael A.; Forster, Aaron M. "Stress and Strain Heuristics for a Layered Elastomeric Foam at Medium Impact Rates." Paper presented at Society for Experimental Mechanics, Bethel, CT, US. September 14, 2020 - September 17, 2020.

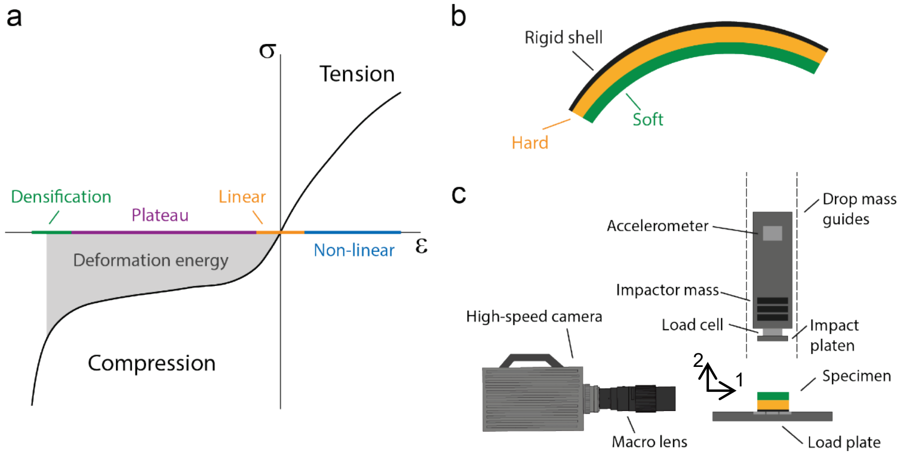

Fig. 1 (**a**) Typical stress-strain response of a foam-like material at constant strain rate. (**b**) Simplified schematic of a bi-layer IMM, with hard and soft layers of foam and a rigid external shell. (**c**) Components (not to scale) of the drop-mass system, including synchronized single camera and load-plate and instrumented (axial load and tri-axial acceleration) adjustable-weight drop mass

METHODS

Foam specimens approximately 50 mm x 50 mm x 25 mm were excised from as-received sheets of a stiff vinyl-nitrile foam (VNW, density approximately 111 kg/m^3) and a less stiff vinyl-nitrile foam (VNB, density approximately 135 kg/m^3). Both are closed-cell viscoelastic foams. Specimens were either monolithic foam or layered in a VNB (bottom) + VNW (top) or, as in the schematic of Fig. 1b and depicted in Fig. 3a, VNW (bottom) + VNB (top).

For our impact-like (i.e., O(10 J) and O(10 ms)) experiments we employ a custom-designed, instrumented drop-mass, which was previously presented to the SEM community [10]. A custom digital image correlation (DIC) algorithm [11] designed for finite deformations was incorporated into the instrumented drop tower experiments using high-speed imaging, see the schematic in Fig 1c. Typical settings and calibrations for DIC analysis are summarized in Table 1. Images for DIC were captured with a 1:2 macro lens (standoff distance approximately 0.5 m) at a framing rate of 10 kHz (exposure 1/20 000 s, f/5.6). The load plate captured synchronized force data at 50 kHz and the drop mass recorded triaxial accelerations and axial loads on an independent clock. The displacement field data is used to compute the surface strain tensor via a spatial differentiation filter. Strain rate history is computed using temporal central differencing. Table 2 describes the test conditions used in the drop tests. Monolithic materials were subjected to a 0.4 m drop of approximately 12 J of energy. Layered foams were approximately twice the height of the monolithic foams, therefore these were subjected to a 3x increase in energy, approximately 36 J, to achieve a similar degree of compressive strain as the monolithic cases.

RESULTS AND DISCUSSION

The scalar data outputs from the drop mass technique include the peak acceleration of the drop mass, the peak force applied to the top of the specimen, and peak force transmitted through the specimen. These results are given for the monolithic foams and both stack configurations in Table 2. The stiffer VNW was more effective at mitigating a 0.4 m drop (lower peak accelerations and forces) than the softer, but denser, VNB foam. Both foams had relatively short dominant relaxation times -

Table 1 Image and process parameters for digital image correlation of a typical monolithic specimen

Parameter	Value
Camera Noise	0.026%
Prefilter	Gaussian, 3 px by 3 px, σ = 0.5
Run mode	FFT-based, Hybrid stepping
Image size	818 px by 765 px
Subset size (final)	16 px by 16 px
Step	8 px
Strain filter	Optimal-7 tap
Virtual strain gauge	58 px
Temporal (rate) filter	Central difference
Interpolation	Cubic spline
Measurement points	10185

Static image strain uncertainty	ϵ_{11} = 427 μm/m ϵ_{22} = 450 μm/m ϵ_{11} = 261 μm/m

Table 2 Drop mass impact data for impacts on monolithic and layered foams. Data are listed as mean ± one standard deviation for two repeats on two specimens (n = 4) for monolithic foam and two repeats per stack type for layered foam (n = 2)

Specimen	Drop Height (m)	Energy (J)	Peak impactor Acceleration (g)	Peak Applied Force (kN)	Peak Transmitted force (kN)
VNW	0.4	12.3	45.4 ± 3.5	1.09 ± 0.11	1.00 ± 0.07
VNB	0.4	12.3	63.0 ± 2.6	2.03 ± 0.07	1.96 ± 0.06
VNB+ VNW (top)	1.2	36.9	81.3 ± 0.3	2.73 ± 0.03	2.68 ± 0.12
VNW+ VNB (top)	1.2	36.9	71.2 ± 1.9	2.43 ± 0.06	2.31± 0.06

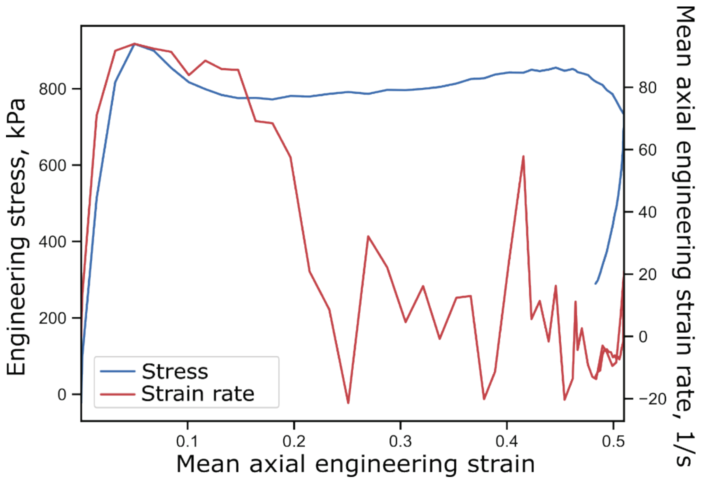

Fig. 2 A typical stress vs. strain and strain-rate vs strain result with mean axial engineering surface strain, ϵ_{22}, and mean axial engineering surface strain rate $\dot{\epsilon}_{22}$ from a 0.4 m impact on VNW

approximately 6.2% and 2.7% residual strain after 100 ms recovery time from impacts of approximately 36.9 J and 12.3 J yielding approximately 83% and 75% axial compressive engineering strain, respectively for VNW and VNB. For the monolithic foam samples, the axial engineering stress (left axis, computed via the measured cross section of the specimen) and the mean full-field axial strain rate (right axis) are plotted as functions of the mean full-field axial engineering strain, see Fig. 2. In this case, the 12.3 J impact leads to approximately 50% strain – enough to initiate an upturn in the stress response (i.e., densification of the foam), although the relative magnitude may be confounded by rate dependency in the material. Note, however, that this is semi-quantitative, since robust boundary conditions (i.e. uniaxial stress) are not established. In the initial loading the strain rate reaches approximately 90 1/s, but as the impact continues this is reduced to less than 20 1/s during the onset of densification.

In the multilayer case, a simple stress versus strain plot holds limited meaning, and instead we use a reduction of the DIC data to interpret the experiment. Peak acceleration and force measurements varied between the VNW+VNB and VNB+VNW configurations, indicating that the stacking order likely leads to measurable differences in impact mitigation. These effects can be further elucidated via the strain history from the DIC analysis. As an example, we take the case of a 36.9 J impact on a VNW+VNB layered foam, the undeformed configuration image of which is shown in Fig. 3a. Since the strain is highly non-uniformly distributed through the height of the specimen, a map of axial strain as a function of height of the specimen (the 2-direction) and post-impact time is given in Fig. 3b. Each time slice represents the mean axial engineering strain ϵ_{22} taken

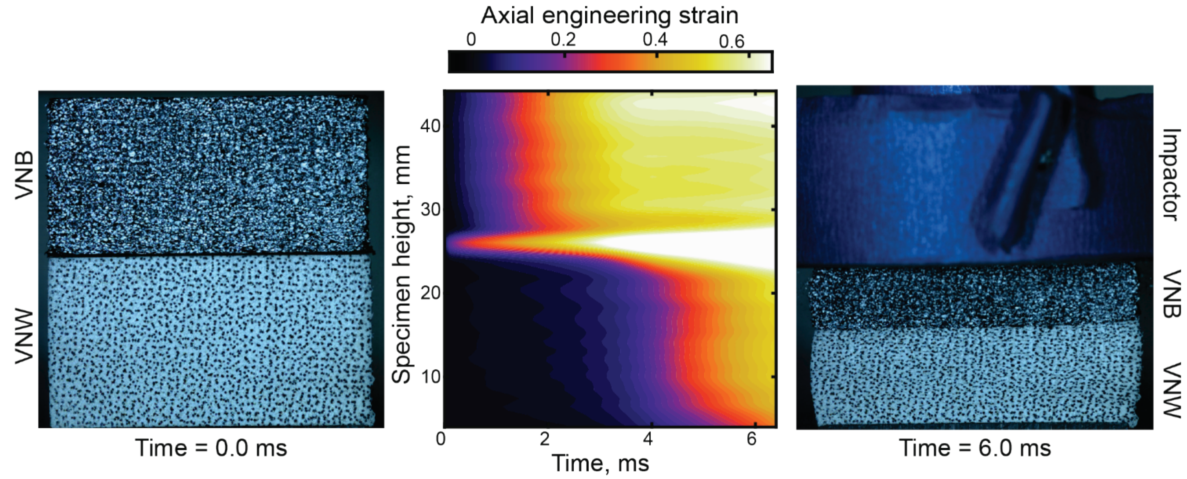

Fig. 3 Snapshot of the multilayer VNW+VNB foam in the undeformed and deformed configurations with the evolution of mean (in the 1-direction) axial strain ϵ_{22} during the first ca. 6 ms of a 36.9 J impact shown as a contour map

across the $x_1$direction. From this representation we see that in approximately the initial 2 ms of loading, the top layer deforms relatively uniformly until it reaches saturation at approximately 50% strain (i.e., approaching the densification strain). Apparent strain rapidly builds at the interface – likely an artificial strain since initial conformal contact is not guaranteed at the VNB/VNW interface and speckle pattern characteristic dramatically change – which warrants further investigation since interfaces are typically challenging for accurate DIC measurements. At approximately 4 ms the lower layer begins to rapidly take on strain, although less uniformly than the top layer, and this strain continues to increase beyond 6 ms into the impact event.

CONCLUSION

We have added digital image correlation to the instrumented drop tower experiment and used this to briefly investigate both monolithic and layered foams. The stress-strain and strain rate-strain behaviors, based on full-field measured strains of the specimen surface, are shown during the drop for monolithic foam. An example of layered foam with a strain distribution as a function of time is also given. These measurements highlight the complexity of the impact event compared to the well-controlled conditions of a conventional uniaxial compression test. The extraction of strains from a layered foam system highlights the non-uniformity of the material system response and possibly also the role of interfaces during impact. In the future, 3D-DIC will be employed to establish measurement criteria for elastomeric dissipative materials and the effects of layering strategies will be addressed.

ACKNOWLEDGEMENTS

The authors thank Dwight Barry for assistance fabricating foam specimens.

Abstract

Accurate, optics-based measurement of feature sizes at deep sub-wavelength dimensions has been conventionally challenged by improved manufacturing, including smaller linewidths, denser layouts, and greater materials complexity at near-atomic scales. Electromagnetic modeling is relied upon heavily for forward maps used to solve the inverse problem of optical measurements for parametric estimation. Machine learning (ML) approaches are continually under consideration, either as a means to bypass direct comparison to simulation or as a method to augment nonlinear regression. In this work, ML approaches are investigated using a well-characterized experimental data set and its simulation library that assumes a 2-D geometry. The benefits and limitations of ML for optical critical dimension (OCD) metrology are illustrated by comparing a straightforward library look-up method and two ML approaches, a data-driven surrogate model for nonlinear regression using radial basis functions (RBF) and multiple-output Gaussian process regression (GPR) that indirectly applies the simulated intensity data. Both RBF and GPR generally improve accuracy over the conventional method with as few as 32 training points. However, as measurement noise is decreased the uncertainties from RBF and GPR differ greatly as the GPR posterior estimate of the variance appears to overestimate parametric uncertainties. Both accuracy and uncertainty must be addressed in OCD while balancing simulation versus ML computational requirements.

1. INTRODUCTION

Inexpensive, non-destructive, and relatively fast optical approaches permeate overlay metrology,[1,2] defect inspection,[3,4] and critical dimension (CD) metrology[5] in advanced semiconductor manufacturing. Unlike defect and overlay metrologies, optical CD (OCD) metrology has been strongly dependent upon electromagnetic simulations to yield forward maps for the inverse problem of determining CDs and optical properties from intensity measurements. The downward scaling of semiconductor features has prompted not only improvements in electromagnetic simulations[6] but also reductions in measurement wavelength[7] and the rigorous incorporation of prior knowledge (e.g., hybrid metrology[8–12]) to extend the continued utility of OCD even as dimensions are deep sub-wavelength and approaching near-atomic scales.

The clear goal of OCD of sub-wavelength features is determining the set of parameters, $\mathbf{p} = \{p_1, \ldots p_T\}$, where T is the number of free parameters in the simulation, that best represent the measurand. Generally, optical data are collected for combinations of several measurement conditions (e.g., angle, wavelength, polarization, *etc.*) that can be labeled as $\boldsymbol{\omega}_1, \ldots, \boldsymbol{\omega}_t$, where t is the total number of conditions. The optical data collected at each $\boldsymbol{\omega}_i$ can be classified as $\mathbf{I} = (I_1, \ldots, I_t)^\intercal$ and the simulated data are $\mathbf{f_I}(\boldsymbol{\omega}, \mathbf{p}) = [f(\boldsymbol{\omega}_1, \mathbf{p}), \ldots, f(\boldsymbol{\omega}_t, \mathbf{p})]^\intercal$. Most often, nonlinear regression is utilized to determine the estimate $\hat{\mathbf{p}}$ from the relationship

$$\mathbf{I} = \mathbf{f_I}(\boldsymbol{\omega}, \mathbf{p}) + \boldsymbol{\epsilon}, \tag{1}$$

where $\boldsymbol{\epsilon}$ is an error term.

To improve OCD further, researchers and technologists are contemplating the use of artificial intelligence (AI) and machine learning (ML) towards determining $\hat{\mathbf{p}}$ with two divergent approaches emerging: First, one

Barnes, Bryan; Henn, Mark-Alexander. "Contrasting Conventional and Machine Learning Approaches to Optical Critical Dimension Measurements." Paper presented at Metrology, Inspection, and Process Control for Microlithography XXXIV, San Jose, CA, US. February 24, 2020 - February 27, 2020.

could abandon the long-held practice that experimental data need to be connected directly to simulation data. In simplest terms, the measurements $\mathbf{I}$ could be fed directly into ML to yield $\hat{\mathbf{p}}$. Second, ML could be centered on improving existing regression approaches for solving Eq. 1. In selecting between these two approaches for metrology, it is crucial that ML needs to yield not only $\hat{\mathbf{p}}$ but also the variances $\sigma^2_{\hat{\mathbf{p}}} = \{\sigma^2_{\hat{p}_1}, \ldots, \sigma^2_{\hat{p}_T}\}$. Of the first approach, Bischoff *et al.* reported fitting of 0.25 μm patterns using neural networks, but no uncertainties were reported.[13] Robert *et al.* reported an estimation of values using neural networks and also variance estimation using a second neutral network, but they clarify "variables are assumed to be not correlated". Rana *et al.* indicated industrial viability with reports of uncertainty using neural networks but without specific derivation.[14]

The second approach, the use of ML approaches to augment regression, has recently gained attention. Hammerschmidt *et al.* employed a Bayesian approach with a Newton-like method to quantify the parameters.[15] Heidenreich *et al.* reported a polynomial chaos based surrogate model for EUV scatterometry measurements with errors determined from Markov-Chain Monte Carlo sampling of the posterior distribution.[16] Later, Hammerschmidt *et al.* reported the use of Gaussian processes in Bayesian optimization, also referred to as Gaussian process regression in that work, using a Taylor expansion to quantify uncertainties in scatterometry.[17] In each of the works, results for the values were comparable with prior approaches at fitting.

In this work, previously published data are reprocessed to consider the challenges and opportunities of both the first and second approaches. The implementation of Gaussian process regression (GPR) presented here (unlike in Refs.[17,18]) circumvents direct application of Eq. 1 to proceed straight from $\mathbf{I}$ to $\hat{\mathbf{p}}$ through ML, although the ML training and validation are completely informed by rigorous electromagnetic simulations. GPR is a well-studied ML approach notable in that GPR can simultaneously calculate both a mean and a variance using multiple outputs (here, geometrical parameters) even with correlation.[19] Alternatively, radial basis functions (RBF) are trained and validated to augment the solution of Eq. 1 to yield improved values for the parametric means and variances.[20] These two approaches will be compared against a straightforward application of a conventional library look-up method. For the ML approaches, the complexity and computational expense of modern OCD modeling will be considered through the lens of data scarcity, a reduction in the number of training points, or n_{TP}, that are available in the existing library. Comparisons will show that even with smaller values of n_{TP}, both GPR and RBF yield generally good values for $\hat{\mathbf{p}}$, that RBF yields relatively small uncertainties based on its variance, but that this GPR method as presented appears to overestimate parametric uncertainties.

2. EXPERIMENTAL TECHNIQUE AND SAMPLE DETAILS

The experimental data used in this work were collected from scatterfield microscopy measurements in an angular scan mode. Scatterfield microscopy combines sophisticated illumination engineering in a high-magnification imaging platform with optimized information collection about targets of interest from the full 3-D electromagnetic scattered field. Overviews of the method are available as Ref.[22,23] Similar approaches have been deemed "micro-scatterometry".[24,25] Specifically, using Köhler illumination as illustrated in Fig. 1, an aperture in the conjugate to the back focal plane of the objective lens leads to an angularly resolved illumination beam (illumination NA

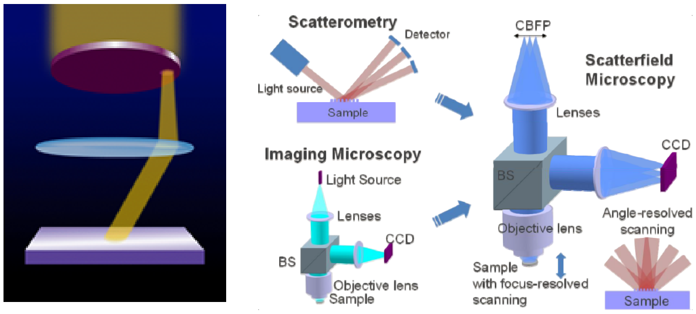

Figure 1. Angularly resolved scatterfield microscopy. (left) Schematic showing angularly resolved illumination. (right) Angle-scanning capabilities due to an aperture in the conjugate to the back focal plane (CBFP). Reprinted from Ref.[21]

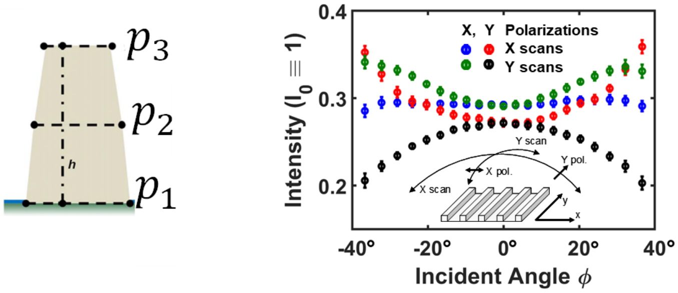

Figure 2. L100P300 Parameterized geometry and example data set. Measured intensities as functions of incident polarization and scan direction, with X, Y defined relative to line direction. Intensity here is unitless after normalization by the incident intensity $I_0 \equiv 1$. Error bars are 1σ uncertainties in the measured values. After Ref.[27]

$\approx$ 0.13) at the sample plane. This light is either reflected or scattered depending on the characteristics of the sample. The large collection NA $\approx$ 0.95 allows the capture of scattered light between $\phi = -72°$ to $72°$. For these experiments, the field-of-view of collection path was focused solely on the target of interest, a periodic array of patterned lines. The experimental wavelength is $\lambda = 450$ nm

The patterned structures under test are three scatterometry targets patterned using a focus/exposure matrix to yield variations in linewidth. The specific target is the "L100P300" target produced by SEMATECH,[26] with the notation implying a nominal line width of 100 nm and a period of 300 nm. These data have been of great utility, having been reported for initial demonstrations of Scatterfield Microscopy,[22] in pioneering work on hybrid metrology,[10, 11] as well as in a recent investigation of the treatment of potential experimental bias.[27] In these works, the geometry has been parameterized using a dual trapezoid model yielding three floating parameters, with a fixed height. Dimensional measurements from this sample have been reported from scanning electron microscopy (SEM)[22] and from atomic force microscopy (AFM).[8] Although its dimensions far exceed those of current technology nodes, comparisons can be made among the ML results as well as these prior data. Furthermore, with a large library of over 2000 simulated $\mathbf{f_I}(\boldsymbol{\omega}_i, \mathbf{p})$ in-hand, multiple realizations of sub-sampling of that library have been performed to yield additional rigor to the observed trends in accuracy and uncertainty.

3. METHOD DERIVATIONS

In this section, summaries describing the estimation of the parametric values $\hat{\mathbf{p}}$ and their uncertainties $\sigma_{\hat{\mathbf{p}}}$ are presented. Other sources cover the derivation of the RBF and GPR approaches more thoroughly (see the documentation for Ref.[20] and Ref.,[19] respectively).

3.1 Commonalities between Library look-up and RBF

Both library look-up and RBF utilize a weighted least squares fit. The weights are based on the known measurement errors, $\sigma_{\mathsf{meas},i}$, at each of the $\boldsymbol{\omega}_i, i = 1, 2, \cdots, t$ for the measurements I_i. In this work, $T = 84$ by concatenating the four angle scans in Fig. 2 into a single vector. This approach leads to the function

$$\chi^2(\mathbf{p}) = \sum_{i=1}^{t} \frac{1}{\sigma^2_{\mathsf{meas},i}} |f(\boldsymbol{\omega}_i, \mathbf{p}) - I_i|^2, \tag{2}$$

the weighted χ^2 (chi-square) function, which can also be expressed as:

$$\chi^2(\mathbf{p}) = [\mathbf{f_I}(\boldsymbol{\omega}, \mathbf{p}) - \mathbf{I}]^\intercal \, \mathbf{V}^{-1} \, [\mathbf{f_I}(\boldsymbol{\omega}, \mathbf{p}) - \mathbf{I}] \,, \tag{3}$$

with

$$\mathbf{f_I}(\boldsymbol{\omega}, \mathbf{p}) = [f(\boldsymbol{\omega}_1, \mathbf{p}), f(\boldsymbol{\omega}_2, \mathbf{p}), \ldots, f(\boldsymbol{\omega}_t, \mathbf{p})]^\intercal \,, \;\; \mathbf{I} = (I_1, I_2, \cdots, I_t)^\intercal \tag{4}$$

and for this work,

$$\mathbf{V}^{-1} = \left(\delta_{ij}\frac{1}{\sigma^2_{\mathsf{meas},i}}\right)_{i,j=1,\dots,t} \in \mathbb{R}^{t\times t}, \tag{5}$$

and as uncorrelated errors are assumed here $\mathbf{V}^{-1}$ is a diagonal matrix.

In addition, it can be shown that the uncertainties in $\hat{\mathbf{p}}$ can be calculated using the covariance matrix

$$\mathbf{\Sigma} = \left(\mathbf{J}^{\mathsf{T}}_{\mathbf{f_I}}\mathbf{V}^{-1}\mathbf{J}_{\mathbf{f_I}}\right)^{-1}, \tag{6}$$

where $\mathbf{J}_{\mathbf{f_I}}$ is the Jacobian of the model function. It is through Eqs. 5 and 6 that Library Look-up and RBF are both sensitive directly to measurement noise.

3.2 Library look-up

In the library look-up scheme, χ^2 is evaluated at a subset of $\mathbf{f_I}(\boldsymbol{\omega}_i, \mathbf{p})$ for which $\mathbf{p}$ are aligned on a grid such that for a given p_j there exists nearest neighbors (NN_-) and (NN_+) such that $p_{j(NN_-)} < p_j < p_{j(NN_+)}$ with $p_{i\neq j}$ being equal. The value of $\mathbf{p}$ which yields the smallest χ^2 is in this scheme the best fit $\hat{\mathbf{p}}$. The Jacobian is approximated using

$$\mathbf{J}_{\mathbf{f_I}} = \left(\frac{\partial f_i}{\partial p_j}\right)_{i=1,\dots,t,j=1,\dots,T} \in \mathbb{R}^{t\times T}, \frac{\partial f_i}{\partial p_j} \approx \frac{\Delta f_i}{\Delta p_j} \approx \frac{f_{i(NN_+)} - f_{i(NN_-)}}{p_{j(NN_+)} - p_{j(NN_-)}}. \tag{7}$$

Using additional nearest neighbors (if available) may improve this ratio through averaging of f_i, but here these simple approximations are used to quickly assess $\hat{\mathbf{p}}$ and $\sigma_{\hat{\mathbf{p}}}$.

3.3 Radial Basis Function Interpolation

Library look-up does not interpolate the function among points in the simulation domain, and for modern OCD such an extensive library seems impractical. One solution is to avoid evaluating the function directly by interpolating on a grid of already calculated values. Again, the RBFs are calculated using a subset of the entire library made up of n_{TP} entries where TP represents "training points"; this nomenclature comes from the ML community and shall be used for both RBF and GPR. The parameters for which $\mathbf{f_I}(\boldsymbol{\omega}, \mathbf{p})$ is evaluated are $\mathbf{p}_i = (p_{i1}, p_{i2}, \dots, p_{iT}), i = 1, \dots, n_{\mathsf{TP}}$ with

$$\mathbf{\Pi} = \begin{pmatrix} \mathbf{p}_1 \\ \vdots \\ \mathbf{p}_{n_{\mathsf{TP}}} \end{pmatrix} \in \mathbb{R}^{n_{\mathsf{TP}}\times T}, \mathbf{f_I}(\mathbf{\Pi}) = \mathbf{\Phi} = \begin{pmatrix} \mathbf{f_I}(\mathbf{p}_1)^{\mathsf{T}} \\ \vdots \\ \mathbf{f_I}(\mathbf{p}_{n_{\mathsf{TP}}})^{\mathsf{T}} \end{pmatrix} \in \mathbb{R}^{n_{\mathsf{TP}}\times t}, \tag{8}$$

where T remains the number of parameters and t the number of measurement conditions, i.e., the length of an individual measurement vector.

The interpolation problem then amounts to find an approximation $\widetilde{\mathbf{f_I}}$ to the function $\mathbf{f_I}$ such that

$$\widetilde{\mathbf{f_I}}(\mathbf{p}, \mathbf{\Pi}, \mathbf{\Phi}) \approx \mathbf{f_I}(\mathbf{p}). \tag{9}$$

For the sake of clarity we will write $\widetilde{\mathbf{f_I}}(\mathbf{p})$ for the function in Eq. 9 if it is clear what library $\{\mathbf{\Pi}, \mathbf{\Phi}\}$ is being used.

Assume we have a set of functions $\rho_i : \mathbb{R}^T \to \mathbb{R},\ i = 1, \dots, N,$ such that for all $j \in \{1, \cdots, t\}$, we can approximate the j-th component of $\mathbf{f_I}$, i.e. the scalar function $f_j(\mathbf{p})$ by

$$f_j(\mathbf{p}) \approx \sum_{i=1}^{N} a_{ji}\rho_i(\mathbf{p}). \tag{10}$$

In the RBF approach specific functions are utilized that depend only on the distance of the parameter vector $\mathbf{p}$ from the different grid points $\mathbf{p}_i$, and an additional hyperparameter r as

$$\rho_i\left(\mathbf{p}, r\right) = \rho\left(\|\mathbf{p} - \mathbf{p}_i\|, r\right), \; i = 1, \ldots, n_{\mathsf{TP}}, \tag{11}$$

hence $N = n_{\mathsf{TP}}$ in Eq. 10. Specifically, the multiquadratic radial basis functions,

$$\rho_i\left(\mathbf{p}, r\right) = \sqrt{\|\mathbf{p} - \mathbf{p}_i\|^2 + r^2}, \; i = 1, \ldots, n_{\mathsf{TP}} \tag{12}$$

have been utilized with the hyperparameter r determined from leave-one-out cross-validation (LOOCV)[28] and the optimal hyperparameter $\hat{r}$ found using a particle-swarm optimization (PSO) algorithm, see Ref.[29] The matrix $\mathbf{A}$ (derived elsewhere[20]), consisting of the t coefficient vectors $\mathbf{a}_i = \left(a_{i1}, \ldots, a_{in_{\mathsf{TP}}}\right)^{\mathsf{T}} \in \mathbb{R}^{n_{\mathsf{TP}}}$ determined from Eq. 10, given as

$$\mathbf{A} = \left(\mathbf{a}_1, \cdots, \mathbf{a}_t\right)^{\mathsf{T}} \in \mathbb{R}^{t \times n_{\mathsf{TP}}}, \tag{13}$$

is also optimized using PSO. Using $\mathbf{A}$ we can calculate the approximation of all t entries to the model function for an arbitrary parameter vector $\mathbf{p}$ by

$$\widetilde{\mathbf{f}}_{\mathbf{I}}\left(\mathbf{p}\right) = \mathbf{A} \cdot \mathbf{P}\left(\mathbf{p}\right), \text{ with } \mathbf{P}\left(\mathbf{p}\right) = \left[\rho_1\left(\mathbf{p}\right), \ldots, \rho_{n_{\mathsf{TP}}}\left(\mathbf{p}\right)\right]^{\mathsf{T}} \in \mathbb{R}^{n_{\mathsf{TP}}}. \tag{14}$$

To quickly summarize, the training step for RBF solves for $\hat{r}$ and $\mathbf{A}$ that are used in the determination of $\widetilde{\mathbf{f}}_{\mathbf{I}}\left(\mathbf{p}\right)$ which can be shown to yield

$$\hat{\mathbf{p}} = \operatorname{argmin}\left\{\left[\widetilde{\mathbf{f}}_{\mathbf{I}}\left(\mathbf{p}\right) - \mathbf{y}\right]^{\mathsf{T}} \mathbf{V}^{-1} \left[\widetilde{\mathbf{f}}_{\mathbf{I}}\left(\mathbf{p}\right) - \mathbf{y}\right]\right\}, \tag{15}$$

where $\mathbf{y}$ is a general form, and is $\mathbf{I}$ specifically here as in Eq. 3. The derivation of the Jacobian of $\widetilde{\mathbf{f}}_{\mathbf{I}}\left(\mathbf{p}\right)$, $\mathbf{J}_{\widetilde{\mathbf{f}}_{\mathbf{I}}}$, can be found elsewhere,[20] but as with the library look-up, the parametric mean and uncertainty are both directly tied to the measurement uncertainty through $\mathbf{V}^{-1}$.

3.4 Gaussian Process Regression

In this implementation of Gaussian process regression, which has followed the derivation set forth by Liu *et al.*,[19] we rethink the relationships between the geometry and its scattering and attempt a vastly different ML approach. Instead of trying to establish a functional relationship between the geometry parameters and the optical response, i.e., trying to find the function

$$\mathbf{f}_{\mathbf{I}} : \mathbf{p} \mapsto \mathbf{f}_{\mathbf{I}}\left(\mathbf{p}\right), \tag{16}$$

and minimize the difference between a particular measurement $\mathbf{y}$ and the function value to determine the optimal value of geometry parameters, we want to establish a direct relationship between measured intensities and geometry parameters, i.e., find a function such that

$$\mathbf{g} : \mathbf{I} \mapsto \mathbf{g}_{\mathbf{p}}\left(\mathbf{I}\right), \tag{17}$$

informed by observed measurements and/or simulated values $\mathbf{I}$ at various measurement conditions $\boldsymbol{\omega}_1, \ldots, \boldsymbol{\omega}_t$.

In order to keep the notation simple we will in the following assume that we only want to determine a single parameter value p instead of a vector of parameter values $\mathbf{p}$, before giving a brief explanation on how to address the latter with a multi-output Gaussian process (MOGP). Similar to the previous approach we assume that the observations, that are now the values of the parameter of interest, are noisy realizations of the underlying model, such that

$$p = g_p\left(\mathbf{I}\right) + \epsilon_s, \; \epsilon_s \sim \mathcal{N}\left(0, \sigma_s^2\right). \tag{18}$$

Note, that there is no relationship between ϵ_s in Eq. 18 and ϵ in Eq. 1, nor is there a relationship between σ_s and the measurement noise σ_{meas} in Eq. 2.

In Gaussian process regression the target function in Eq. 18 is approximated by interpreting it as a probability distribution in a function space, more precisely as a collection of random variables, such that any finite number of which have a joint Gaussian distribution. As such it is completely defined by its mean function $m(\mathbf{I})$ and the covariance function $k(\mathbf{I},\mathbf{I}')$. We can therefore write a Gaussian process as

$$g_p(\mathbf{I}) \sim \mathcal{GP}\left[m(\mathbf{I}), k(\mathbf{I},\mathbf{I}')\right], \tag{19}$$

and furthermore, w.l.o.g., assume the mean function to be zero. In order to reduce the complexity of the problem the choice of the covariance function is limited to a certain class of functions that can be characterized by a few parameters.

In this study, a simple exponential (SE) kernel has been applied, defined here as

$$k_{\mathsf{SE}}(\mathbf{I},\mathbf{I}') = \sigma^2 \mathsf{exp}\left(-\frac{||\mathbf{I}-\mathbf{I}'||}{2l}\right), \tag{20}$$

where the signal variance σ^2 represents an output scale amplitude and l represents a characteristic length scale. Here, σ and l are the hyperparameters ω for this kernel that must be fitted in order to realize the optimal GPR. Indeed, not only is this similar to RBF, but this kernel is itself a radial basis function also.

Because of the Euclidian norm in Eq. 20, a function of the vector difference between two intensity vectors with t elements is reduced to a scalar value. This is both a benefit (by speeding up the calculation) and a challenge (by removing information from the regression). Contrast this with the RBF interpolation, which in Eqn. 11 reduces a function of two vectors of length n_{TP} into a scalar value also. Alternative kernels including non-radial kernels should be explored further for use in GPR-based OCD metrology.

Thus, in the context of Eq. 17, there exists a set of training points $\mathcal{I} = \{\mathbf{I}_1, \ldots, \mathbf{I}_{n_{\mathsf{TP}}}\}$ from the input domain with associated output observations $\mathcal{P} = \{p(\mathbf{I}_1), \ldots, p(\mathbf{I}_{n_{\mathsf{TP}}})\}$, that we can arrange in a vector $\mathbf{p} = [p(\mathbf{I}_1), \ldots, p(\mathbf{I}_{n_{\mathsf{TP}}})]^{\mathsf{T}}$. Assume now that $\mathbf{I}$ need not (as defined above) be from simulation but rather comes instead from experiment as $\mathbf{y}$. Again following Ref.[19] and since a Gaussian process is a stochastic process wherein a finite subset of random variables follows a joint Gaussian distribution, the joint prior distribution of the observations $\mathbf{p}$ together with $g_p(\mathbf{y})$ is

$$\begin{bmatrix} \mathbf{p} \\ g_p(\mathbf{y}) \end{bmatrix} \sim \mathcal{N}\left(\begin{bmatrix} \mathbf{0} \\ 0 \end{bmatrix}, \begin{bmatrix} \mathbf{K}(\mathcal{I},\mathcal{I}) + \sigma_s^2 \mathbf{E}_{n_{\mathsf{TP}}} & \mathbf{k}(\mathcal{I},\mathbf{y}) \\ \mathbf{k}(\mathbf{y},\mathcal{I}) & k(\mathbf{y},\mathbf{y}) \end{bmatrix}\right), \tag{21}$$

where $\mathbf{K}(\mathcal{I},\mathcal{I}) \in \mathbb{R}^{n_{\mathsf{TP}} \times n_{\mathsf{TP}}}$ is the symmetric and positive semi-definite covariance matrix with the element $\mathbf{K}_{ij} = k(\mathbf{I}_i, \mathbf{I}_j)$, $\mathbf{k}(\mathcal{I},\mathbf{y}) \in \mathbb{R}^{n_{\mathsf{TP}}}$ denotes the vector of covariances between the n_{TP} training points and the test point $\mathbf{y}$, and $\mathbf{E}_{n_{\mathsf{TP}}}$ is the identity matrix in $\mathbb{R}^{n_{\mathsf{TP}} \times n_{\mathsf{TP}}}$. Be aware that we understand the term point in a topological sense, since both the training points and the test point are vector quantities.

It can be shown that for a single-output Gaussian process regression, the prediction mean $\hat{g}_p(\mathbf{y})$ and prediction variance $\sigma_p^2(\mathbf{y})$ are

$$\hat{g}_p(\mathbf{y}) = \mathbf{K}(\mathbf{y},\mathcal{I})^{\mathsf{T}} \left[\mathbf{K}(\mathcal{I},\mathcal{I}) + \sigma_s^2 \mathbf{E}_{n_{\mathsf{TP}}}\right]^{-1} \mathbf{p}, \tag{22}$$

and

$$\sigma_p^2(\mathbf{y}) = k(\mathbf{y},\mathbf{y}) - \mathbf{K}(\mathbf{y},\mathcal{I})^{\mathsf{T}} \left[\mathbf{K}(\mathcal{I},\mathcal{I}) + \sigma_s^2 \mathbf{E}_{n_{\mathsf{TP}}}\right]^{-1} \mathbf{K}(\mathbf{y},\mathcal{I}). \tag{23}$$

To use Eqs. 22 and 23 for prediction, we need to infer the hyperparameters $\boldsymbol{\theta}$ in the covariance function k by minimizing the negative log marginal likelihood (NLML) as

$$\boldsymbol{\theta}_{\mathsf{opt}} = \arg_{\boldsymbol{\theta}}\min\ \mathsf{NLML}, \tag{24}$$

where

$$\mathsf{NLML} = -\log \pi(\mathbf{p}|\mathcal{I},\boldsymbol{\theta}) = \frac{1}{2}\mathbf{p}^{\mathsf{T}}[\mathbf{K}(\mathcal{I},\mathcal{I}) + \sigma_s^2 \mathbf{E}_{n_{\mathsf{TP}}}]^{-1}\mathbf{p} + \frac{1}{2}\log|\mathbf{K}(\mathcal{I},\mathcal{I}) + \sigma_s^2 \mathbf{E}_{n_{\mathsf{TP}}}| + \frac{n_{\mathrm{TP}}}{2}\log 2\pi. \tag{25}$$

After inferring $\boldsymbol{\theta}$, GPR can be applied to test data sets.

For brevity, we also state without additional derivation the formulation of a multi-output GPR in which we want to determine a T-dimensional parameter vector. We will assume that we have observations of the multiple parameters that share the same underlying set of training points, i.e., we have one set $\mathcal{I} = \{\mathbf{I}_1, \ldots, \mathbf{I}_{n_{\mathsf{TP}}}\}$ from the input domain and n sets of corresponding output observations $\mathcal{P}_i = \{p_i(\mathbf{I}_1), \ldots, p_i(\mathbf{I}_{n_{\mathsf{TP}}})\}$, each of which organized in a vector $\mathbf{p}_i = [p_i(\mathbf{I}_1), \ldots, p_i(\mathbf{I}_{n_{\mathsf{TP}}})]^\intercal$, and define the concatenated vector $\mathbf{p} = [\mathbf{p}_1^\intercal, \ldots, \mathbf{p}_T^\intercal]^\intercal$. For the MOGP we will furthermore assume that we have a single kernel function k that accounts for the different parameters by different coefficients a_{ii} for the different output parameters. Furthermore using a single underlying kernel function allows us to take correlations between the different output parameters into consideration by defining:

$$\mathbf{K}_M(\mathcal{I},\mathcal{I}) = \mathbf{A} \otimes \mathbf{K}(\mathcal{I},\mathcal{I}) = \begin{bmatrix} a_{11} \cdot \mathbf{K}(\mathcal{I},\mathcal{I}) & \cdots & a_{1T} \cdot \mathbf{K}(\mathcal{I},\mathcal{I}) \\ \vdots & \ddots & \vdots \\ a_{T1} \cdot \mathbf{K}(\mathcal{I},\mathcal{I}) & \cdots & a_{TT} \cdot \mathbf{K}(\mathcal{I},\mathcal{I}) \end{bmatrix} \in \mathbb{R}^{n_{\mathsf{TP}} \cdot T \times n_{\mathsf{TP}} \cdot T}, \tag{26}$$

with $\mathbf{K}(\mathcal{I},\mathcal{I})$ as in the single-output GPR. In this case the prediction mean and variance are given as

$$\hat{g}_{\mathbf{p}}(\mathbf{y}) = \mathbf{K}_M(\mathbf{y},\mathcal{I})^\intercal \left[\mathbf{K}_M(\mathcal{I},\mathcal{I}) + \boldsymbol{\Sigma}_s\right]^{-1} \mathbf{p}, \tag{27}$$

and

$$\boldsymbol{\Sigma}(\mathbf{y}) = \mathbf{K}_M(\mathbf{y},\mathbf{y}) - \mathbf{K}_M(\mathbf{y},\mathcal{I})^\intercal \left[\mathbf{K}_M(\mathcal{I},\mathcal{I}) + \boldsymbol{\Sigma}_s\right]^{-1} \mathbf{K}_M(\mathbf{y},\mathcal{I}), \tag{28}$$

respectively. Here

$$\boldsymbol{\Sigma}_s = \sigma_s^2 \mathbf{E}_{n_{\mathsf{TP}}} \otimes \mathbf{E}_T \in \mathbb{R}^{n_{\mathsf{TP}} \cdot T \times n_{\mathsf{TP}} \cdot T},$$

and $\mathbf{K}_M(\mathbf{y},\mathbf{y})$ and $\mathbf{K}_M(\mathbf{y},\mathcal{I})$ are defined analogous to the single-output case taking into account Eq. 26. Note that in the learning phase of the MOGP we therefore need to determine the entries $\{a_{ij}\}_{i,j=1,\ldots,T}$ of the matrix $\mathbf{A}$ in addition to the kernel's hyperparameters $\boldsymbol{\theta}$. However, requiring the matrix to be symmetric and positive semi-definite helps to reduce the total number of floated variables.

4. TRAINING AND VALIDATION DATA

4.1 Methodology

For the two ML approaches, RBF and GPR, the simulation data will be treated as if these data are computationally expensive, while utilizing over 1000 library points on a grid in library look-up as a comparison. For the ML approaches, this data scarcity will appear similar to Fig. 3, except that at each n_{TP} the actual points in the parameter space will be varied at each realization. Specifically, for $n_{\mathsf{TP}} = 16, 32, \ldots, 128$ there are 112 realizations for each of five values of the simulated "measurement" noise $\sigma_{\mathsf{noise}} = 10^i, i = \{-6, \ldots, -2\}$ where the incident intensity $I_0 \equiv 1$. For $n_{\mathsf{TP}} = 256$, the number of realizations is smaller, between 64 and 80. In training and validation, $\sigma_{\mathsf{meas}} \equiv \sigma_{\mathsf{noise}}$. For all methods, this noise is applied to the validation data while for RBF and library-look up, it is also used in the formation of the matrix $\mathbf{V}^{-1}$.

As can be inferred from the small markers in Fig. 3, the simulation data library is not equally distributed throughout the simulation domain. In each realization, the validation set is indexed randomly while the n_{TP}

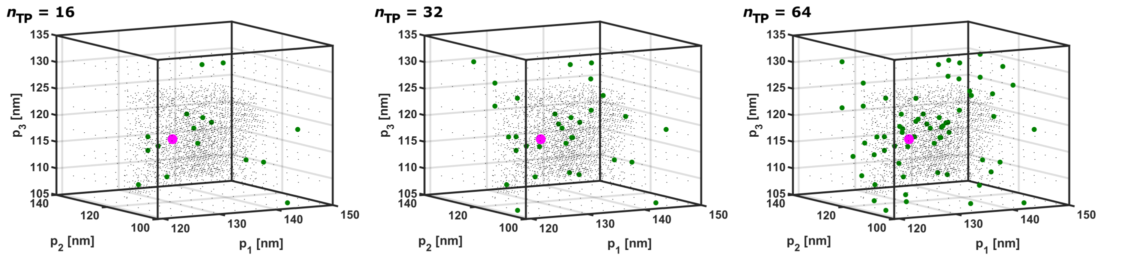

Figure 3. Examples of data scarcity in the simulation space. Validation, training points vary among n_{TP} except in Sec. 4.4
.

training data are selected through draws of random values for the parameters, normally distributed about the center of the simulation domain. With each triplet of values drawn, the closest library entry is indexed. If the candidate index matches the validation point or is repeated, a new candidate is drawn until n_{TP} points are determined.

Two key metrics are required to evaluate these approaches. It is clear that the parametric uncertainties of each parameter must be compared against each other, as well as the parametric values. A single value for comparing the accuracy among the methods can be taken from the GPR literature,[19] the relative average absolute error (RAAE). The RAAE is defined for a general function $f(\mathbf{x})$ and its expectation value $\hat{f}$ as

$$\text{RAAE} = \frac{\Sigma_{i=1}^{n_{\mathsf{TP}}} |f(\mathbf{x}_i) - \hat{f}(\mathbf{x}_i)|}{n_{\mathsf{TP}} \times \sigma(f_{\mathsf{train}}(\mathbf{x}))}, \tag{29}$$

where $\sigma(f_{\mathsf{train}}(\mathbf{x}))$ is the standard deviation of the training data.

In the analysis that follows, the RAAE and parametric uncertainties are compared after hundreds of realizations. Fig. 4 illustrates one such metric, the uncertainty in p_2 computed using all entries in the library look-up at $\sigma_{\mathsf{noise}} = 10^{-3}$. To compare among the different approaches, bar and whisker plots will illustrate the distribution of the RAAE and uncertainty from the training and validation steps and the parametric values from RBF and GPR in the testing step.

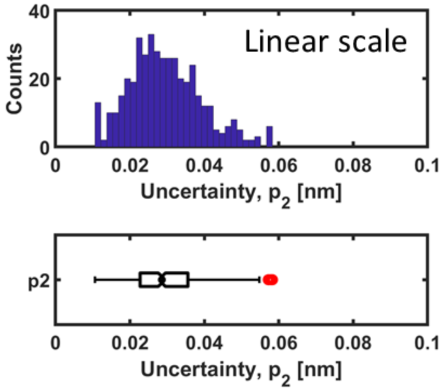

Figure 4. (top) Histogram of uncertainty values from library look-up for $\sigma_{\mathsf{noise}} = 10^{-3}$. (bottom) Example box-and-whisker plot for quickly conveying the distribution from these multiple realizations. In this work, lower and upper box edges show the 25th and 75th percentiles respectively (q_{25}, q_{75}); narrowest notch point is the median (50th percentile); minimum whisker length extends to the outermost data point beyond the box (see left side) while maximum whisker length is $1.5 \times (q_{75} - q_{25})$ (see right side); each outlier beyond the whisker range is shown individually using a symbol.

4.2 Accuracy

The accuracy of the library look-up mode is illustrated at the bottom of in Fig. 4. These data are to be compared against the resulting RAAE values from RBF and GPR as functions of n_{TP} with $\sigma_{\mathsf{noise}} = 10^{-3}$.

Figure 5 shows that for this three-parameter model and sample, only $n_{\mathsf{TP}} \geq 32$ is required to attain a lower (thus better) RAAE than from library look-up. Both the augmenting of the regression through RBF and the indirect use of simulation data through GPR allow far fewer simulations for improved validation set accuracy over the more straightforward conventional approach. Accuracy as expected improves with increases in n_{TP}. Values for the RAAE between GPR and RBF are similar.

4.3 Uncertainty

The major difference observed in this investigation is among the uncertainties in the validation set. As seen in Section 3, both the estimated parametric mean and parametric uncertainties can be determined from RBF and GPR without disregarding correlations among parameters.

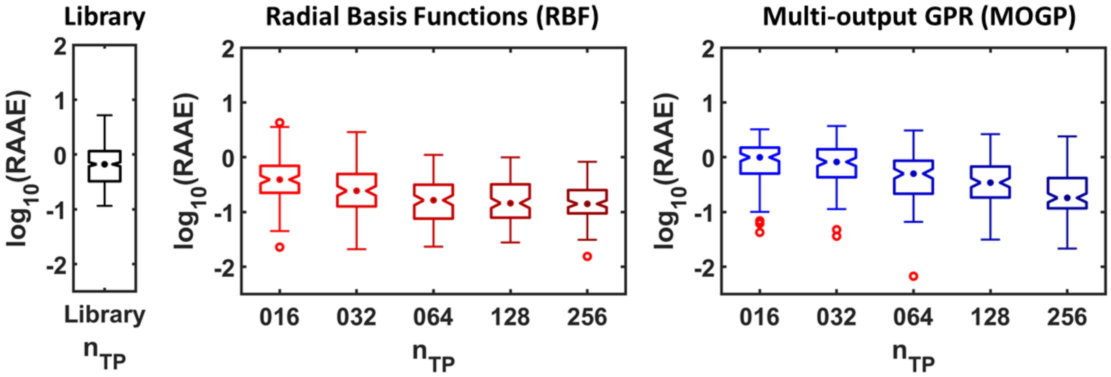

Figure 5. Accuracy of RBF and GPR versus library look-up as a function of n_{TP} for these training and validation data. In general, increasing n_{TP} decreases RAAE, indicating improved accuracy. If notches between any two of these box plot do not overlap, one may conclude that their two medians differ with 95 % confidence.

A key test is the scaling of the uncertainty with the measurement noise. As also established in Section 3, the measurement uncertainty is incorporated into the covariance matrix for both library look-up and RBF such that the parametric uncertainties should scale linearly with σ_{noise}. However, σ_{noise} only indirectly enters into the estimation of the covariance matrix through the application of this noise to the ”measurement” data. It was uncertain if this would translate into changes in uncertainty.

In Fig. 6, the expected behavior is observed from library look-up and RBF. Furthermore, the RBF interpolation consistently appears to reduce the uncertainty relative to library look-up by about two orders of magnitude. However, it is unclear if the measurement noise affects the GPR similarly. Here, there is a slight uptick in uncertainty between $\sigma_{\mathsf{noise}} = 10^{-3}$ and $\sigma_{\mathsf{noise}} = 10^{-2}$, but the uncertainty remains unchanged for $\sigma_{\mathsf{noise}} \leq 10^{-3}$. Notably, GPR yields a higher estimate of the uncertainty than either library look-up or RBF interpolation, suggesting a near constant factor in the uncertainty that is independent of measurement noise except for large values of σ_{noise}. Note also, training of the RBF involves solving for both $\mathbf{A}$ in Eq. 13 and hyperparameter r from Eqn. 11, a total of $1 + (t \times n_{\mathsf{TP}})$ parameters, while here GPR training solves for the two hyperparameters σ and l in Eqn. 20. Incorporating additional hyperparameters in the GPR might positively influence the uncertainty from GPR.

4.4 Monte Carlo Assessment of GPR Uncertainty

To assess this nature of the uncertainty estimated from GPR, the numerical experiment was repeated for the multi-output GPR, but instead of picking a new subset of points from the library of size n_{TP} on each realization,

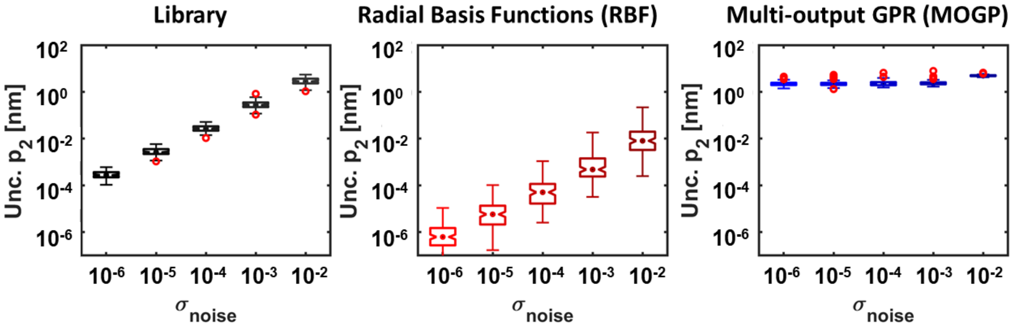

Figure 6. Uncertainty of parameter 2 (middle width) of RBF and GPR versus library look-up as a function of σ_{noise} for these training and validation data. As intensities have been normalized to the incident intensity, σ_{noise} is also unitless.

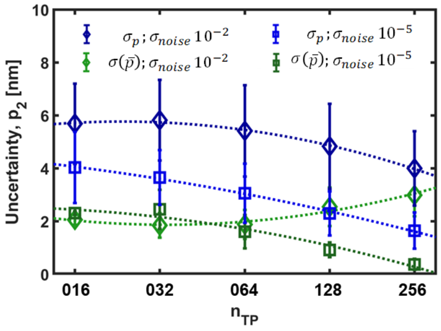

Figure 7. Comparisons of the variance of the middle width estimated by the GPR, σ_p^2, to the variance of the middle width $\sigma^2(\bar{\mathbf{p}})$ from Monte Carlo as a function of n_{TP}, the number of training points. Error bars are one standard deviation from 112 realizations.

multiple realizations were performed using the exact same points at each realization for n_{TP} points. Furthermore, as n_{TP} increased, the previous points were retained. That is, there were not new random draws for $n_{\mathsf{TP}} = 64$ compared to $n_{\mathsf{TP}} = 32$ but rather the subset for $n_{\mathsf{TP}} = 64$ contained 32 new points as well as the points considered at $n_{\mathsf{TP}} = 32$ (which also contained the points for $n_{\mathsf{TP}} = 16$.) For all these simulations, the validation point also remained the same with only its measurement noise varied on each realization, applied at each of the experimental measurement conditions $\boldsymbol{\omega}_1, \ldots, \boldsymbol{\omega}_t$ independently assuming a Gaussian distribution. GPR was performed for 112 realizations for each combination of n_{TP} and σ_{noise}. This approach not only allows the estimation of the posterior mean with its variance, $\sigma(\mathbf{p})$, but also allows computation of the variance of the mean parametric value $\bar{\mathbf{p}}$, or $\sigma^2_{\bar{\mathbf{p}}}$. The uncertainties are shown in Fig. 7 for $\sigma_{\mathsf{noise}} = 10^{-2}$, a relatively large amount of measurement noise and also a much lower value, $\sigma_{\mathsf{noise}} = 10^{-5}$.

Figure 7 illustrates a nearly factor of two difference between the uncertainties $\sigma(\bar{\mathbf{p}})$ and σ_p for low noise. From this additional investigation, GPR as presented here may overestimate its variance except for high noise and a relatively large number of training points. Note that the mean of the parameter estimate only approaches zero for low noise and $n_{\mathsf{TP}} = 256$. Additional work is required to further close the two orders-of-magnitude or more gap in uncertainties between RBF and GPR observed in Fig. 6.

5. RBF AND GPR TESTING

With the discrepancies among RBF and GPR uncertainties, only the parametric values will be considered from these testing results. The experimental measurement noise varied for each measurement condition $\boldsymbol{\omega}_1, \ldots, \boldsymbol{\omega}_t$ but on average, with the incident intensity $I_0 \equiv 1$, the magnitude fell between $\sigma_{\mathsf{noise}} = 10^{-2}$ and $\sigma_{\mathsf{noise}} = 10^{-3}$, for reference.

In Ref.[8] three specific target dies were measured and reported. For consistency, these same three die are measured here using the library look-up and ML approaches. In Fig. 8, the library look-up value is plotted as the dotted line in each individual panel. The leftmost column shows the measurement from each of the die and its label as identified in Ref.:[30] Dies (-1,-1), (0,0), and (1,1). The top row for each die shows the GPR fits to the three parameters identified in Fig. 2, while the bottom row for each die shows the RBF results. For Dies (1,1) and (0,0), the ML-based fits generally agree with the conventional library look-up approach.

Notable problems appear for the RBF fits for the third die, Die (-1,-1). Noted with ellipses on the bottom-most row, there is strong evidence of the distribution of parametric value splitting into two values across the range of n_{TP}. This is highly indicative of an additional local minimum to the weighted χ^2 fitting. Fortunately, the literature has shown a path towards a remedy in two steps. First, in the documentation to Ref.,[20] it is clear that the optimal parameter from RBF can be evaluated using and

$$\hat{\mathbf{p}} = \operatorname{argmin}\left[\left(\widetilde{\mathbf{f}}_{\mathbf{I}}\left(\mathbf{p}\right) - \mathbf{y}\right)^{\mathsf{T}} \mathbf{V}^{-1} \left(\widetilde{\mathbf{f}}_{\mathbf{I}}\left(\mathbf{p}\right) - \mathbf{y}\right)\right]. \tag{30}$$

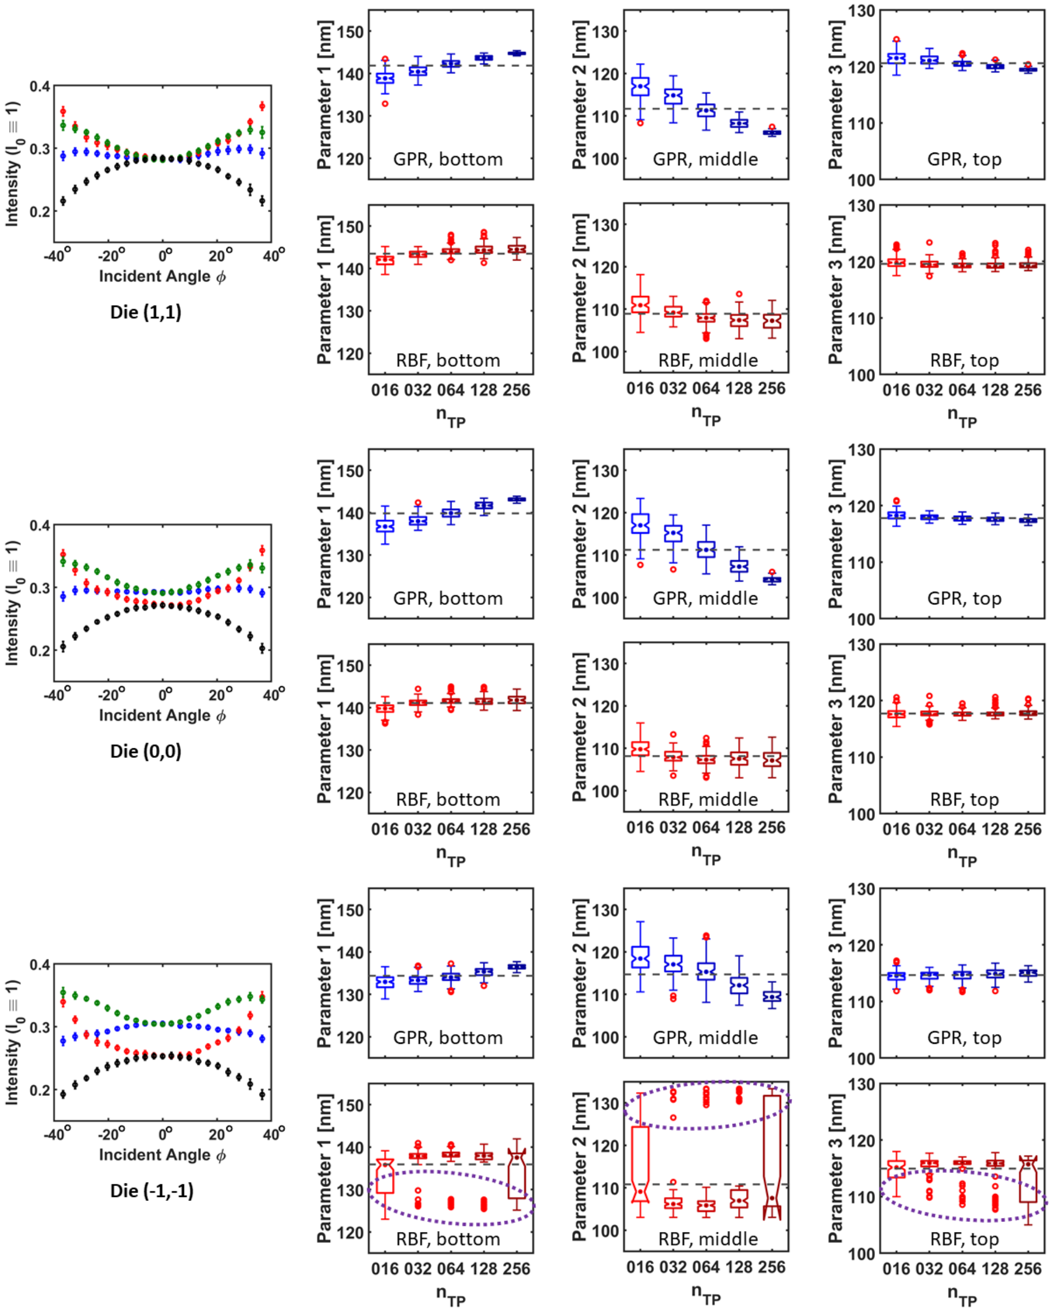

Figure 8. Realizations of the RBF and GPR compared to current library look-up best-fit values. In the left column, measurement error bars are 1σ uncertainties. Box and whisker plots follow definitions in Fig. 4. Ellipses in the bottom-most row indicate the presence of an additional local minimum in the global optimization.

Second, it has been reported that for Bayesian optimization, an objective function can be added to the maximum posterior estimate by means of Bayes' theorem as prior knowledge about non-physical self interactions (e.g., to prevent nonphysical geometries).[17] While the parametric values at this local minimum are physical, they contradict our prior knowledge of these samples from SEM and AFM measurements, and a similar penalty term can be applied. No such function was applied here to illustrate the challenges even for RBF of the inverse problem.

6. CONCLUSION

The need for robust, quantitative machine learning remains especially as sample complexity, improved electromagnetic modeling, and added parameters increase electromagnetic simulation time. While ML can add computational time, this may be smaller in comparison to simulation requirements. Two general approaches have been analyzed, with RBFs augmenting the use of simulated data, while GPR as presented was used to avoid direct application of simulation data. Conventional and ML techniques proved to generally agree on parametric values, but it is clear from the validation steps that uncertainties from GPR here are more problematic than those from RBFs. Testing on experimental data yielded general agreement but a local minimum complicated the fitting in RBF. There are potential solutions to be found for decreasing GPR uncertainty and for constraining the range of allowed fits in RBF due to prior information. These both suggest that additional study is warranted.

Work in Progress: Towards Usable Updates for Smart Home Devices

Julie M. Haney and Susanne M. Furman

National Institute of Standards and Technology (NIST)**, Gaithersburg, MD, USA
{julie.haney, susanne.furman}@nist.gov

Abstract. ***Background.*** Smart home device updates are important tools for remediating security vulnerabilities.
Aim. We aim to understand smart home users' perceptions of and experiences with updates.
Method. We interviewed 40 smart home users and analyzed a subset of data related to updates. We are also planning a broader, follow-on survey.
Results. Users experienced inconsistency in update transparency and methods, were confused about how and if updates are applied, and seldom linked updates to security.
Conclusion. Our efforts will provide a new understanding of smart home updates from a usable security perspective and how those are similar/different to views on updates of conventional IT.

Keywords: Smart home · Updates · Cybersecurity · Usability.

1 Introduction

Internet of things (IoT) smart home updates are a critical mechanism by which manufacturers can distribute patches to remediate security vulnerabilities. Updates may be one of the few tools users have to secure their devices since other configurable security options are limited or unavailable. Unfortunately, technologists have found that update mechanisms may be inconsistent across devices [8]. Even among security professionals, the number one threat to IoT was viewed as "difficulty patching Things, leaving them vulnerable" [16]. Despite technology experts identifying issues, the user perspective on smart home updates has not yet been fully explored.

To better understand experiences and challenges with smart home updates, we analyzed a subset of data from a broader, in-depth interview study of 40 smart home users aimed at investigating general experiences with, perceptions of, and opinions about smart home devices, including aspects of privacy and security. This paper focuses on analysis of update-related data only. By exploring this subset of the interview data, we begin to gain insights into perceptions and

** Certain commercial companies/products are identified in this paper to foster understanding. This does not imply recommendation or endorsement by NIST.

Haney, Julie; Furman, Susanne M. "Towards Usable Updates for Smart Home Devices." Paper presented at 10th International Workshop on Socio-technical Aspects in Security, Guildford, UK. September 17, 2020 - September 17, 2020.

usability of smart home updates, including what role, if any, users perceive updates as playing with the security of their devices. Preliminary analysis suggests that users experience inconsistency in update transparency and methods, as well as confusion about how and if updates are applied. More concerning, most study participants did not relate smart home device updates to security, so they might not have been as inclined to install updates immediately.

Since updates were not a major focus of the interview study, we wish to delve deeper into user update experiences and perceptions, especially on a per-device basis. To that end, we are planning a follow-up survey to gather responses from a broader population of smart home owners. When completed, we hope our research will have several contributions. We will provide novel insights into end user perceptions, experiences, and challenges with updates within the context of smart home devices from both a usability and security perspective. In addition to identifying similarities to prior research focused on updates of other types of computing devices, we hope to discover ways in which smart home device updates may be different or more challenging. Our results may also inform the design of smart home device update mechanisms and notifications to provide a more usable platform for deploying critical security patches when necessary.

2 Related Work

2.1 User Update Behaviors

While no prior studies have explored update behaviors for smart home technologies, researchers have investigated these behaviors for other information technology (IT). People delay software updates for a number of reasons, including a lack of awareness of the upgrade value; interruption of computing activities; and possible negative consequences of applying the update [6, 18]. Users may also have a difficult time understanding the relationship between software updates and security [6]. Ultimately, users must balance the risk and costs of updating against potential benefits [19].

2.2 IoT Updates

A number of critical security vulnerabilities for smart home devices have been identified in recent years, highlighting the need for timely updates [2]. However, there are unique challenges to IoT updates [9]. IoT manufacturers may be inexperienced with security feature and update mechanism design. Economic incentives for providing updates and long-term support for inexpensive and disposable devices may not exist, leaving devices vulnerable to attack. NIST discovered that information on IoT updates is not always readily available to consumers and that updates are not always done in a secure manner [8]. From a technology perspective, IoT devices are often memory, processor, and battery constrained, making updates more challenging to deploy while managing integrity and confidentiality of the updates and potential software dependencies [1, 11, 12].

Several researchers focused on security labels for IoT products. Emami-Naeini et al. [4] showed consumer openness to IoT privacy and security labels, including update information. Morgner et al. [15] investigated consumer preferences for security update information on mandatory IoT product labels. They concluded that security update labels, especially those focused on the availability period (how long the manufacturer guarantees to provide updates) may have a significant impact on consumer product selection.

Although the technical limitations of IoT updates and potential of labels have been discussed, to the best of our knowledge, no prior literature addresses potential usability issues with *smart home* updates through the eyes of consumers, a gap our study hopes to address. Lin and Bergmann [14] suggested that smart home devices should implement updates with little or no user intervention. Emami-Naeini et al. [4] interviewed smart home users, noting that most desired automatic updates because of convenience. However, they made no further observations for recommendations with respect to updates. Other researchers explored user perceptions of smart home privacy and security but did not discuss updates(e.g., [17, 21, 20].

3 Methodology

From February to June 2019, we interviewed 40 smart home users to understand their perceptions of and experiences with smart home devices. NIST's Research Protections Office approved the study. Prior to the interviews, we informed participants of the study purpose and how data would be protected with generic identifiers (e.g., P14_U) not linked to individuals.

3.1 Participant Recruitment and Demographics

We hired a consumer research company to recruit adult users of smart home devices from a database of individuals living in a large U.S. metropolitan area who had agreed to be contacted about research opportunities. To determine eligibility, prospective participants completed an online screening survey about their smart home devices, their role with the devices (e.g., administrator, user), and other demographic information. After reviewing the screening information, we selected participants if they were active users of at least two different types of smart home devices. In line with current interview compensation rates in our region, participants were given a $75 prepaid card.

Participants had diverse professional backgrounds with only eight in an engineering or IT field. Thirty-two of the 40 participants had installed and administered their devices (indicated with an A after the participant ID), and eight were non-administrative users of the devices (indicated with a U). Fifty-five percent were male and 45% were female. Seventy percent were between the ages of 30 and 49. Participants were highly educated with 45% having a master's degree or above and another 50% with a BS/BA. All but one participant had three or more individual smart home devices, with 38 having three or more different categories of devices.

Haney, Julie; Furman, Susanne M. "Towards Usable Updates for Smart Home Devices." Paper presented at 10th International Workshop on Socio-technical Aspects in Security, Guildford, UK. September 17, 2020 - September 17, 2020.

3.2 Data Collection and Analysis

We developed a semi-structured interview protocol covering several topics: purchase and general use; installation and maintenance (including updates); privacy; security; and safety. In this paper, we focus only on data related to updates. An IoT content expert who had professionally worked on IoT security in addition to having an extensive, custom smart home, reviewed the interview questions to ensure the use of correct terminology and the consideration of appropriate aspects of smart home ownership. We piloted the interview with four smart home owners from our institution (two device administrators and two non-administrators/users) to determine face validity of questions and language. Based on feedback from the content expert, we added questions for potential "do-it-yourself" users who customize smart home software and hardware to their own specifications (e.g., via writing custom code). After the pilots, minor adjustments were made to to simplify the wording of several questions. Because modifications were minor, the pilot interviews were included in our analyzed data set. After the protocol was finalized, we collected data via 36 additional semi-structured interviews (40 interviews total including pilots) lasting on average 41 minutes. Interviews were audio recorded and transcribed.

We analyzed the interview data using both deductive and inductive coding practices. Initially, each member of the research team individually coded a subset of four interview transcripts using an *a priori* code list based on research questions and open coded for additional concepts as needed. We then met to discuss codes and develop a codebook. Coding then continued until all transcripts were coded by two researchers, who then met to examine and resolve differences in code application and identify relationships and central themes.

4 Methodology

From February to June 2019, we interviewed 40 smart home users to understand their perceptions of and experiences with smart home devices. NIST's Research Protections Office approved the study. Prior to the interviews, we informed participants of the study purpose and how data would be protected with generic identifiers (e.g., P14_U) not linked to individuals.

4.1 Participant Recruitment and Demographics

We hired a consumer research company to recruit adult users of smart home devices from a database of individuals living in a large U.S. metropolitan area who had agreed to be contacted about research opportunities. To determine eligibility, prospective participants completed an online screening survey about their smart home devices, their role with the devices (e.g., administrator, user), and other demographic information. After reviewing the screening information, we selected participants if they were active users of at least two different types of smart home devices. In line with current interview compensation rates in our region, participants were given a $75 prepaid card.

Participants had diverse professional backgrounds with only eight in an engineering or IT field. Thirty-two of the 40 participants had installed and administered their devices (indicated with an A after the participant ID), and eight were non-administrative users of the devices (indicated with a U). Fifty-five percent were male and 45% were female. Seventy percent were between the ages of 30 and 49. Participants were highly educated with 45% having a master's degree or above and another 50% with a BS/BA. All but one participant had three or more individual smart home devices, with 38 having three or more different categories of devices. Appendix B has more detailed demographics along with the types of devices owned by each participant.

4.2 Data Collection and Analysis

We developed a semi-structured interview protocol covering several topics: purchase and general use; installation and maintenance (including updates); privacy; security; and safety (Appendix A). In this paper, we focus only on data related to updates. An IoT content expert who had professionally worked on IoT security in addition to having an extensive, custom smart home, reviewed the interview questions to ensure the use of correct terminology and the consideration of appropriate aspects of smart home ownership. We piloted the interview with four smart home owners from our institution (two device administrators and two non-administrators/users) to determine face validity of questions and language. Based on feedback from the content expert, we added questions for potential "do-it-yourself" users who customize smart home software and hardware to their own specifications (e.g., via writing custom code). After the pilots, minor adjustments were made to to simplify the wording of several questions. Because modifications were minor, the pilot interviews were included in our analyzed data set. After the protocol was finalized, we collected data via 36 additional semi-structured interviews (40 interviews total including pilots) lasting on average 41 minutes. Interviews were audio recorded and transcribed.

We analyzed the interview data using both deductive and inductive coding practices. Initially, each member of the research team individually coded a subset of four interview transcripts using an *a priori* code list based on research questions and open coded for additional concepts as needed. We then met to discuss codes and develop a codebook. Coding then continued until all transcripts were coded by two researchers, who then met to examine and resolve differences in code application and identify relationships and central themes.

5 Preliminary Results

5.1 Update Modes and Notifications

The interviews revealed that update modes may vary from smart home device to device, with some updating automatically and others requiring users to manually initiate updates. In addition, participants discovered available updates in different ways depending on the device. A participant who owned multiple devices said: *"Some of them notify me, others update automatically, and others I'll find out about either through an email or just because I'm kind of monitoring technology news in general"* (P15_A). Another commented:

> *"Some devices will send me a text message... saying that we're going to be updating a device at this time, and it will apply the updates automatically. Other devices, I need to go into their own specialty apps and check what firmware is running and then check for an update. Some devices, I actually have to go to a website and download something, and then my phone, for instance, will update the device"* (P11_A).

Smart home devices that notify users of available updates do so in a variety of ways. Notifications "pushed" to the device's user interface or via the companion app before or after update installation are most common. For example, an owner of a smart doorbell explained how she finds out about updates: *"I see an alert. It says, 'Your Ring doorbell has a new update. Do you want to allow it? Do you want to accept it?' "* (P36_A). Several participants received emails alerting them of available or just-installed updates. Some devices with screen interfaces, such as smart thermostats and televisions, displayed the update notification directly on the device itself. Other smart home owners did not receive push notifications to tell them updates were available. Rather, they had to manually open the companion app and check.

5.2 Update Purpose and Urgency

Participants most often viewed updates as fixing or adding non-security functionality. For example, one participant stated, *"I accept all updates because I believe they'll make things more functional, add new features that I didn't have before"* (P36_A). Interestingly, this perception led to mixed feelings regarding the urgency of applying updates. Several participants who had experienced issues with their devices believed updates were a high priority. A participant who owns a smart video doorbell and security cameras noted that smart home devices *"would have the highest priorities than any of the other apps on my phone... because that's the security of my home"* (P31_A). Another participant talked about experiencing frequent glitches with his devices. Therefore, he viewed regular updates to his devices as being critical:

> *"To me it's not a choice for, at least, internet of things. Sometimes for my computer, I don't update as soon as they tell me I should. I wait for a while to see if anybody reports bad bugs with the new update. I feel that I have to [for a smart home device] in order for it to work at its best"* (P13_A).

However, others thought updates to functionality were lower priority or unnecessary as long as the device appeared to be working properly. A participant described her indifference with respect to updates, *"I don't think that the end user actually really cares. As long as the thing works, it works"* (P40_U). Other participants did not feel they could properly assess the criticality of the update because the manufacturer did not reveal the purpose of the update: *"The information on what the update achieves is unclear"* (P31_A).

5.3 Uncertainty about Update Status

Participants reflected that they may not observe update notifications, do not recall setting an option to automatically install updates, or are not sure if there are configurable options for setting update parameters. These inconsistencies may lead to a sense of uncertainty about whether their devices are being updated or even can be updated. One user remarked about his virtual assistant, *"I don't know when it's [virtual assistant] doing its updates. Like ever. They never ask me. They never prompt me"* (P7_A).

Some participants assumed that the lack of notifications meant that updates must be happening automatically. While possibly true with some devices, this assumption might be flawed for other products. A participant lamented, *"They don't notify me when there's an update. I guess I just kind of assume that they happen as they go. You would think that I'd get an email, but I guess I don't. That might be nice" (P23_A).*

Even though users may have an assumption of automatic updates, the uncertainty due to lack of notification leaves some with a sense of discomfort. For example, one participant stated: *"I'm assuming that updates are being done silently in the background. I don't really know, and it sort of gives the impression that you bought this thing and it's not evolving. . . that it's not expanding and getting new updates"* (P24_A).

5.4 Updates to Apps vs. Updates to Devices

In addition to uncertainty about update status, the interviews revealed that participants often conflated updates to smart home device companion app software (typically installed on a smartphone) with updates to device firmware. They did not realize that updates to apps were not necessarily accompanied by device updates and vice-versa. This was evidenced by participants referencing typical smartphone app update indicators when asked how they know smart home device updates are available. For example, a user of an Android-based phone explained, *"I get a notification. It doesn't say specifically which apps need to be updated. It just says 48 apps need to be updated. Then I go into Google Play, and see my apps, and individually determine which ones I want to update"* (P31_A).

5.5 Update Concerns

Even when update availability was visible, participants voiced concerns about updates causing issues or breaking functionality on their smart home devices. For example, one participant voiced frustration with updates to his smart televisions: *"I've had to reset my TVs many times because the software update didn't work or kind of messed things up"* (P10_A). Updates also have the potential to invalidate previous user configuration settings or necessitate new ones: *"as they come out with updates, particularly significant updates that change the interface, for example, that might be cause for me to go back in and redo some of the settings"* (P15_A).

Two participants expressed concerns about a lack of updates should a manufacturer stop supporting a product. One of these commented,

> *"I would hope that over time the companies that support these devices would continue to update their firmware and basically make them more reliable. I think in some cases that's happened, but I think in other cases the devices just get abandoned"* (P11_A).

5.6 Relationship to Security

Although some updates can be a conduit to fix security vulnerabilities in smart home devices, study participants rarely linked updates to security, with only five mentioning updates in the context of security. Most discussed updates in terms of fixing functionality or adding features. When asked what mitigation actions they take to address any security concerns they might have, only three mentioned applying updates or upgrading products.

Interestingly, two participants recognized the importance of applying updates, but were also concerned about potential security-related consequences. One participant liked that updates to his devices could be done via the internet, but at the same time was concerned because *"it means that someone's reaching in... There's some kind of access from the outside"* (P26_A). Another saw potential for updates to weaken security:

> *"I guess one area where I would be worried about would be adding features that may threaten my privacy and security... I would want to know that the update also gave me the capability of disabling or turning off that feature I might be concerned about"* (P15_A).

6 Discussion

6.1 Comparison to Traditional Updates

We note similarities between our results and those from previous research studies in Related Work. Similarities included: a lack of awareness of the importance of applying updates; a lack of information about the update purpose hindering users' ability to weigh risk and cost against potential update benefits; concern about possible negative consequences of applying updates; and concern about surprise new features being added.

Although similarities exist, we identified several differences in user experiences with smart home updates as compared to updates explored in prior studies. We did not find evidence of concerns about interruption, likely because users do not have the same kind of interactive sessions with smart devices as they would on a tablet, phone, or computer. Our findings additionally suggest that, because devices are often controlled with a mobile companion app, some updates may be overlooked since several participants did not understand the difference between a phone update, an app update, and a device update. We also discovered that participants were concerned about manufacturers discontinuing product support (and therefore, no longer issuing updates) due to the dynamic smart home market. As opposed to updates for more-familiar and widely-used operating systems, applications, and hardware (e.g., those from Apple and Microsoft), our participants were often unaware if updates were available, how to configure automatic updates, or how to check update status. Confusion about update mechanisms may be amplified by the number of smart home devices users own, especially if the products are from various manufacturers with different update models and different modes of notification.

We also acknowledge that the update experience for smart home devices may necessarily have to be different than traditional IT updates because of processing/memory constraints and limited interactive interfaces. Therefore, more research is warranted to investigate a suitable, usable update interface that can accommodate device limitations.

6.2 Informing Usable Updates

Study results may inform more usable update interfaces and mechanisms. Although our focus was on home users, improved update usability can also be especially valuable for IoT administrators in organizations who have to maintain large numbers of devices.

Insufficient information about the purpose and benefit of updates may result in users lacking a sense of urgency about applying updates, especially if devices appear to be working fine. Users may also be uncertain about update status and availability. To help users make informed decisions, manufacturers could provide greater transparency of update purpose and importance of applying an update (perhaps via a criticality rating), which is in concert with Vaniea and Rashidi's recommendation for easy-to-find information on updates [19]. As also recommended by other standards and government organizations [9, 5, 3, 7], manufacturers could be more forthcoming about their update model and support so that users are aware of how update availability will be made known, what actions users should take to install updates, what update configuration and notification options (if any) are available, and how manufacturers will handle discontinuation of product support. Some of these update attributes were addressed in prior work on product labels [4, 15] and showed promise in impacting consumer purchase decisions and providing transparency. However, more research needs to be done to determine whether consumers would even read the labels.

In addition to lack of transparency, many of our participants expressed discomfort or frustration with updates and their ability to control them. Providing additional information on updates can help users feel more confident in their update decisions. In addition, manufacturers could provide options for users to configure automated updates (as recommended in [14]) with configurable notifications of success afterwards. Users could be given options to schedule if and when they receive notifications. To mitigate concerns that updates might break the device or result in unwanted features or settings, devices could support a rollback mechanism, as recommended by others [8, 13, 19]. Users may then be more likely to install an update if they have a way out should there be a problem.

Although we identified issues related to lack of transparency, it must be noted that it is currently unclear as to whether or not consumers would actually read any additional information or in what format they would wish to receive the information. In addition, too much information could be overwhelming and result in user frustration or users just ignoring the information. Therefore, future research should be done to account for consumer preferences.

7 Limitations and Planned Future Work

In addition to typical limitations of interview studies (e.g., self-report and social desirability biases), our study results may have limited generalizability. Our sampling frame of mostly well-educated individuals living in a high-income region in the U.S. may not be fully representative of the global smart home user population. However, our participant population does appear to typify early adopters of smart home devices as identified in industry surveys (for example, [10]).

Our interview study was meant to be exploratory with a goal of identifying areas warranting additional investigation. As such, the interview protocol was broad in covering multiple aspects of smart home ownership and did not focus solely on updates. We also did not ask about updates on a per-device basis (just generally), so are not able to determine if there are different perceptions or experiences depending on the type of device and manufacturer and if some devices are doing a better job at updates than others.

In recognition that more research should be done to delve deeper into users' smart home update experiences, we are in the initial planning phase for an online, quantitative survey of a larger, more diverse sample of smart home users. In addition to asking more questions about perceptions of updates (e.g., importance, purpose), we will obtain per-device experiences and explore what kind of options, if any, users would like in order to gain greater insight and control of update mechanisms. We will also investigate users preferences for update-related information, e.g., what kind of information they would like to receive (if any at all) and desired formats and communication mechanisms.

A Interview Questions

SECTION A: TERMINOLOGY

1. You may have heard the term "internet of things," or IoT for short. Can you talk a little about what you think the internet of things is?
2. You may have heard the term "smart devices." What about devices makes them "smart?"
3. What does it mean to have a smart home?
4. What do you think is the relationship, if any, between the internet of things and smart devices?

SECTION B: PURCHASE & GENERAL USE

[Review list of smart home devices before beginning this section.]

5. Who was involved in the decision to purchase the smart home devices?
6. What are the reasons the smart home devices were purchased?
   - How did you (or a household member) learn about the devices before buying them?
7. What hesitations, if any, did you have about getting the devices prior to purchase?
8. For what purposes do you use your smart home devices?
9. How do you access the devices – remotely with an app, while physically in the home, or both?
   - *If using a virtual assistant:* How do you access your devices using [insert assistant name]?
   - *If using a hub:* Do you use the hub app to access your devices, or do you use an individual app specific to each device?
10. How do others in your household use the smart home devices?
11. What do you like most about the devices? What are the benefits, if any, of having these devices?
12. What do you like least or dislike about the devices?
13. How have your opinions or expectations of the devices changed, if at all, from the time you first used them until now?
14. What concerns, if any, do you have about the devices?
15. In what ways, if any, have you changed your behaviors because of your smart home devices?
16. In what ways, if any, have you become reliant on your smart home devices?
17. What do the other members of your household think about the smart home devices?
18. Have you had visitors to the home who have had to use the smart home devices?
    - *If yes:* How did they use the devices? What did they think?

19. What smart home devices, if any, have you had in the past, but are no longer using?
    - What are the reasons for no longer using this device?
20. What kinds of things would you like to be able to do with your devices, but haven't, don't know how, or are not sure that you can?
21. What devices would you like to get in the future? For what reasons?

SECTION C: INSTALLATION/TROUBLESHOOTING

22. Who installed the smart home devices?
23. Who administers (configures or maintains) the smart home devices?

For Installers:

24. In general, what was your experience with the installation of the devices?
    - What went well?
    - What didn't go as well?
25. Have you ever had to reinstall a device? If so, what were the reasons for the reinstallation?
26. *If have more than one device:* What has been your experience adding additional devices to the home?

For DIYers:

27. In the screening questionnaire you indicated you build your own or create extensions for your smart home devices and platforms. Can you briefly summarize what you've done?

For Administrators:

28. What configuration changes, if any, have you made to the devices since installation?
    - *If participant makes configuration changes:* How often do you make changes?
29. How do you know that updates are available or needed?
30. How are updates done on your device - automatically or do you have to initiate them?
    - *If manual initiation:* How often do you check for updates?
    - How do you decide whether to update or not update?

For Everyone:

31. How do you try to figure out how to do something new with your devices?
    - What sources do you consult or use?
    - *If have a voice assistant:* What has been your experience, if any, adding new skills to your voice assistant?
32. What kinds of problems, if any, have you encountered while using your smart home devices?
    - How did you go about trying to resolve those problems?

SECTION D: PRIVACY

33. What type of information, if any, do you think the devices are collecting?
    - Which of this information, if any, would you consider to be personal?
34. Where do you think the information goes?
35. In what ways, if any, does your device or the device manufacturer provide a means to control or manage what information is collected and how it is shared?
36. What are your concerns, if any, about how information is collected, stored, and used and who can see that information?
    - In what ways, if any, have you acted to minimize or alleviate some of those concerns?
    - What kinds of actions would you like to be able to take to address your concerns, but haven't, don't know how, or are not sure that you can?
37. Who do you think is responsible for protecting the privacy of information collected by your smart home device?

SECTION E: SECURITY

38. What are your concerns, if any, about the security of your devices?
    - In what ways, if any, have you acted to minimize or alleviate some of those concerns?
    - What kinds of actions would you like to be able to take to address your concerns, but haven't, don't know how, or are not sure that you can?
39. What restrictions, if any, are placed on who in your home can use the devices and what they can do?
40. How do you authenticate to or get into any apps associated with the device?
    - What issues or problems, if any, have you experienced with authentication?
41. Does more than one person in your household use an app to access the same device?
    - Does more than one person use the same account and authentication to access the app?
    - What concerns, if any, do you have with multiple people having access to the app?
42. Who do you think is responsible for the security of your smart home devices?

SECTION F: SAFETY

43. In what ways, if any, do you think the devices contribute to safety?
44. In what ways, if any, do you think the devices might pose a safety risk?

SECTION G: CONCLUSION

45. Is there anything else you'd like to add related to anything we've talked about?

***Abstract*—The Internet of Things (IoT) is being widely adopted in recent years. Security, however, has lagged behind, as evidenced by the increasing number of attacks that use IoT devices (e.g., an arson that uses a smart oven, burglary via a smart lock). Therefore, the transparency and accountability of those devices very often become questionable. To that end, formally verifying the system state of those devices against desirable security rules might be a promising solution. However, there is a significant gap between the high-level IoT security recommendations (e.g., NISTIR 8228, NISTIR 8259, OWASP IoT Security Guidance, ENISA Good Practices for Security of IoT, and UK Code of Practice for Consumer IoT Security), and the low-level IoT system data (e.g., sensor data, logs, configurations). This poster aims to bridge this gap by designing an automated technique to define actionable security rules based on those recommendations and enable the security verification of IoT systems.**

***Index Terms*—IoT, security rules, verification**

I. Introduction

The wide-spread adoption of IoT devices is evident in recent years (with the projections of 75.44 billion devices worldwide by 2025 [11]). Most of those devices, however, are reported to suffer from various security threats due to their implementation flaws and misconfigurations [1], [9], [14]; which often question the accountability and transparency of those devices [1], [7]. To address this concern, verifying the system states of IoT devices against a set of security rules might be a promising solution.

However, the existing security standards, e.g., National Institute of Standards and Technology Internal Reports (NISTIR 8228 [7] and NISTIR 8259 [8]), Open Web Application Security Project (OWASP) IoT Security Guidance [10], UK Code of Practice for Consumer IoT Security [6], and European Union Agency for Cybersecurity (ENISA) Good Practices for Security of IoT [5] are intended more for high-level guidelines than for verifying IoT security. For instance, the recommendation *"ensure proper authentication mechanisms"* from OWASP [10] needs to be instantiated to actionable rules, such as *"no smart door opening without PIN"*.

The existing security solutions (e.g., [2]–[4], [14]) in IoT provide an ad-hoc list of rules for various security solutions, such as, application monitoring, intrusion detection, and access control. However, none of these works develops a generic approach to automatically define actionable rules for verifying IoT device security.

This work targets to overcome this limitation of the existing works, and designs a framework to automatically define actionable security rules for IoT. To this end, we first investigate the existing IoT security standards and identify their limitations in verifying IoT security. Then, we present the design and high-level steps of our proposed framework. Finally, we conclude the current status of this work in progress.

II. Challenges in Defining Actionable Security Rules

We investigate several IoT security standards (e.g., NISTIR 8259 [8], OWASP IoT Security Guidance [10], UK code of practice [6], and ENISA good practices [5]), and identify the following challenges in defining security rules from those standards, as they are not specifically designed for this purpose.

- The recommendations in those standards are too high-level and do not include any system specific information; therefore, for deriving actionable security rules, it is essential to obtain the in-depth system knowledge, and and interpret those recommendations in the context of that system knowledge.
- To verify those recommendations using formal tools requires significant effort including interpreting high-level recommendations to low-level security rules, and preparing these rules (e.g., identifying their data sources, and converting them into formal languages) for security verification.

This work aims to bridge this gap and outline the actionable security rules for verification.

III. Threat Model

We assume that IoT devices may have implementation flaws, misconfigurations, and vulnerabilities that could potentially be exploited by malicious entities to violate security rules. To conduct the verification process, our work relies on a remote server or a local hub/gateway. The communication between the devices and our verification server is secure, using their supported end-to-end encryption mechanisms, e.g., Transport Layer Security (TLS). The privacy threats involved with the data sharing of IoT devices are beyond the scope of this research and will be handled in future research through a privacy-friendly verification technique.

Ibrahim, Kayla; Majumdar, Suryadipta; Bastos, Daniel; Singhal, Anoop. "Defining Actionable Rules for Verifying IOT Safety and Security."
Paper presented at 41st IEEE Symposium on Security and Privacy 2020, San Francisco, CA, US. May 18, 2020 - May 20, 2020.

IV. Approach Overview

Fig. 1 shows the high-level design of our proposed solution.

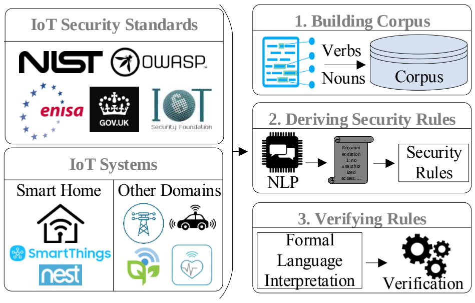

Fig. 1. An overview of our proposed approach

Step 1: Building a Corpus from Security Standards. To build a corpus from the existing IoT security standards, we first parse the contents (i.e., the sections that cover the security guidelines) of those document files. Second, we build a corpus with the relevant terms (i.e., which mainly include the nouns and verbs as those two parts of speech mainly indicate the main message of a recommendation).

Step 2: Deriving Actionable Security Rules. To derive actionable rules, we first extract the key recommendations of those standards by applying several text analytics techniques, such as, term frequency-inverse document frequency (TF-IDF), and natural language processing (NLP) techniques, such as, sentiment analysis [12]. Second, we interpret those key recommendations, apply them in the context of IoT devices, and define actionable security rules for specific cases.

Step 3: Verifying Security Rules. To verify these security rules for actual IoT devices, we translate the actionable security rules into a formal language (e.g., constraint satisfaction problem), collect supporting data for each rule from our smart home testbed, and verify those rules. For verification, we leverage formal verification techniques, e.g., Boolean satisfiability problem (SAT) [13], as it is well-known for its expressiveness, provable security and rigorous results.

V. Preliminary Results

The proposed approach is implemented in a smart home testbed and evaluated for two sample security rules. Fig. 2 shows the total time required for separately verifying the *no unauthorized door opening* and *no image capturing in toilet* security rules. We can easily observe that the execution time is not a linear function of the number of smart homes to be verified. Additionally, our results (not reported here due to space constraint) show that verifying more security rules would not lead to a significant increase in the execution time.

VI. Challenges and Next Steps

While the results of our preliminary experiments indicate the potentiality of leveraging formal tools in IoT security verification, different challenges need to be considered in the next steps of the project. Firstly, the current verification is performed in a remote server, which relies on data sharing and ignores its privacy concerns. Secondly, the Step 2 in Section IV is currently performed manually. Thirdly, there might be domain-specific challenges while adapting our approach in other IoT domains. In the next step, we will explore the feasibility of conducting (fully or partially) the local verification in a hub or gateway; which may require simplifying the workload by developing an incremental approach. Also, we will investigate existing NLP techniques and build an automated technique for Step 2. Finally, we will explore the challenges in applying our approach in other IoT domains.

Abstract. Wireless communication is a key enabling technology central to the advancement of the goals of the Industry 4.0 smart manufacturing concept. Researchers at the National Institute of Standards and Technology are constructing a testbed to aid in the adoption of wireless technology within the factory workcell and other harsh industrial radio environments. In this paper the authors present a new industrial wireless testbed design that motivates academic research and is relevant to the needs of industry. The testbed is designed to serve as both a demonstration and research platform for the wireless workcell. The work leverages lessons learned from past testbed incarnations that included a dual robot machine tending scenario and a force-torque seeking robot arm apparatus. This version of the testbed includes computational and communication elements such that the operation of the physical system is noticeably degraded under the influence of radio interference, competing network traffic, and radio propagation effects applied within the lab. The testbed includes two collaborative grade robot arms, programmable logical controllers, and high-performance computing devices for situational tracking, alerting, and control. The paper is aimed to provide our contribution to the exploration of industrial wireless testbed design while soliciting feedback from fellow researchers.

Keywords: factory communications · wireless · testbed design · smart manufacturing · simulation · IIoT.

1 Introduction

One method for measuring the physical effects of communication loss and information delay within an industrial wireless network (IWN) on manufacturing processes within a workcell is the creation of a testbed for conducting research and demonstrating ideas and technologies using real equipment, control systems, and processes. Testbeds are useful for investigating cyberphysical systems (CPS)

Candell, Rick; Liu, Yongkang; Hany, Mohamed; Montgomery, Karl; Foufou, Sebti. "Smart Manufacturing Testbed for the Advancement of Wireless Adoption in the Factory." Paper presented at IFIP 17th International Conference on Product Lifecycle, Rapperswil, CH. July 05, 2020 - July 08, 2020.

impacts in that physical systems are entirely real or at least partially real. A CPS is a tightly coupled integration of physical, computing, and communications processes. As such, events within the computing and communications processes impact the physical process. Within a testbed, physical processes such as robot dynamics do not have to be simulated because gravity, inertia, and system dynamics are inherently present and measurable. Additionally, within a testbed, the electromagnetic properties are present, and their impacts on the physical networking devices are felt and equally measurable in terms of information loss and delay. These losses and delays influence the performance of the network and lead to abnormalities in the performance of the physical system.

CPS Theoretical Model Consulting the theoretical model of a CPS shown in Fig. 1, the physical process instrumented with sensors produces one or more sensor outputs, Y, which are transmitted through a network such as an industrial wireless network. Interference and multi-path phenomena may cause losses and delay as the received sensor information $\bar{Y}$ arrives at the control system. The control system then uses $\bar{Y}$ to act upon the physical system by sending commands, U which may arrive as delayed or lost, demoted by $\bar{U}$, at the physical process. The differences between $\bar{Y}$ and Y and between $\bar{U}$ and U cause changes in the behavior of the physical process. The severity of those changes will depend on the resilience of the control system and the properties of the physical system, itself.

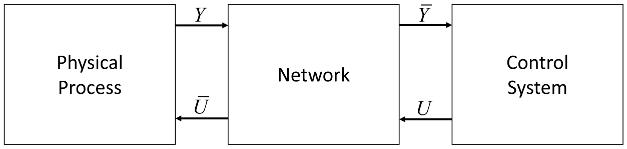

Fig. 1. Theoretical representation of a cyberphysical system.

Motivation While theoretical modeling and simulation are helpful in understanding CPS behaviour, they lack the accuracy of the real-world systems. Therefore, testbeds are used to reproduce larger physical systems on a smaller scale using computing and communication devices and real physical components such as edge devices and robots. The National Institute of Standards and Technology (NIST) has produced a series of industrial wireless testbeds with use cases ranging from chemical production and confined space sensing to robotic machine tending and force controlled actuation. All of these incarnations of the testbed addressed real needs with use cases of low-rate time considerations on the order of 100 ms or more. However, with the emerging requirement of robotic mobility and remote joint actuation in semi-autonomous robotic systems, a new use case is necessary to conduct future research within the testbed. This use case must be selected such that perturbations within the IWN are rapidly reflected within the physical system. The testbed itself should be implemented to measure in real-time both informational and operational performance commensurate with the use case.

Contributions The contributions of this work are as follows: 1) We present our lessons learned conducting experimental studies with past incarnations of the NIST industrial wireless testbed; 2) we present our use case requirements and testbed considerations for a general industrial wireless testbed that readily demonstrates cyberphysical effects rapidly in humanly detectable fashion when information loss and delay are introduced; 3) we present the functional design of the testbed which implements our proposed use case.

Paper Organization The paper is organized as follows: In Section 2, previous relevant academic works are presented. Then in Section 3, lessons learned from past incarnations of software-based and hardware-in-the-loop testbed simulations are reviewed. Next, in Section 4, requirements for the new use case motivated primarily by robotic mobility is addressed along with the requirements for the testbed platform itself. In Sections 5 and 6, the proposed use case and testbed are elaborated in detail. Concluding remarks are given in the final section.

2 Related Work

Wireless communication technologies have been proactively extending their footprints onto the factory floor from non-critical process monitoring services to more deterministic transmission of mission-critical application data [6]. Standardization bodies have released their own visions of service requirements on industrial wireless communications [5, 1]. The European Telecommunications Standards Institute (ETSI) has classified a series of use cases in industrial sectors, mainly as machine-typed communications, and identified corresponding radio transmission requirements on individual classes [5]. The Third Generation Partnership Project (3GPP) has also identied service requirements for industrial wireless use cases and address them in their 5G cellular use scenarios, e.g., massive machine-type communications (mMTC) and ultrareliable and low-latency communications (URLLC) [1]. However, justification of specific values regarding key performance metrics is barely disclosed in these efforts. Recently, there is an ongoing discussion on calibrating wireless service requirements to truly reflect system needs in typical industrial communications scenarios, e.g., factory workcells [12].

Validating industrial wireless requirements and further evaluating candidate solutions have proven challenging. Existing validation approaches can be classified into three main categories: theoretical analysis, software simulation, and hardware testbed. Theoretical analysis has been widely used to showcase performance trend by statistically modelling traffic load and link quality [14]. However, it is very difficult to model complex industrial use cases where factors for both network performance and manufacturing productivity need to be captured thoroughly, especially when transmissions are closely associated with process precision and plant safety. Being widely used to verify theoretical analysis and project system performance, simulation techniques have the flexibility of scaling up and finely tuning the studied use case under different conditions. However, experts in their own domains (e.g., industrial engineers and communications engineers) often find it difficult to select/develop appropriate simulation modules for components that fall out of their expertise, who tend to make over-simplified or erroneous modeling assumptions that deviates the delivery of trustworthy results. Recently co-simulation tools have been developed to jointly mimic behaviors of component systems/networks of CPS in a hierarchical High-Level Architecture (HLA) [13]. Jeng *et al.* introduced a factory co-simulator that jointly considers the production pipeline across multiple workstations and information interaction between them through the network [9]. Such work can also be further extended to the hardware-in-the-loop (HIL) experiments to render more accurate estimation on the performance with tested equipment [3]. Being built upon mathematical models, simulation methods also encounter similar design issues to keep a balance between depiction accuracy and computation efficiency. Besides software-based evaluation, testbeds have been developed to test existing wireless techniques and prototypes in the emulated industrial use cases. Lucas-Estan *et al.* designed experiments to test wireless link redundancy schemes in a multi-robot testbed which is focused on improving reliability of wireless transmissions [11]. Given vast diversity and variability of industrial use cases, the design of effective testbed for individual use cases becomes a key to the success of wireless deployment. NIST engineers have examined the impact of wireless links on industrial system performance through a series of testbeds [3, 7, 8, 4, 2]. Based on lessons learned in these practices, we will examine design principles to highlight industrial wireless requirements in this paper.

3 Lessons Learned from Past Testbed Incarnations

In this section, we discuss the lessons learned from various previous tesbeds that have been used in the NIST industrial wireless systems (IWS) lab. These previously developed testbeds and experimental studies can be found in [3, 7, 8, 4, 2].

3.1 Tennessee Eastman Chemical Factory

In [3], industrial wireless communications devices were deployed for pressure, temperature, and flow sensors data transfer for the control of a simulated chemical factory. IEEE802.15.4-based protocols were deployed such as WirelessHART and ISA100.11a. Both simulations and HIL experiments were performed for this application in [10] and [3], respectively. We found that, generally, process control applications with large time constant can be impacted by communications impairments when the wireless channel is poor for an extended period of time.

The existing WirelessHART and ISA100.11a can perform adequately for these applications while the wireless sensors are connected to the network. However, we found that networks were not robust to events outside the scheme of information transmission such as the loss of a router node, gateway, etc. due to power loss or similar incidents.

Moreover, comparing simulations to HIL experiments, we found that experimental studies are needed to reflect the more realistic impacts of protocol implementation and higher layer protocol impacts such as by Modbus. We have deployed a channel emulator to replicate the impact of electromagnetic propagation in industrial environments on CPS performance. We have also learned that abstract network performance criteria such as packet loss and packet latency may not reflect the communications impact on the production process and hence physical process related criteria should be evaluated in various experimental studies.

3.2 Confined Space Gas Sensing Testbed

In [7], we performed an experimental study on a testbed which is very similar to the chemical factory use case in Section 3.1 such that a similar HIL concept is deployed. The main difference is that different wireless channel models were deployed and different types of information were transferred. In the confined space case, the simulated gas levels at different points of the confined space are transferred over wireless using HIL simulation, and the effectiveness of a safety alerting application is considered. In this setup, we found that the communications protocol implementation could impact the system performance where the implemented Modbus protocol has an update period of 2 seconds which is much slower than the signal and channel variations. We also found that testing can be performed on the signal-level for sensors and actuators signals in case of unavailability of network-level metrics. However, we concluded that the network-level metrics are needed to further understand the reasons behind the measured performance.

3.3 3D Gantry System Testbed

In [8], a commercial 3D gantry system was deployed where the g-code commands to control the gantry system were streamed using a WiFi network. In this experimental study, we found that while converting an originally wired testbed to a wireless one, a ground truth measuring technique has to exist in order to quantify the system performance and hence the wireless impact on performance. Generally, ground truth measurements can be obtained through instrumented feedback from the system, if exists, or through a remote observer where a vision tracking system was deployed in this testbed.

Similar to previously discussed testbeds, the definitions of physical process metrics are needed where these metrics have to be impacted by wireless communications impairments. In this experiment, where g-code command delays made the 3D gantry to halt at a specific location waiting for the following command, performance metrics, such as dwell time and production rate, were considered. The main lesson learned in this experimental study was that queuing of the control commands can mitigate the impact of rapid changes in the wireless channels i.e., keeping a buffered set of commands at the remote station can help to keep the process running. Buffering is not always a viable solution in latency-sensitive applications.

3.4 Force Seeking Apparatus Testbed

In [4], a force seeking apparatus was built using a robot arm and an attached force-torque sensor (FTS). A single wireless channel is deployed where the FTS transmits the force value to the robot controller which reacts when a specific threshold is reached. A machine learning algorithm is used to estimate the interference level on the wireless channel based on tracking the robot arm movements. In this study, we assessed the impact of interference on the physical performance of a fast process where the direct relation between wireless channel quality and the process is quantified. In single wireless channel scenarios, we study only the impact of external interference while competing traffic scenarios are not considered. Hence, we concluded it would be desirable to have a testbed with multiple deployed wireless nodes allowing us to study channel contention scenarios. We also found that the FTSs are not designed to be used wirelessly where large delays can cause dropping the connection with the robot controller. The dropped connection requires resetting the FTS control box to continue its operation which is not acceptable in industrial processes. We concluded that, in general, the industrial devices should be designed to handle information loss and delay more readily through means of mitigative control system programming or user adjustment of device parameters rather than hard-coding total system failure.

3.5 Dual Robot Machine-Tending Testbed

In [2], a more comprehensive testbed was built where two robot arms, one supervisory PLC, and four machine emulators worked together to perform a pick-and-place task. The supervisory control signals to the robot controllers and the machines were transmitted wirelessly. The data for the network traffic and the status of the machines and robot arms were collected. Although, we were able to show the impact of wireless on the network-level metrics, such as packet latency, the impact of wireless on the physical process was almost negligible because only supervisory commands were transferred wirelessly. The latency of supervisory commands were significantly lower than the scan time of the control loop causing negligible physical impact. We discovered that in-network contention is more impactful than electromagnetic interference. Moreover, we discovered that multiple source of contention impacted the system more compared to a single traffic source.

We have also run experiments using both periodic and event-based Modbus polling for the communications between the supervisor and the robot controllers. We found that periodic Modbus polling is more robust to the channel because no timeout warnings may occur. However, it is less bandwidth efficient than the event-based counterpart. On the other hand, event-based Modbus polling is preferred in wireless communications scenarios not to interfere with other network activities. Moreover, access to the robot arm middleware would allow more control of Modbus polling properties. As a result, a middleware alternative such as robot operating system (ROS) would be suitable.

4 Requirements for New Use Case

To enable adoption of an effective use case for deployment in the NIST industrial wireless testbed, development of clear requirements is a necessary and an essential first step. Using our lessons learned and experience, it was required that the new use case proposed have noticeable physical impact under degraded communications situations, have industry relevance, and have an accessible software middleware.

Noticeable Physical Impact Learned from Section 3.5, the new use case requires noticeable physical impact from the degradation of communication. Such degradation occurs commonly in wireless communications. In the use case, wireless links are used to carry traffic to control the physical action directly; thus, any significant fluctuation in latency or reliability of the wireless link will be immediately noticeable by measurement or observation. In past incarnations, physical manifestations from communication loss and delay were not immediately noticeable because the physical systems were more immune to information disturbances in the wireless network.

Industry Relevance Constructing a use case that is similar to the types of applications used by industry is required as the findings discovered will be relevant. This requirement suggests that a new use case should perform a similar task or physical operation that is found in industrial applications.

Access to Software Middleware Many current industrial devices do not support wireless communications in their design. Such devices have proven to have difficulties in compatibility with current wireless solutions, e.g., overly strict timeout thresholds, such as with Modbus client configurations, which may trigger system failures as described in Sections 3.4 and 3.5. Therefore, it is asserted that the desired industrial wireless testbed provide access to the software residing between applications and the industrial wireless networking stack on each host.

5 Proposed Use Case

In this section, we explain briefly the proposed dual robot leader-follower use case. We first introduce the design of the use case where the major system components are defined. Then, we validate that the proposed use case satisfies the use case requirements in Section 4.

5.1 Design

In Fig. 2, the physical process is shown where two robot arms equipped with FTSs are collaborating in lifting a semi-rigid object. Dual robot object lifting is a general industrial approach used for heavy lifting and over-sized material handling. Typically, stationary robots used for lifting communicates through wired technologies. However, the need for flexible manufacturing and mobile robots in future factories requires the deployment of wireless technologies for communications between robots. In the leader-follower schemes, one robot is assigned the rule of the leader to achieve a certain control objective. The other robot, the follower, takes specific actions relative to the leader to maintain a desired relation with the leader with respect to the position or forces on the lifted object. As a result, communications between the leader and the follower plays a crucial role in maintaining the integrity of the lifted object and preventing collisions for the mobile robots.

The control of the leader-follower scenario allows the follower to take decisions based on transferred information about the leader activity. The leader information is transferred using a deployed industrial wireless network. Furthermore, the control of the leader-follower scenario could be done in a centralized approach. In the centralized approach, the centralized controller makes decisions about the follower actions based on the joint state information transferred by the both robots. Moreover, we attach an FTS to the lifted object in order to measure the applied forces and study the impact of wireless communications on the lifted object.

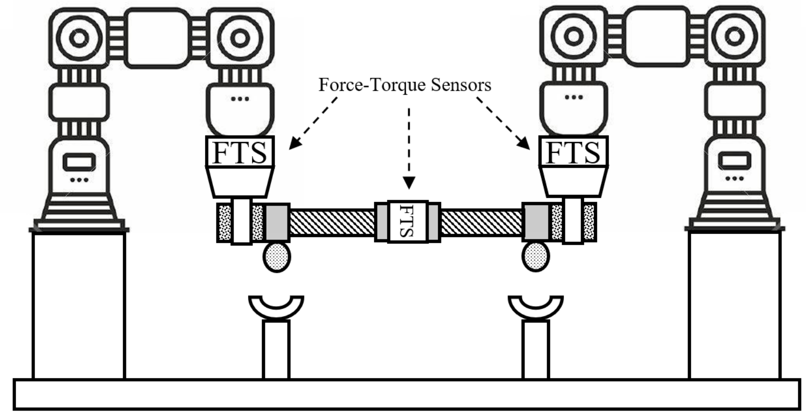

Fig. 2. The leader-follower use case diagram.

5.2 Requirement Coverage

This proposed use case was selected by incorporating the lessons learned from previous use cases in Section 3 and to satisfy the discussed use case requirements in Section 4. In the proposed use case, the goal is to get a direct impact of wireless communications on the physical process through having the leader-follower relation between the robots. Any latency or reliability issues in the information transfer between the leader and the follower is expected to affect the desired relation between them. The impact of wireless communications on the physical process can be measured through the position feedback of the robot arms and the FTSs. Capture of network data is made possible through the use of network probes strategically placed throughout the testbed. Similarly, capture of performance data of the physical system is made possible by instrumenting the testbed with ground truth measurement and recording probes such that variables such as forces, torques, positions, velocities, and accelerations are captured independently of the wireless network. We deploy a master clock to synchronize all the collected physical process and network traffic data. Finally, this proposed use case replicates a realistic scenario which can be found in heavy lifting and over-sized material handling.

6 Proposed Testbed

6.1 Architecture

The testbed serves as an evaluation platform that emulates workcell operations in the proposed use case and measures the impact of node interactions on the production performance. As shown in Fig. 3, it consists of three main subsystems according to their different roles: *workcell modules*, *network components*, and *measurement devices*. In the designed architecture, subsystems are connected with each other through predefined interfaces and integrated as a complete evaluation process. Design details of each one will be elaborated in the following section.

6.2 Components

Workcell modules include testbed components that participate in manufacturing tasks, e.g., robots and their controllers in the leader-follower use case. In the testbed, we deploy two Universal Robots (UR) UR3 CB-series robots that serve as actors in the leader-follower use case. Each UR3 is equipped with a 6 degree-of-freedom (6-DoF) robot arm, one control box, and peripheral devices, known as URCaps, which include a Robotiq gripper and a 6-axis force-torque sensor attached to the end effector. Instead of using proprietary UR programs, the control of robots implements agents atop the robot operating system (ROS) middleware which provides a rich set of options in control functions and peripheral support for UR3. In ROS, robot-oriented processes are identified as separate

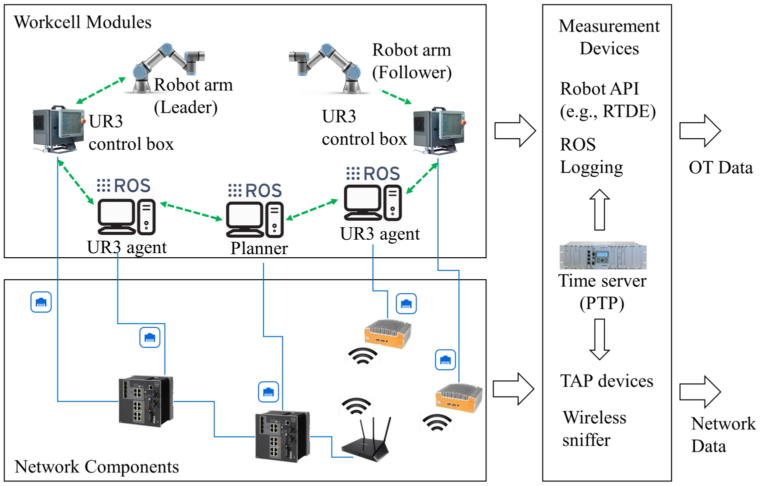

Fig. 3. Workcell testbed architecture

function nodes which can be distributed across multiple physical machines being connected through the network. As shown in Fig. 3, the testbed hosts three computers running Ubuntu 18.04 with the ROS Melodic distribution. Two of them serve as UR3 agents where ROS UR3 drivers are installed to adapt universal ROS functions and commands to UR3 features. The coordination between the leader and the follower can be realized through the peer-to-peer communications between UR3 agents. In this case, the third machine, i.e., the ROS planner, performs motion planning for both robots. There is another feasible approach in which both UR3 agents report to the planner who will resolve their joint trajectory actions and reply to both with respective action commands.

Network components are network devices that enable workcell modules to communicate with each other for job-oriented information exchange and process control. Each workcell module in the testbed contains one or more built-in Ethernet interfaces. Two Cisco IE-4000 industrial gigabit Ethernet switches serve as the wired network backbone. Ethernet-wireless adapters are used to replace wired connections by enabling wireless communications between modules. Fig. 3 illustrates an example of connecting to the follower robot through wireless. The testbed uses IPv4 addresses to manage communication devices. Additional network connections are also planned in the testbed that provide measurement data links and other complimentary features, such as time synchronization services.

Measurement devices collect data including but not limited to manufacturing progress, machine status, link quality, and network health. Table 1 summarizes

Table 1. Testbed measurement data collections

Data	Source	Type	Time Synced	Format
Actual joint status (e.g., position, velocity, and acceleration)	UR3 joints	Workcell	Yes, PTP	CSV
URCap force and torque	FTSs at UR3 end effectors	Workcell	Yes, PTP	CSV
ROS UR3 control (Leader/follower status)	ROS UR3 agents	Workcell	Yes, PTP	CSV
ROS Motion planning output (target joint status)	ROS master	Workcell	Yes, PTP	CSV
Force and torque (ground truth)	FTS at the lifted object	Workcell	Yes, PTP	CSV
Ethernet packet captures	TAP	Network	Yes, PTP	PCAP
Wireless packet captures	Wireleess sniffer	Network	Yes, PTP	PCAP

data to be collected and saved for further analysis. Specifically, production-related workcell data and network data are monitored and captured at different measurement devices. The former ones are usually collected through UR3's API, e.g., the real-time data exchange (RTDE), or saved locally in workcell modules, e.g., the ROS logging at ROS nodes; the latter ones are mainly captured by traffic analysis tools, such as test access point (TAP) devices for real-time traffics in Ethernet links and the wireless sniffer. Note that the testbed uses real-time readings from the FTS at the lifted object as the ground truth for measuring the performance of coordinated operations between the leader and the follower. Besides, timing information is also rendered and embedded into each record so that discrete events can be aligned in time to review the operation logic and network behaviors in future analysis. Therefore, the testbed can implement the precision time protocol (PTP) to provide the sub-microsecond level accuracy across the networked distributed clocks. A Meinberg M900 time server is used as the central PTP master clock that supports the IEEE 1588-2008 (PTPv2) standard.

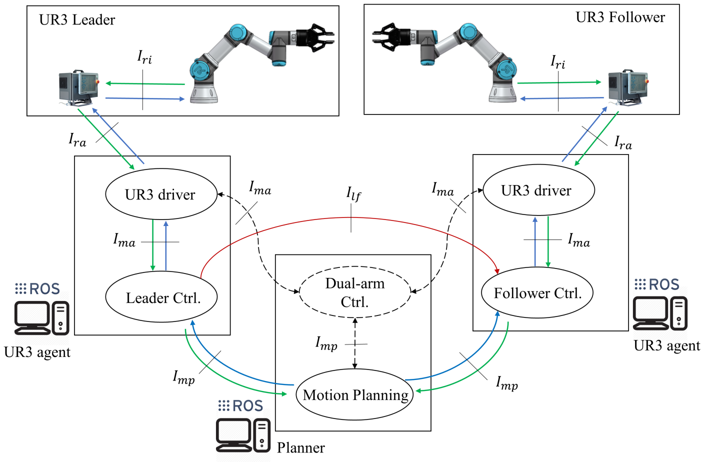

Fig. 4. Testbed interfaces

6.3 Interfaces

Fig. 4 illustrates interfaces between workcell modules that are used to enable the coordination between the two actors in the proposed leader-follower use case. As data communications are directional, we define the *upstream* data flow to be the one from the end node, i.e., the UR3 robot arm, toward the planner which is denoted by green arrows in the figure. The *downstream* data is reversed and denoted in blue. When the leader(follower) has its own controller residing in the agent machine, the leader will routinely share its motion information to the follower, either as geometrical variables or force-torque readings, which allows the follower to track the leader's trajectory and calculate its own route to keep the metrology bar in the desired state. In another case when the ROS planner also takes over the control mission, a new dual-arm control node will replace the separate controllers in UR3 agents. The flows will be updated accordingly which are illustrated as dashed arrows in Fig. 4.

Table 2 summarizes interfaces defined for data exchanges between different nodes. Note that each interface contains data in both upstream and downstream directions. Except I_{ri} for UR3 internal traffics, the other interfaces are built for communications between ROS nodes. ROS provides three communication styles including synchronous request/reply interactions ("services"), asynchronous data streaming ("topics"), and data storage in a parameter server. We will use the testbed to explore the capability of wireless links in support of different communications styles in selected interfaces. For each interface, a set of protocols is listed for which the use case will be tested. Ethernet is used for baseline performance testing, while wireless local area network (WLAN) protocols

Table 2. Testbed interface specifications

Interface	Protocol	Data		Note
		Upstream	Downstream	
UR3 internal, I_{ri}	Serial	UR3 and URCap status	Joint trajectory action	UR3 proprietary
UR3-ROS, I_{ra}	Ethernet WLAN	Robot status	Joint trajectory action	ROS UR3 driver
ROS master-agent, I_{ma}		Robot status	Joint trajectory action	ROS topics/services
ROS motion planning, I_{mp}		Target trajectory	Joint trajectory action	ROS topics/services
Leader-Follower, I_{lf}		Force-torque-based or geometrical trace		ROS topics/services

such as IEEE 802.11 will be used when a wireless protocol is employed. Fifth generation wireless (5G) is envisioned as well when resources come available.

7 Conclusions

In this paper, we have presented the next evolution of an industrial wireless testbed. The testbed is designed with the goal of investigating use cases that will noticeably degrade under the influence of radio interference, competing network traffic, and radio propagation effects applied within the lab. One specific use case is presented in which two robots perform a coordinated lift operation using either a geometric leader follower or a force-torque minimization control scheme. In the control scheme presented, wireless links are used to carry joint state information such that lost or delayed state information immediately impacts physical action. Capture of performance data of the network and physical systems is made possible by the use of probe devices. Our testbed will serve as a research and demonstration platform for reliable industrial wireless deployment and control system strategies. Finally, our work is presented with lessons learned from past incarnations of our wireless testbed such that our work may help others construct better wireless testbeds by learning from our successes and failures. Once completed, results from our testbed will be made available through reports, papers, and publication of data sets.

Disclaimer

Certain commercial equipment, instruments, or materials are identified in this paper in order to specify the experimental procedure adequately. Such identification is not intended to imply recommendation or endorsement by the National Institute of Standards and Technology, nor is it intended to imply that the materials or equipment identified are necessarily the best available for the purpose.

***Abstract*—This paper describes a metrology instrument designed for detecting noise and interference in digital communications. A quadrature detector downconverts in-phase and quadrature channels, which are each digitized at high speed. This architecture makes the upper and lower signal sidebands separable by digital processing, and has spectral resolution that is unprecedented in conventional analog detection. Several considerations for design, system characterization and calibrations are discussed.**

***Index Terms*—Measurement, noise, radiometer, sideband separating downconversion, standards.**

I. Introduction

Noise is an ultimate limiting factor in the performance of wireless communication links. With the proliferation of communication devices leading to the worldwide spectrum shortage, the ever-rising noise floor becomes more and more prominent in both licensed and unlicensed frequency bands. An accurate quantification of noise and interference level with its spectral, temporal, and geographic signatures has increasing importance for wireless and radar engineering, spectrum users, and objective assessment by policymakers.

Microwave radiometers are a ubiquitous noise-measurement tool in the metrology community. Conventionally, noise detection has been implemented with analog detectors. Although analog detectors have functioned well in measuring stable noise sources with minimal frequency dispersion, analog detection is less flexible and suffers from limited frequency selectivity, which limits its practical application for modern spectrum users.

At the National Institute of Standards and Technology (NIST), we have started building a metrology-grade radiometer centered on digital detection. By leveraging the existing thermal noise reference standards and rigorous uncertainty analysis, the new instrument will enable us to measure noise and interference signals traceably and with dramatically improved spectral resolution.

II. Design of Digital Radiometer

Although it is possible to directly sample a broadband signal centered at a frequency of interest with a high-speed digitizer, in our new digital radiometer we downconvert from the radio frequency (RF) first to improve tuning flexibility, and energy efficiency, and to reduce cost.

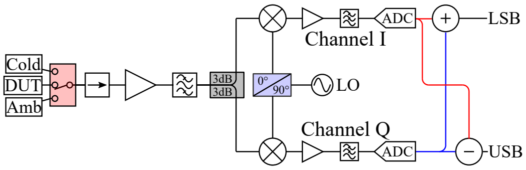

Fig. 1. A block diagram of the digital radiometer with the IQ downconversion configuration.

Conventional radiometer detectors typically use double-sideband (DSB) downconversion. The DSB-downconverted intermediate-frequency (IF) signal is an aggregation of the upper-sideband and lower-sideband spectral components. As a result, the DSB architecture cannot unambiguously distinguish between signals with asymmetrical spectra. In order to preserve the ability to distinguish signals in both sidebands, sideband-separating downconversion needs to be used. In the communication field, this technique is equivalent to in-phase (I) and quadrature (Q) mixing. As shown in Fig. 1, the RF signal to be detected is split into two nearly identical signal-processing chains; the I channel and the Q channel. The only difference between these channels is a 90° offset between the local oscillator (LO) signals driving the IQ mixers, accomplished by the quadrature hybrid divider. The downconverted IQ signals are eventually sampled by a dual-channel analog-to-digital converter (ADC). Next, digital processing is implemented to account for non-idealities of the IQ channels, calibrate the absolute magnitude with the known noise references, and ultimately reproduce the upper- and lower-sideband spectra of the signal.

Before the signal enters the digital domain, a significant amount of amplification is required to bring the low-level thermal noise signal within the ADC dynamic range. The power level of the noise signal associated with the NIST noise reference standards is typically around -90 dBm. More than 100 dB gain may be required to compensate additional conversion and cable losses. Prior to any amplification stages, isolators are used to minimize the variation of the input impedance seen by the radiometer, which is critical in metrology applications. The filters reduce amplifier saturation, suppress out-of-band harmonics and the LO leakage, and eliminate aliasing into the ADC.

III. System Characterization and Calibration

A. Receiver Stability

In light of the significant signal gain in the system, radiometer receiver stability with time is a serious concern. Consequently, frequent calibrations of the digital radiometer

Lu, Xifeng; Gu, Dazhen; Kuester, Dan. "Digital Radiometer for Traceable Spectrum Sensing." Paper presented at Conference on Precision Electromagnetic Measurements (CPEM), Denver, CO, US. August 24, 2020 - August 28, 2020.

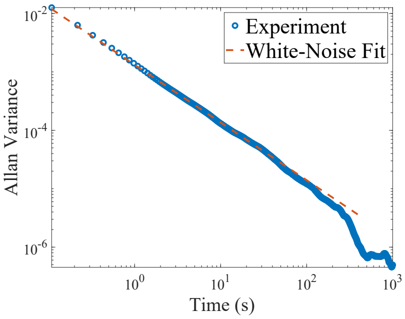

Fig. 2. Allan variance of the digitally sampled data from the radiometer when a thermal noise source was connected.

against known NIST references may be required for a traceable measurement. Measurements of noise reference standards constitute "dead time", during which we cannot measure spectral emissions from a device under test. There is thus a trade-off between accuracy and availability.

To maximize availability, it is important to determine how often the calibration needs to be refreshed. To that end, the Allan variance has been proven a reliable technique to characterize the receiver stability and estimate the calibration intervals. The Allan variance allows characterization of the system drift by identifying frequency-dependent noises other than white noise [1]. Figure 2 shows the Allan plot of the digital-radiometer data and indicates an excellent receiver stability up to more than 50 s in a controlled lab environment. The Allan variance result provided a guidance of the calibration period on the order of about 1 minute.

B. IQ Imbalance

Ideally, the addition of the I and Q signals would produce the lower-sideband spectrum, while the subtraction of the two would produce the upper-sideband spectrum. In practice, the imperfection of analog components leads to differences in the complex gain (a combination of the phase delay and magnitude amplification) between the two channels, which results in IQ imbalance. Because of the IQ imbalance, the simple addition and subtraction of the IQ baseband signals do not cleanly separate of the lower- and upper-sideband spectra. Even meticulous selection of the analog components can only achieve uncalibrated sideband rejection of 20 dB or less [2].

To overcome the IQ imbalance, a calibration can be performed with digital data to improve the sideband rejection. A sine tone at a known frequency can be injected into the digital-radiometer frontend, from which a complex-valued calibration coefficient is chosen to null the digital spectrum output at the image frequency. The coefficients for each of the lower sideband (LSB) and upper sideband (USB) are

$$C(f) = \begin{cases} \frac{X_{\mathrm{I}}(f_{\mathrm{LO}}-f)}{X_{\mathrm{Q}}(f_{\mathrm{LO}}-f)}, & \text{for LSB } f < f_{\mathrm{LO}}, \\ \\ -\frac{X_{\mathrm{I}}(f_{\mathrm{LO}}-f)}{X_{\mathrm{Q}}(f_{\mathrm{LO}}-f)}, & \text{for USB } f > f_{\mathrm{LO}}, \end{cases} \tag{1}$$

where, X_{I} and X_{Q} are the Fourier transformed time-series data in the I and Q channels, respectively. As an example, we can estimate $C(1.8\,\mathrm{GHz})$ from the downconverted IQ baseband signal at -0.3 GHz when the LO frequency is fixed at 1.5 GHz.

C. Spectral Resolution

Application to spectrum sensing simultaneously in multiple frequency allocations requires transformation into the frequency domain. Mathematically, this type of analysis is equivalent to the projection of a time series onto a set of orthogonal basis [3]. The most common method is the discrete Fourier transform (DFT). However, the DFT of a time series that is non-periodic sequence and acquired on a finite interval cause apparent energy leakage in the frequency spectrum of the signal. For a series of size N sampled at a frequency of f_{s}, the DFT spectrum can be expressed by

$$\check{X} = \Pi \circledast X, \tag{2}$$

where $\check{X}$ is the resultant finite-DFT spectrum of the signal, and X is the actual spectrum of the signal. The symbol $\circledast$ denotes convolution, and Π is the Fourier transform of the boxcar function spanning over the observation interval N/f_{s}; i.e. a set of the sinc functions centered at $-\frac{N}{2}\frac{f_{\mathrm{s}}}{N}$, $(-\frac{N}{2}+1)\frac{f_{\mathrm{s}}}{N}, \ldots, (\frac{N}{2}-1)\frac{f_{\mathrm{s}}}{N}$. Spectral components of signals with their base-band representation at other frequencies introduce non-zero projections on all bases, causing the spectral leakage.

To mitigate the spectral leakage problem, a modified basis set is required so that an arbitrary signal would primarily project onto it with its center frequency in the closest vicinity of the signal frequency. This manipulation is equivalent to multiplicatively applying a window to the time series sampled by the ADC. A number of windowing functions will be tailored for applications specific to the communication signals of interest [4]. Window design considerations include the equivalent bandwidth, the flatness within the pass band, the side-lobe peak level. Regardless of what window functions are used, the spectral analysis of the digitally sampled signal will produce much finer spectral resolution than what exists in the analog radiometers.

IV. Conclusion

In summary, we designed a digital radiometer by use of IQ mixing and ADC sampling for measuring noise and interference in communication applications. Taking advantage of existing NIST thermal-noise standards, the digital radiometer enables traceable spectrum measurements. Uncertainty analysis will be shown in the extended paper.

The Design of an Instrument to Realize Small Torque at NIST

Leon Chao, Rafael Marangoni, Frank Seifert, Darine Haddad, Jon Pratt, David Newell, and Stephan Schlamminger
National Institute of Standards and Technology, 100 Bureau Dr., Gaithersburg MD 20899
leon.chao@nist.gov

***Abstract*—After the recent redefinition of the International System of Units (SI), torque no longer needs to be traceable to a calibrated mass in a gravitational field suspended from a known lever arm and disseminated through a chain of torque transducers.**

An SI-traceable torque can be directly realized using the Kibble principle where a torque is generated by a calibrated electromagnetic transducer. Here, a set of theoretical designs for a new instrument aimed at direct realization of torque to 0.1% accuracy is analyzed and examined for feasibility. With careful attention to magnet design, a robust and easily implemented torque calibrator can be built.

***Index Terms*—Torque metrology, Kibble balance, precision engineering design**

I. Introduction

From aircraft and automobiles down to cell phones and wrist watches, mechanical assemblies are held together with threaded fasteners whose optimal performance and reliability depend on accurate application of torque. For example, six million components of a Boeing 747 are constrained together by millions of threaded fasteners secured using the correct amount of torque, applied by technicians using torque wrenches or torque screwdrivers.

The technical standard ISO 6789 by the International Standard Organization, for example, requires all torque wrenches and screwdrivers to be calibrated every 5000 uses or once per year [1]. These handheld tools are calibrated by torque sensors which typically have relative uncertainties of 0.25% and are traceable to torque transducers ultimately calibrated by deadweight torque machines. Currently, the lowest uncertainty deadweight torque machine in the USA has a relative uncertainty of 2×10^{-5} [2]-[3].

The existing traceability is simple, reliable, and convenient for the most part; however, at torques below 1 N m the handling of small mass artifacts required to calibrate the deadweight machines is difficult, irreproducible, and burdensome.

Torque is expressed as a product of force and length in units of Newton-meter (N m). A deadweight machine relies on a measured force generated by a calibrated mass in a known gravitational field applied at a well-characterized lever arm distance. The recent redefinition of the International System of Units (SI) enables new approaches to traceable realization of units of measure. Mechanical force no longer needs to be traceable to a mass artifact, but rather it can be realized through electromagnetic force, ultimately traceable to quantum standards [5]. Furthermore, by implementing the Kibble principle to be discussed in the next section, the previously required lever arm length measurement becomes obsolete.

The Fundamental Electrical Measurements Group at NIST is investigating the design of a tabletop industrial instrument for realizing torque using the Kibble method, drawing inspiration from [4]. The instrument under consideration aims to realize small torques with a relative uncertainty of 0.1%. The instrument seeks to exploit convenient electrical and time standards traceable to quantum standards to achieve a robust alternative to present cumbersome practices for torques below 1 N m.

II. Theory of the Kibble Principle for rotation

Given a rigid loop of conductive wire with an enclosed area A traveling through a magnetic field with flux density B, the centroid of the loop has velocities v_x, v_y, and v_z and angular velocities about each axis ω_x, ω_y, and ω_z. The total flux Φ through the loop is

$$\Phi = \oiint \vec{B} \cdot d\vec{A}. \tag{1}$$

The induced voltage V, according to Faraday's law of induction [6] that appears across the open terminals of the loop is

$$\begin{aligned} V &= -\frac{\mathrm{d}\Phi}{\mathrm{d}t} \\ &= -\left(\frac{\partial\Phi}{\partial x}v_x + \frac{\partial\Phi}{\partial y}v_y + \frac{\partial\Phi}{\partial z}v_z + \right. \\ &\qquad \left. \frac{\partial\Phi}{\partial\theta_x}\omega_x + \frac{\partial\Phi}{\partial\theta_y}\omega_y + \frac{\partial\Phi}{\partial\theta_z}\omega_z\right). \end{aligned} \tag{2}$$

If assuming the loop is an open circuit and attached to the end of a rotor capable of undergoing rotation $\omega_{z'}$ where z' is aligned to gravity, then each off-axis velocity component is solely determined by $\omega_{z'}$ and can be expressed as

$$\begin{aligned} v_x = \omega_{z'}\frac{\partial x}{\partial\theta_{z'}}, \quad v_y = \omega_{z'}\frac{\partial y}{\partial\theta_{z'}}, \quad v_z = \omega_{z'}\frac{\partial z}{\partial\theta_{z'}}, \\ \omega_x = \omega_{z'}\frac{\partial\theta_x}{\partial\theta_{z'}}, \quad \omega_y = \omega_{z'}\frac{\partial\theta_y}{\partial\theta_{z'}}, \quad \omega_z = \omega_{z'}\frac{\partial\theta_z}{\partial\theta_{z'}}. \end{aligned} \tag{3}$$

Substituting eq. 3 into eq. 2, the following expression for the induced voltage of the loop at angle $\theta_{z'}$ undergoing instantaneous angular velocity $\omega_{z'}$ is obtained

$$\begin{aligned} V &= -\omega_{z'}\left(\frac{\partial\Phi}{\partial x}\frac{\partial x}{\partial\theta_{z'}} + \frac{\partial\Phi}{\partial y}\frac{\partial y}{\partial\theta_{z'}} + \frac{\partial\Phi}{\partial z}\frac{\partial z}{\partial\theta_{z'}}\right. \\ &\quad \left. + \frac{\partial\Phi}{\partial\theta_x}\frac{\partial\theta_x}{\partial\theta_{z'}} + \frac{\partial\Phi}{\partial\theta_y}\frac{\partial\theta_y}{\partial\theta_{z'}} + \frac{\partial\Phi}{\partial\theta_z}\frac{\partial\theta_z}{\partial\theta_{z'}}\right) \\ &= -\omega_{z'}\frac{\mathrm{d}\Phi}{\mathrm{d}\theta_{z'}} = -\frac{\mathrm{d}\Phi}{\mathrm{d}t}. \end{aligned} \tag{4}$$

Chao, Leon; Marangoni, Rafael; Seifert, Frank; El Haddad, Darine; Pratt, Jon R.; Newell, David B.; Schlamminger, Stephan. "The Design of an Instrument to Realize Small Torque at NIST." Paper presented at NCSLI (National Conference of Standards Laboratories International) Workshop & Symposium, Denver, CO, US. August 22, 2020 - August 27, 2020.

We will refer to measurement of the voltage induced by the rotor as the *angular mode* of operation.

Now suppose that the motion is halted and an electrical current I is passed through the same loop of wire generating a torque about the z' axis. We will refer to the measurement of this current as the *torque mode*.

Consider the energy E of the coil,

$$E = \Phi I \tag{5}$$

so that torque Γ about z' can be expressed as

$$\begin{aligned}\Gamma &= -\frac{\mathrm{d}E}{\mathrm{d}\theta_{z'}} \\ &= -I\left(\frac{\partial\Phi}{\partial x}\frac{\partial x}{\partial\theta_{z'}}+\frac{\partial\Phi}{\partial y}\frac{\partial y}{\partial\theta_{z'}}+\frac{\partial\Phi}{\partial z}\frac{\partial z}{\partial\theta_{z'}}\right. \\ &\quad\left.+\frac{\partial\Phi}{\partial\theta_x}\frac{\partial\theta_x}{\partial\theta_{z'}}+\frac{\partial\Phi}{\partial\theta_y}\frac{\partial\theta_y}{\partial\theta_{z'}}+\frac{\partial\Phi}{\partial\theta_z}\frac{\partial\theta_z}{\partial\theta_{z'}}\right) \\ &= -I\frac{\mathrm{d}\Phi}{\mathrm{d}\theta_{z'}}.\end{aligned} \tag{6}$$

If the system remains identical between the voltage measurement and the torque measurement, i.e. both measurements are taken at the same $\theta_{z'}$, then the partial derivatives of the the spacial coordinates, subsequently named the *calibration factor* denoted by ξ and equal to $-\mathrm{d}\Phi/\mathrm{d}\theta_{z'}$, will be eliminated when eqs. 4 and 6 are combined to become

$$\frac{V}{\omega_{z'}} = \frac{\Gamma}{I} \quad \text{and hence} \quad \Gamma = \frac{VI}{\omega_{z'}}. \tag{7}$$

Interestingly, this method of torque realization is independent of any lever arm measurement.

III. Design Overview

Torque wrenches and screwdrivers are often calibrated at the point of use with handheld commercial low torque reaction sensors. As an example, a series of five commercial devices are required to fully span from 0.01 N m to 1 N m and each have a relative uncertainty of 0.25% of its full measurement range [7]. The NIST Torque Instrument (NTI) should directly realize torque spanning the entire range of 0.01 N m to 1 N m with a relative uncertainty of 0.1% or better to offer a competitive alternative.

Two designs are analyzed in this manuscript. Design type X shown in fig. 1 utilizes a magnet system where the magnetization points along the X direction. Design type Z as shown in fig. 2 uses a magnet system where the magnetization points along the Z direction.

Each design consists of two identical permanent ring magnets oriented in attraction but vertically separated to form an air gap and concentrically fixed to a central shaft. The shaft rotates via a low friction bearing such as an air bearing. A D-shaped coil is fixed in space as shown in fig. 3, vertically centered in the air gap.

The magnet system is free to rotate relative to the coil for angular mode. Rotation can be achieved either by direct drive of a motor or the end user may provide a physical impulse. The rotation is sensed with a rotary encoder mounted centered on top of the upper magnet.

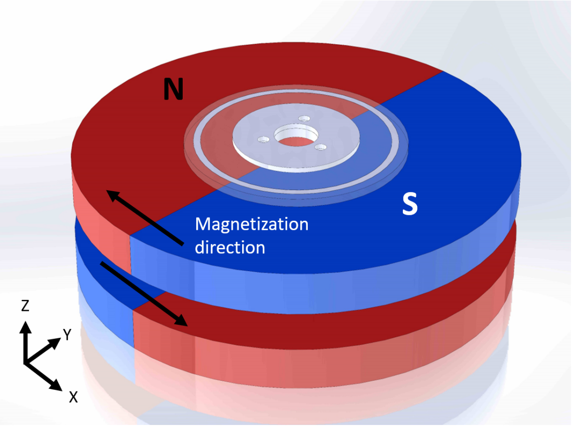

Fig. 1. Type X magnet configuration. Magnetization is along the X direction. Rotary optical encoder scale is mounted to the top of the upper magnet. Central shaft and bearing are hidden for clarity.

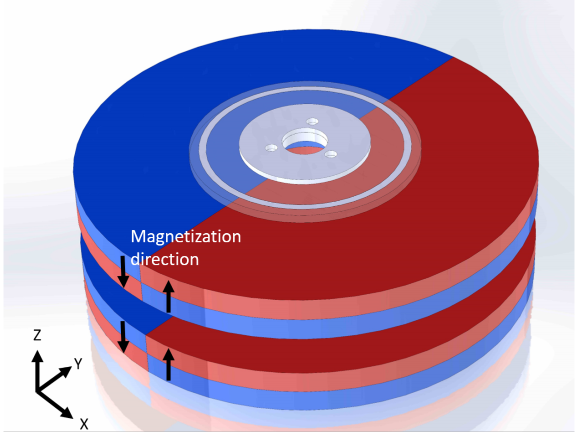

Fig. 2. Type Z magnet configuration. Magnetization is along the Z direction. Rotary optical encoder scale is mounted to the top of the upper magnet. Central shaft and bearing are hidden for clarity.

Like most Kibble-style instruments, measuring the calibration factor accurately in angular mode is the central challenge. Thus, we speculate an absolute determination of $\omega_{z'}$, or more specifically the change in rotational angle $\mathrm{d}\theta_{z'}$, will be the largest metrological hurdle. Insightful design of the magnet system can reduce the difficulty, as explored later in section V.

The vertical component of the magnetic flux density $B_{z'}$ in the air gap is plotted in figs. 4 and 5 for the Type X and Z magnet system, respectively. For the Type X magnet system, $B_{z'}$ is most dense near the outer edges furthest away from the split line. For the Type Z magnet, $B_{z'}$ is close to uniformly distributed throughout the air gap with a polarity difference between the two halves.

Based on the theory discussed in section II, the NTI functionality is neither affected by coil geometry nor ec-

Paper presented at NCSLI (National Conference of Standards Laboratories International) Workshop & Symposium, Denver, CO, US. August 22, 2020 - August 27, 2020.

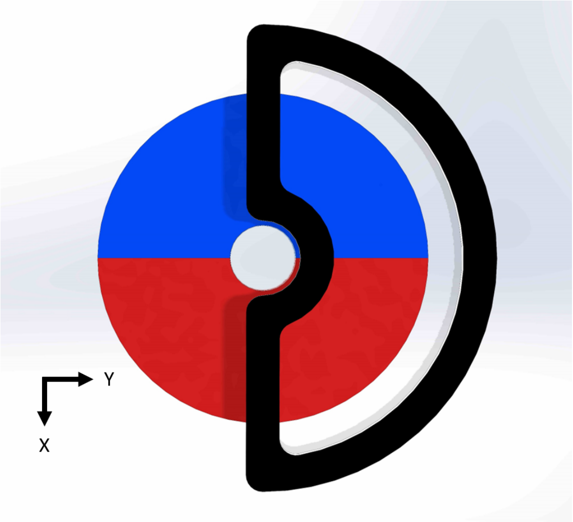

Fig. 3. Top view of magnet assembly where the upper magnet and encoder scale are hidden for clarity to show D-Coil. This orientation represents where $\theta_{z'} = 0$.

centric magnet motion, as long as these parameters do not vary between both angular and torque mode and the motion along the eccentric path is measurable. Furthermore, while the uniformity of the magnetic flux also does not play a role in the theoretical operation of the NTI, it does govern experimental aspects such as the sampling method for measuring the angular velocity.

In torque mode, we must minimize friction, magnetic, and gravitational forces in the central bearing to maximize sensitivity while maintaining single DOF motion. Additionally, it is still unclear how the torque wrench or torque screwdriver should interface with the NTI, especially if both are magnetic.

IV. Feasibility Calculations

To bound the design parameter space, we assume a maximum torque of $\Gamma = 1\,\mathrm{N\,m}$ and aim for an approximate size of 130 mm diameter × 36 mm height, similar to existing geometries of other calibration instruments in this range of torques.

A. Magnet System

For both Type X and Z, an NdFeB ring with geometry of 130 mm outer diameter × 12 mm height with a 25 mm inner bore will be used for this feasibility assessment. NdFeB was chosen for its high magnetic flux density and relatively high temperature coefficient of $10^{-3}\,\mathrm{K}^{-1}$. Half of the magnet has the opposite polarity as the other with a magnetic flux density magnitude of $\mid B \mid = 1\,\mathrm{T}$, a magnitude achievable by most magnet manufacturers. A second identical disk is concentrically mounted to the first, offset by 12 mm where the air gap is defined. Again, the magnetic flux density $B_{z'}$ on the midplane of the air gap was simulated for both Type X and Z in figs 4 - 5. The magnet is set to rotate at angular velocity $\omega_{z'} = 6\pi$ rad/s, three rotations per second, a reasonable speed for generating larger voltages between 1-10 V in the coil.

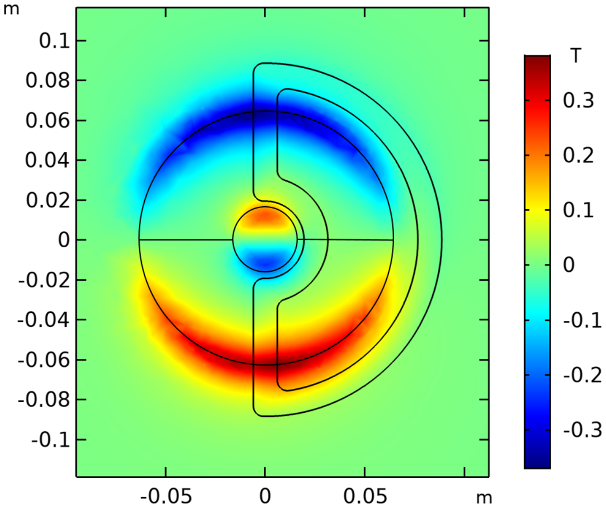

Fig. 4. Finite Element Analysis of the Type X magnetic flux density $B_{z'}$ distribution along the midplane of the air gap. Highest flux concentrations are along the edges of the magnet system furthest from the split line.

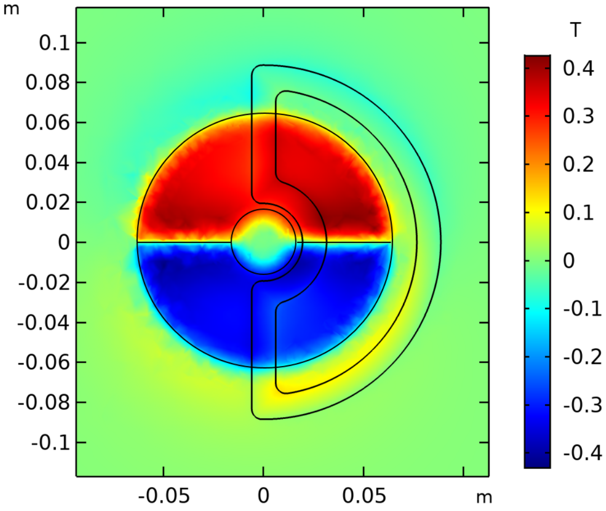

Fig. 5. Finite Element Analysis of the Type Z magnetic flux density $B_{z'}$ distribution along the midplane of the air gap. The flux concentration is more uniformly distributed throughout the air gap area.

B. Coil

The D-shaped coil will have a cross-sectional area of 12 mm × 6 mm, allowing for about 500 turns of AWG-26 wire, and an overall average radius r_e of 6.5 cm or an enclosed coil area of approximately $60\,\mathrm{cm}^2$, about half the footprint of one magnet. Covering half the magnet optimizes the sweep range for which maximum torque is generated. The maximum allowable current in AWG-26 wire is 2.2 A.

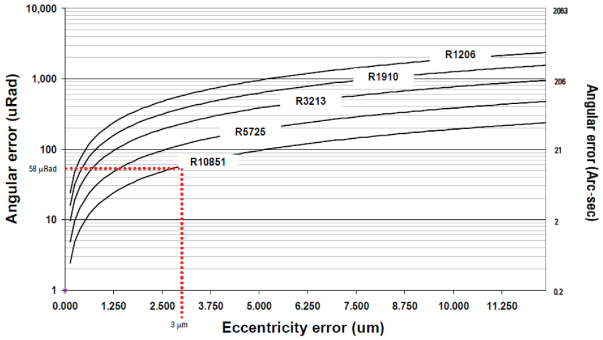

Fig. 6. The effect of eccentricity on angular accuracy over 2π radians as specified by the manufacturer, MicroE [8]. The rotary glass scale model R5725 will be used with a Mercury M1500 read head. For errors below $20\,\mu$rad, the eccentricity error on the concentricity alignmnent of the scale to the axis of rotation must be below $1\,\mu$m.

C. Rotary Encoder

In our baseline design, a microE R5725[1] rotary encoder scale will be rigidly mounted to the top surface of the top magnet and a microE Mercury M1500 read head was chosen for prototyping because this model is readily available for use by our group. The achievable uncertainty by this encoder is specified as 1 µrad when it is perfectly aligned, i.e., when the rotational run out of the scale is zero. Otherwise, the eccentricity of the trajectory causes an error over a full revolution indicated by fig. 6. Various alignment techniques can be implemented to reduce the eccentricity error but all require additional electronics.

D. Voltage, Current and Timing Measurement Hardware

It is assumed that the hardware capabilities of measuring voltage, current, and time to 0.1 % pale in comparison with that of the rotary encoder. General ideas regarding this topic are expounded upon in section V.

V. Measurement scheme

It is generally proper metrological practice to conduct measurements using an A-B-A scheme meaning a torque mode measurement is conducted both before and after an angular mode measurement. The methodology for measuring each mode is discussed.

A. Angular Mode

Recall from section II that the calibration factor ξ measured in angular mode is defined as

$$\xi = -\frac{\mathrm{d}\Phi}{\mathrm{d}\theta_{z'}} = \frac{V}{\omega_{z'}}, \tag{8}$$

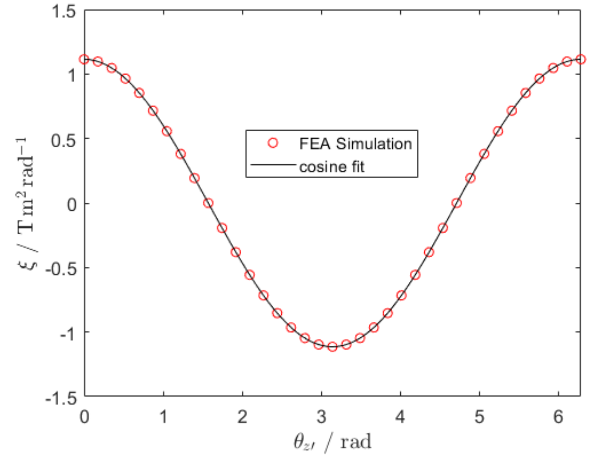

Fig. 7. Calibration factor ξ plotted over a full revolution of the Type X magnet. Torque extrema $(\mathrm{d}\xi/\mathrm{d}\theta_{z'} = 0)$ occur at $\theta_{z'} = n\pi$ where $n = 0, 1, 2, \ldots$. The points follow a cosine with an amplitude of $1.1\,\mathrm{T\,m^2\,rad^{-1}}$ (black line). A cosine fit can be applied to resolve the profile shape.

where the two variables, V and $\omega_{z'}$, must be determined to a relative uncertainty of 0.1% or better. Angular velocity $\omega_{z'}$ is measured by taking the change in rotational angle $\Delta\theta_{z'}$ over a measured time duration Δt.

However, the two different types of magnet systems proposed allow for two different methods of sampling $\Delta\theta_{z'}$. For the type X, the calibration factor is plotted over one revolution of the magnet in fig. 7 and follows a cosine. Hence, a high resolution angular measurement is not required. Instead, it can be substituted with a simple optical flag which is tripped once every revolution. $\Delta\theta_{z'}$ would have a baseline resolution of 2π rad and the Δt would be the time for one revolution or 0.33 s. The calibration factor could be interpolated with a cosine fit. The drawback to this method is that the true calibration factor profile must not have distortion greater than 0.1% from a cosine fit. If two identical magnets are unattainable, the cosine profile can be "tuned" to the proper shape with precision iron yokes or by allowing X-Y adjustability between the two magnets.

For the Type Z setup, the calibration factor is plotted over one revolution of the magnet with a calibration factor profile as shown in fig. 8. Here it is difficult to predict the profile shape a priori thus a cosine interpolation is invalid and rapid sampling of angular position and time must be achieved. Torque extrema where a wide region of $\mathrm{d}\xi/\mathrm{d}\theta_{z'} = 0$ occur at $\theta_{z'} = n\pi$ rad where $n = 0, 1, 2, \ldots$. At these angles, the change in ξ only exceeds 0.1% when $\theta_{z'} > n\pi \pm 50\,\mathrm{mrad}$.

Let's assume here that $\Delta\theta_{z'}$ needs to be sampled every 20 mrad to resolve the profile. Thus, the absolute angular error allowed for this measurement would be $20\,\mu$rad. Referencing fig. 8, the rotary scale eccentricity error must be less than 1 μm.

Given the magnet has an angular velocity of $\omega = 6\pi\,\mathrm{rad\,s^{-1}}$, the induced voltage would have a peak value on the order of 10 V making the voltage metrology of 0.1% relatively trivial

[1] Certain commercial equipment, instruments, and materials are identified in this paper in order to specify the experimental procedure adequately. Such identification is not intended to imply recommendation or endorsement by the National Institute of Standards and Technology, nor is it intended to imply that the materials or equipment identified are necessarily the best available for the purpose.

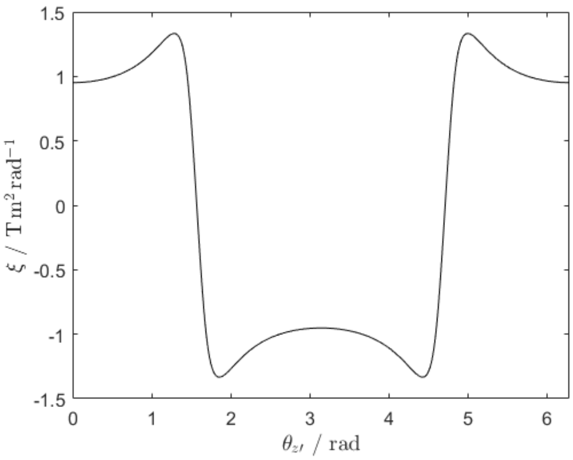

Fig. 8. Calibration factor ξ plotted over a full revolution of the Type Z magnet. Torque extrema where a wide region of $\mathrm{d}\xi/\mathrm{d}\theta_{z'} = 0$ occur at $\theta_{z'} = n\pi$ rad where $n = 0, 1, 2, ...$ High resolution sampling of $\omega_{z'}$ and V are necessary to resolve the profile shape.

compared to the angular metrology. For example, a Fluke 177 handheld multimeter already meets performance specifications with an accuracy of 0.09% for DC voltage measurements. Though such a device is lacking in terms of external triggering features and timing jitter on when the voltage is actually measured, it demonstrates that obtaining a sufficiently accurate DC voltage measurement is not difficult.

The same is true for the time metrology. For example, a low cost ublox LEA-M8F time and frequency reference can run independent of GPS with a 1×10^{-7} hold-over after 24 hours. Since a computer will be necessary for operating the NTI, the embedded computer clock provides another option that meets the timing measurement needs.

B. *Torque Mode*

Once ξ is determined in angular mode, the magnet is to be servoed to $\theta_{z'} = 0$ or π rad where the torque is at an extremum, i.e. $\mathrm{d}\xi/\mathrm{d}\theta_{z'} = 0$. With a controllable current source, a current I will be applied. The current will be measured either directly or via the equivalent voltage drop across a calibrated resistor. A torque wrench or screwdriver to be tested is then inserted into the NTI and I is increased until the tool clicks. It is critical to design the system such that the magnetic interaction between the tool and the NTI is minimized otherwise an additional source of error appears. This torque is measured as

$$\Gamma_{\mathrm{on}_1} = \xi I_{\mathrm{on}_1} \tag{9}$$

Next, a null measurement is conducted with the tool removed. Any spurious torques from bearing friction or gravity loading will be measured here as

$$\Gamma_{\mathrm{off}} = \xi I_{\mathrm{off}} \tag{10}$$

Finally, following the A-B-A measurement principle, a bracketing torque measurement is taken

$$\Gamma_{\mathrm{on}_2} = \xi I_{\mathrm{on}_2} \tag{11}$$

The torque generated by the NTI to calibrate the tool under testing is defined as

$$\Gamma_{\Delta} = \xi(\frac{I_{\mathrm{on}_1} + I_{\mathrm{on}_2}}{2} - I_{\mathrm{off}}) \tag{12}$$

By injecting the maximum allowable current 2.2 A into the coil at $\theta_{z'} = 0$, the Type Z magnet system can generate a peak torque of 2.1 N m, almost twice that of the Type X system of 1.1 N m due to its magnetization naturally pointing along the Z direction.

VI. Coil Optimization

It is interesting to take notice of the residual magnetic field residing outside of the air gap bounds. Examining figs. 4 - 5, a faint halo encircles the outer circumference of the magnet and has a $B_{z'}$ value of approximately 0.1 T or -0.1 T. In the Type X model, the sign of this halo $B_{z'}$ value matches that of its corresponding magnet edge and in the Type Z model, the sign of $B_{z'}$ is opposite of its corresponding magnet edge. This sheds insight on how to determine the optimal radius r_e of the coil to maximize the output torque.

Fig. 9 shows the maximum torque capability each system as a function of coil radius r_e at $\theta_{z'} = 0$. In the Type X system, there is no clear maximum since the flux density in the halo has no sign change, i.e. the optimal r_e is ∞ . Subjectively, one can choose r_e based on diminishing returns which most likely lies in the range of 8 - 9 cm. In the Type Z system, a clear maximum exists as the flux density in the halo goes through a sign change. Thus the coil radius where maximum torque can be attained is 6.7 cm.

The amount of power dissipation by the D coil at maximum current is on the order of 100 W, which makes the calibration factor to first order independent of thermal expansion but may present a safety concern to the user due to power density. This issue can be treated with thermal management techniques such as heat sinks or by modifying the parameters of the electromagnet, i.e. increasing $B_{z'}$, decreasing coil resistance, or by adding a second D-coil on the unused half of the electromagnet.

VII. Discussion

The two designs proposed have both advantages and practical limitations associated with fabrication and alignment of components. The advantage of Type X is that it is a sampling-free method since a perfect cosine ξ profile is assumed and verified by the induced voltage signature. A single optical flag can be implemented instead of a rotary encoder which is difficult to align. The caveat is the cosine profile must not have a distortion of more than 0.1% from a true cosine function. This is governed by the physical alignment and variation of magnetization between the two magnets and may prove difficult to achieve.

A possible remedy could be to add X and Y adjustability of one magnet relative to the other so that the cosine shape

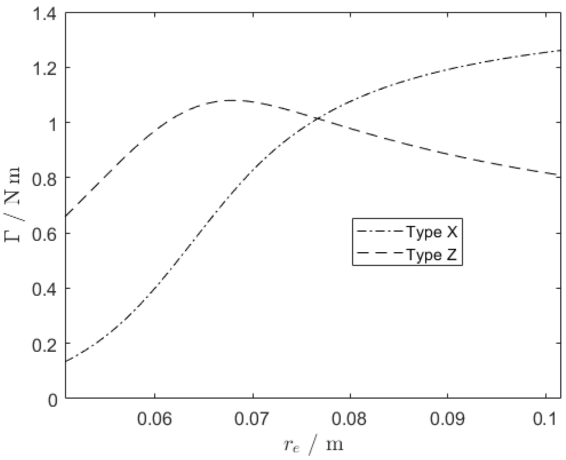

Fig. 9. Output torque with varying coil radii r_e for the Type X and Type Z magnets when at $\theta_{z'} = 0$. Maximum torque for Type Z is when $r_e = 6.7\,\text{cm}$.

can be empirically "tuned" by observing the induced voltage signal over multiple rotations.

The advantage and disadvantage of Type Z is opposite of to that of Type X. The level of alignment and variation of magnetization between the two magnets are relaxed since the entire ξ profile is to be scanned. The meticulous alignments required for Type X are shifted onto aligning the rotary encoder scale instead as the geometric center of the scale must be coincident with the axis of motion of the magnet system.

A possible remedy could be to widen the flat spot and increase $\Delta\theta_{z'}$ where $\xi < 0.1\%$, thereby lowering the error due to eccentricity of the encoder scale. This can be achieved by installing precision iron yokes to steer the magnetic flux to obtain a more uniformly distributed magnetic field in the air gap.

No matter which design, both require high levels of inter-component alignments and careful attention to ensure the magnetic interaction between the tool to be calibrated and the NTI is negligible. It seems wise to take a hybrid approach, perhaps using the encoder for a low resolution scan of the Type X magnet profile, relaxing the criteria for both a near-perfect encoder scale alignment and a near-perfect cosine interpolation.

VIII. Conclusion

A theoretical feasibility study was conducted at NIST for a method to directly realize small torques for calibrating torque wrenches and torque screwdrivers geared towards end users and the results show promise. A maximum torque of approximately $1.1\,\text{N m}$ can be achieved with both the Type X and Type Z designs. The next steps include the detail designing of both types of magnet systems and procure the components necessary for prototyping. The prototypes will be measured against one another to fundamentally determine which model is superior. Further research will be required for ultimately evolving the prototype into a commercial product and will depend on collaborating with instrument manufacturers.

The UCEF Approach to Tool Integration for HLA Co-Simulations

Thomas Roth, Christopher Lemieux and Martin Burns
National Institute of Standards and Technology
Gaithersburg, Maryland, U.S.
thomas.roth@nist.gov, christopher.lemieux@nist.gov, martin.burns@nist.gov

***Abstract*—Cyber-Physical Systems (CPS) are complex systems that require expertise from multiple domains in their design, implementation, and validation. One cost-effective technique for validation of CPS is the integration of two or more domain-specific simulators into a joint simulation called a co-simulation. Standards such as the High Level Architecture (HLA) have been developed in part to simplify the co-simulation development process. However, CPS co-simulation still requires significant expertise, especially when the goal is the integration of a new domain-specific tool or simulator. The U.S. National Institute of Standards and Technology (NIST) has released a software platform called the Universal CPS Environment for Federation (UCEF) to simplify the development of CPS co-simulations. UCEF provides two approaches to integrate tools and simulators. The first approach is a Java library called the UCEF Gateway that limits the development effort to a list of callback functions in a well-defined simulation life cycle. The second approach is a Representational State Transfer (REST) server developed using the gateway for applications that can implement a Transmission Control Protocol (TCP)/Internet Protocol (IP) client. This paper describes how both approaches are implemented to expedite the integration of new domain-specific tools and simulators.**

***Keywords*-application programming interface, co-simulation, cyber-physical systems, high level architecture, tool integration**

I. Introduction

The design and implementation of Cyber-Physical Systems (CPS) requires significant expertise from multiple domains to ensure smooth operation. For a more formal definition, CPS consist of devices that use logical computation informed by measurements of the environment to actuate physical changes. CPS are common in critical infrastructure such as smart manufacturing, autonomous vehicles, and smart grid [1]. Failure of these systems has great economic and social costs, and validation is required to minimize the risk of failure prior to deployment. However, deployed CPS can be larger than city-scale and it is impractical to prototype all design decisions due to the immense cost associated with deployment. One cost-effective validation technique to overcome this challenge is co-simulation. Co-simulation is the integration of multiple domain-specific simulators into a common execution environment to produce results that more closely resemble the deployed system. The integration of existing simulators is a more scalable solution than the development of new, more complex simulators that can model all CPS dynamics in a single environment. It is quite common in smart grid research, for instance, to perform co-simulation that integrates a network simulator with a power system simulator [2].

The IEEE 1516-2010 High Level Architecture (HLA) is one standard for the co-simulation of distributed processes [3]. A single simulator or process is defined as a federate, and the collection of interacting federates is defined as a federation. The federation communicates and coordinates over middleware called a Runtime Infrastructure (RTI) which can be thought of as a shared message bus. The RTI provides a set of standardized services to the participating federates to facilitate the co-simulation. HLA was designed to be comprehensive and defines all the services that could be useful in distributed simulation whether or not those services are frequently used.

While HLA provides a rich and complete service set [4], the standard is complex and has features that may see minimal use in practical applications. Of the more frequently used HLA services, several can be implemented the same across all federates regardless of the domain or objective of any given experiment. But there is little publicly available information on which services are frequently used, and little guidance on how the services could be implemented to be reusable in a wide range of use cases. None of the services defined in the standard are labeled as optional, and it is not clear which parts of the standard must be implemented and which parts can be safely ignored. From the authors' experiences, learning HLA is a significant many-month process that does not greatly simplify the challenges of co-simulation.

The U.S. National Institute of Standards and Technology (NIST) is one of many groups that are developing software tools to reduce the burden of co-simulation development. The NIST tool, the Universal CPS Environment for Federation (UCEF), was released as a virtual machine that provides code generation of the HLA services for different simulators based on simple user-designed models [5]. One goal of UCEF is to provide a portable development environment where users can develop co-simulations without a background in distributed computing and the HLA standard. However, UCEF is only as powerful as the number of its supported simulators and the ease at which new simulators can be integrated.

This paper presents the approach to tool integration in UCEF. This approach makes assumptions on the HLA service set — in particular, it assumes that most of the services are not used — and uses those assumptions to produce a checklist of functions that must be implemented to integrate new simu-

Roth, Thomas; Lemieux, Christopher; Burns, Martin. "The UCEF Approach to Tool Integration for HLA Co-Simulations." Paper presented at Workshop on Design Automation for CPS and IoT, Sydney, AU. April 21, 2020 - April 21, 2020.

lators. Two methods for tool integration are presented: a Java library that can be extended to implement a new federate type, and a Representational State Transfer (REST) Application Programming Interface (API). These methods have been used to integrate several smart grid simulators into UCEF, and were developed out of a need to support software developers with no prior co-simulation experience.

The remainder of the paper is organized as follows. Section II provides an overview of related research into simplification of the co-simulation development process. Section III presents a brief overview of the UCEF software platform. The first approach to tool integration using a Java library is presented in Section IV, and the second approach using a REST API is presented in Section V. The paper is then concluded with Section VI.

II. Related Work

Several software platforms have been created to accelerate the HLA development process. These platforms let users model a CPS using a Domain Specific Modeling Language (DSML) and leverage code generation to transform user models into code that executes a subset of the HLA services. For instance, a user might define the input and output requirements of a federate in a table, and the software platform could then transform that table into skeletal code that requires minimal implementation from the user. At the forefront of these software platforms are the commercial design tools released by different HLA RTI vendors to simplify the use of their products [6][7]. While these tools are compatible with other RTI implementations, the HLA research community has attempted to develop open-source alternatives that perform similar functions due to concerns over cost.

One of the earlier open-source software platforms for HLA was the Command and Control Wind Tunnel (C2WT) produced from the Institute for Software Integrated Systems at Vanderbilt University. C2WT uses extensions to a graphical modeling environment called the Generic Modeling Environment (GME) to support the modeling and code generation of HLA federations [8]. Because GME was a desktop application that could only be accessed by one user, it was difficult to use in organizations that required model sharing between collaborators, and therefore a web-based variant was developed called the Web-based Generic Modeling Environment (WebGME) [9]. Vanderbilt University updated C2WT to use WebGME in a new software platform called the Cyber-Physical Systems Wind Tunnel (CPSWT). Public instances of CPSWT are hosted in the cloud at Vanderbilt University and the source code is available online through their GitHub repository [10]. NIST collaborated with Vanderbilt University to produce an offline version of CPSWT with additional support for several smart grid simulators. NIST released this software platform as an Ubuntu virtual machine called UCEF [5]. Other similar approaches have used Systems Modeling Language (SysML) diagrams to generate C++ executables compatible with Simulink models [11], and extensions to Eclipse that incorporate a DSML for HLA that can generate code for C++ federates [12]. All these software platforms attempt to minimize the implementation burden on the user by making assumptions on the default implementations of certain HLA services and using code generation.

Another significant contribution to the HLA open-source community is the HLA Development Kit Framework (DKF) [13]. The DKF is not a software platform, but an open-source Java library based on Java annotations. It provides a basic class structure that can be extended through inheritance to implement Java federates, and provides default implementations of most HLA services in parent and helper classes. In addition to the Java source code, the DKF is packaged with examples, tutorials, and documentation for the creation of federates using its simplified federate life cycle.

Another example that defines a federate life cycle with default implementations of the HLA can be found in [14]. This is not a software platform, nor a reusable library, but an example implementation of one federation using a well-defined life cycle. It defines a modular Federation Object Model (FOM) for data exchange between independent systems and prescribes a specific life cycle for federates in the form of state machines.

The Functional Mockup Interface (FMI) is a more recent co-simulation standard run as a Modelica Association Project [15]. While HLA attempts to define the complete set of services that could be useful in a distributed simulation, including services not commonly used in practice, FMI takes the opposite approach of trying to define the minimal set of functions required for co-simulation. FMI research efforts face similar challenges in trying to make the standard more accessible to users without deep knowledge of co-simulation. There are tool chains that use SysML models and code generation to automate portions of the federation development process [16], and there is a C++ library that can be leveraged to provide default implementations for most of the FMI functions [17].

In all of these cases, the goal has been to abstract the full range of HLA services and FMI functions that are visible to the end user, and provide default implementations for the set of services and functions that are federate independent. The reduced service set can then be considered as an API which minimizes user interaction with the standards documents. As a consequence, all the implementations are incompatible as they redefine in different ways the standardized services and function sets to improve user accessibility. The remainder of this document describes how the HLA services were redefined for the UCEF software platform.

III. Universal CPS Environment for Federation

The software efforts to simplify federation development share several common elements: they are often open-source projects that use some graphical language that leverages code generation to transform user models into federate code. However, there is often an assumption that it’s easy - or even possible - for a user to install and configure the software environment. Information technology (IT) policies such as firewall rules can prevent activities such as the installation of

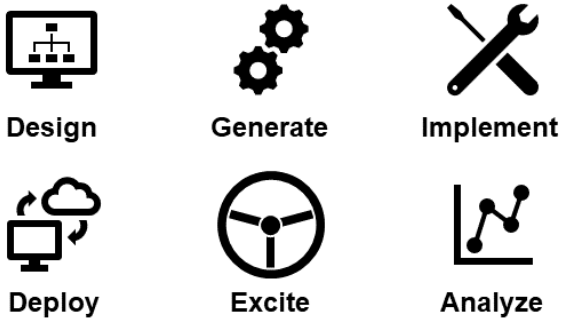

Fig. 1. The stages of Federate Development (top row) and Federation Deployment (bottom row) in the UCEF workflow

new software or access to a user account with administrative rights. These policies can make it very challenging to use some of the solutions mentioned in the related work.

This section provides an overview of the NIST software platform UCEF [5]. UCEF is a portable development environment created to expedite the development of HLA federates and federations. The main feature that distinguishes UCEF from similar approaches is its distribution as a self-contained virtual machine. This makes UCEF non-intrusive, easy to redistribute, and easy to install. It is distributed as an Ubuntu 16.04 virtual machine that runs a local WebGME server. The WebGME front end provides a graphical web environment where users can model federations using simple building blocks, and the back end uses JavaScript plugins that transform these models into stub code for different simulators. The current version of UCEF supports several simulators in the smart grid domain that include GridLAB-D, TRNSYS, and LabVIEW with additional support for native Java and C++ applications. The ease of development in UCEF rises from the separation of a federate implementation into two layers: a user layer which implements the federate behavior, and an infrastructure layer generated from WebGME that provides the default implementations for most HLA services.

Figure 1 shows the stages from federate development to federation deployment in the UCEF workflow. The current version of UCEF implements the top row related to federate development which consists of the stages Design, Generate, and Implement. These three stages produce an executable piece of software that can be run on any compute environment ranging from the UCEF virtual machine, to a desktop computer, to a node in the cloud. While UCEF also generates some simple bash scripts for deployment, the bottom row on federation deployment is still under development and the three stages of Deploy, Excite, and Analyze are notional.

The *Design* stage uses WebGME with the HLA metalanguage produced at Vanderbilt University for their platform CPSWT. A user produces a graphical model of a federate in a web browser which includes the specification of its simulator type (such as LabVIEW or Java program) and its various inputs and outputs. Figure 2 shows an example of a simple federate designed in this environment that both subscribes to and publishes one HLA message. Because WebGME is a web-application running on the local virtual machine, this modeling phase does not require an Internet connection despite the use of an web browser.

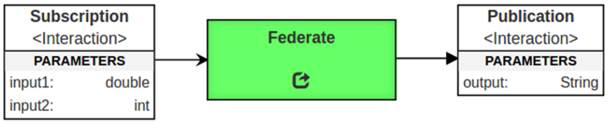

Fig. 2. An example WebGME Federate Model

The *Generate* stage is initiated when the user clicks a run button in WebGME to execute its code generation plugins on the federate model. WebGME plugins are written in JavaScript and use Embedded JavaScript Templates (EJS) to define the artifacts that should be generated for each of the supported simulator types. All artifacts produced from WebGME in UCEF are output as Apache Maven projects, regardless of whether they contain Java code. These artifacts have dependencies on the open-source Java RTI Portico and will not work with other RTI implementations [18].

The *Implement* stage varies dependent on the type of federate that was designed and generated, and may occur outside of the UCEF virtual machine. Appropriate domain-specific tools are used to implement each federate type, so Java files are implemented in Eclipse and LabVIEW projects are implemented in LabVIEW. In the cases that require an active license, such as LabVIEW, the generated files will have to be moved to a licensed machine to complete the federate development process.

Figure 3 shows how UCEF implements these three stages of the federate development process. The UCEF virtual machine contains a local WebGME server that is preconfigured with support for various types of simulators. When a user finishes the design and generate stage, stub code for the modeled federates is available outside of the UCEF virtual machine that can connect to an RTI and participate in a federation execution without any additional user implementation. However, the stub federate code contains no behavior and must be implemented by the user to fulfill its design goal. All the simulators shown in Figure 3, in addition to native Java and C++ applications, have been integrated into UCEF using the two approaches described in this paper.

The bottom row of Figure 1 on federation deployment is a notional representation of how deployment could work in UCEF. A federate designed in UCEF can be removed from the virtual machine and deployed in any environment, from a laptop to the cloud. Therefore, the mechanical process of deployment depends on an infrastructure that was provisioned and configured independent of the UCEF virtual machine, and this process may have significant differences from one work environment to another. There are, however, general deployment activities where UCEF could provide useful tools to expedite the deployment process.

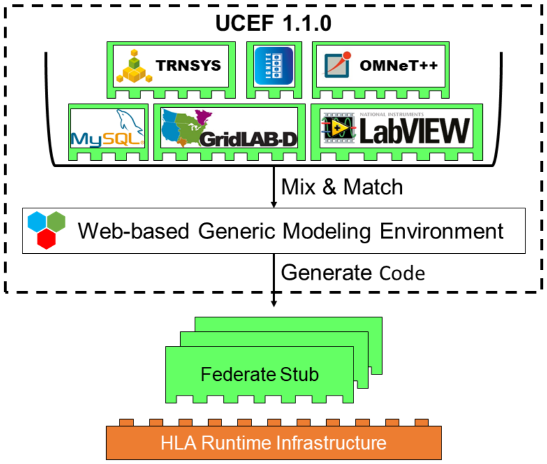

Fig. 3. Federate Development in UCEF

The federation *Deploy* stage needs to package the federates and their dependencies for deployment. First, the user needs to select the federates that should be deployed. It's possible that multiple instances of the same source code could be deployed as different federates in the same federation, and the selection process should handle this case. Then, the artifacts that contain the federates and their dependencies need to be collected from some database and packaged for deployment.

Once deployed, federates will be either configured or driven to execute a desirable scenario. The *Excite* stage perturbs the federation execution using a combination of static configuration files and dynamic runtime messages. For this stage, a simple scripting language could be incorporated into WebGME to generate configuration files that script the runtime behavior of federates. In addition, a suite of federates that enable user interaction – using either a graphical interface or a web server – could be developed and packaged with UCEF.

The *Analyze* phase involves both runtime monitoring of the federation and the use of database storage for offline analysis. For both cases, analytic federates are required to either allow user interaction at runtime or interface with different database systems for data logging.

The current version of UCEF supports the generation of bash scripts to run the federates in the virtual machine, and includes a database federate to store the results of the federation execution. The remainder of this paper focuses on the first row related to federate development and discusses how code generation, and default HLA service implementations, have been used to simplify the federate development process in UCEF.

IV. UCEF Gateway

The first approach to ease federate development is an open-source Java library called the UCEF Gateway that implements a simplified federate life cycle [19]. The gateway implements a main loop that yields control to user-implemented callback functions at specific points in this life cycle. The gateway was developed based on the following three requirements:

1) usable without HLA expertise
2) easy to integrate new things
3) agnostic to the federation data model

To satisfy the first two requirements, the gateway does not support the following HLA services: federation save, federation restore, ownership management services, and data distribution management services. A UCEF federation executes one experiment from start to finish and then terminates, without federates joining or leaving during the federation execution. Therefore, there is no need to load a prior state or handle the distribution of object instances due to sudden changes in the federation membership. The data distribution management services are useful for improved scalability, but the HLA implementation of regions as an unsigned integer is unwieldy. Each federate implementation must have the same region encoder and decoder functions to have consistent interpretations of the integer value, and this creates a new scalability problem due to the difficulty of configuration management. It's better to address scalability using traditional networking approaches rather than the use of HLA regions [20].

The third requirement distinguishes the UCEF Gateway from the HLA DKF which requires explicit Java annotations for declared variables that represent federation data. This requirement was derived from the need for a mechanism to ease the integration of entire simulators, not individual simulations. A simulator requires one reusable federate implementation that can support any simulation with an arbitrary data model. An approach that requires specification of a data model will need additional user implementation whenever a federate is integrated into a new domain or scenario, which defeats the purpose of a gateway library.

Since its release, the UCEF Gateway has been used to integrate several simulators: GridLAB-D, TRNSYS, and LabVIEW. Based on the lessons learned from these applications, a revised version with a modified federate life cycle has been released. This section summarizes the UCEF Gateway and highlights the modifications since its original publication.

A. Time Management Strategy

The gateway executes a well-defined life cycle with callbacks to the user application that can be used to define federate behavior. During the callbacks, the user code can use the public methods of the gateway library to perform functions such as sending data to the federation and querying the FOM. The gateway defines the time management strategy on behalf of the user application, and this strategy cannot be modified. All gateway implementations are both time constrained and time regulating to operate in lockstep with federation logical time. Logical time progression uses the HLA time advance request service with a fixed step size for the duration of the federation execution. The logical step size can be configured by the user in the gateway configuration files. At this time, the next event request service is not supported.

Roth, Thomas; Lemieux, Christopher; Burns, Martin. "The UCEF Approach to Tool Integration for HLA Co-Simulations." Paper presented at Workshop on Design Automation for CPS and IoT, Sydney, AU. April 21, 2020 - April 21, 2020.

During its life cycle, the gateway assumes the federation has three synchronization points: ready to populate, ready to run, and ready to resign. The gateway assumes that another federate registers these synchronization points, and that federate also determines when the federation synchronizes on each point. In UCEF this federate is called the federation manager, and it gates progression through the federate life cycle by delaying its synchronization until it determines the federation is ready to progress. These synchronization points divide the federate life cycle into three distinct stages: initialization, logical time progression, and termination.

B. Federate Life Cycle

Figure 4 shows the UCEF Gateway federate life cycle. The rectangles are the user-implemented callback functions. Several transitions between callbacks depend on federation synchronization events, which are indicated with a labeled dotted line below the transition. A gateway implementation can block on the first transition, labeled *JoinFederation*, when it tries to join a federation that has not yet been created. The other synchronization events correspond to the three synchronization points discussed in the previous subsection on time management. In addition, the transition labeled *time advance grant* blocks until the federation as a whole advances its logical time to the next logical time step.

Table I describes each callback function in the life cycle. Four of the callback functions that begin with the word *receive* are consolidated in Figure 4 as the single state *receive data*. The order of these callbacks is arbitrary and interleaved, as it depends on the RTI implementation. It is possible that some of the *receive* callbacks do not occur for a given logical time step, and that the callbacks occur in different orders between logical time steps. However, all the *receive* callbacks will be handled prior to the gateway invoking the *step* callback.

The life cycle and callback functions do not show the public methods available in the gateway library for interaction with the federation. Some of these methods are intuitive, such as sending data to the federation and querying for the data type of received data. These methods are summarized in the original gateway publication, and unchanged in the revised version. Of note is that the gateway library provides a polling mechanism to receive new data that can be executed anywhere in the life cycle except *before join federation* and *before exit*. Although Figure 4 seems to indicate that data arrives in one bulk read operation each logical time step, the user application could choose to poll for data where it is needed. The two noted exceptions are merely because the gateway does not exist as a federate in a federation for those two stages of the life cycle, so the poll data operation is undefined.

A few of the callback functions are new since the original release of the UCEF Gateway. The callback *before join federation* was added to give a user a proper initialization method in the life cycle rather than relying on the Java constructor to serve this role. The *before first step* and *before ready to resign* callbacks were added to give unique meaning to the first and last logical time step of a simulation. Before these callbacks were introduced, conditional logic had to be inserted into the *step* callback to determine whether a time step was an intermediate or edge step. This complicated the user code more than the addition of two optional callbacks that could be ignored when the first and last steps are not distinguished. Likewise, the *receive object registration* and *receive object deleted* callback were added to prevent the use of conditional logic inside the *receive attribute reflection* callback when processing an object instance for the first time. While this has led to the introduction of five additional callback functions, the default behavior for each callback is a no-operation.

V. REST API

The UCEF Gateway was intended to simplify federate development by providing reasonable default implementations for the HLA services that did not change between federate implementations. However, in practice, most gateway applications that integrated simulators into UCEF used a simple client-server architecture with TCP/IP sockets. It is much easier to embed a socket in a simulator to pump its data to a server than extend the simulator source code to implement the gateway callback functions. This common use of the gateway led to redundant socket code between gateway implementations — a problem the gateway was designed to alleviate — and the creation of unique communication protocols for each simulator. This section describes the first attempt at a REST API built using the UCEF Gateway to provide a common server implementation for these TCP/IP socket applications. This REST API is available as a standalone federate distributed with UCEF that can be incorporated into any federation.

The reusable TCP/IP server was implemented as a REST API rather than a custom socket protocol for three reasons. First, the client code would be shielded from the potentially long synchronization delays caused by HLA logical time progression. A sensor or small Internet of Things (IoT) device might want to produce a stream of data at a constant frequency and avoid blocking calls. The fast response of a REST implementation will support these devices without the need for a multi-threaded implementation. Second, the REST implementation eliminates the need for constant heartbeat messages between the client and server to ensure a persistent socket connection. This reduces the overhead for the client implementation. Third, the REST API introduces another layer of abstraction that may make it easier for users to develop new federates without knowledge of the HLA standard.

The HLA standard already defines a REST API for interacting with the RTI [21][22]. It is important to note that the standard API exposes the complete set of RTI services, which includes the services that are rarely utilized and the services where default implementations are sufficient for most use cases. Use of the standard API represents a significant implementation burden on the user, and loses the benefits of a simplified approach like the UCEF Gateway. For this reason, a new REST API implemented on top of the UCEF Gateway was developed and is presented in this section.

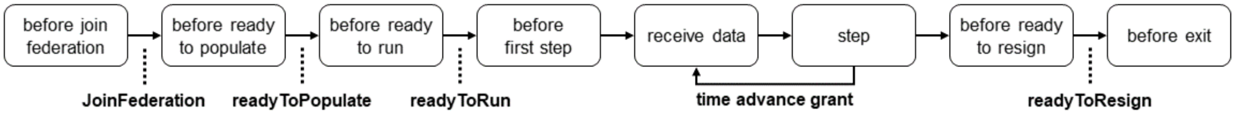

Fig. 4. UCEF Gateway Life Cycle

TABLE I
GATEWAY CALLBACK FUNCTIONS

Callback	Description
before join federation	Perform basic initialization that is HLA independent, such as initialization of data structures
before ready to populate	Perform initialization that requires a joined federation, such as registration of object instances
before ready to run	Perform initialization that requires other federates, such as the exchange of initial values
before first step	Perform one-time actions for the first logical time step, such as starting a simulation
receive object registration	Handle a discovered object instance
receive attribute reflection	Handle an attribute reflection for one discovered object instance
receive object deleted	Handle a removed object instance
receive interaction	Handle one received interaction
step	Perform the logic executed each logical time step, such as updating object attributes
before ready to resign	Perform one-time actions for the last logical time step, such as the exchange of final values
before exit	Perform any cleanup, such as stopping the simulation and closing output files

TABLE II
LIST OF ENDPOINTS

Endpoint	Method	Request Format	Response Format
/status	GET	(none)	FederateStatus
/join	POST	ClientPost	FederateStatus
/dostep	POST	ClientPost	FederateStatus
/ping	POST	(none)	200 OK

A. Endpoints

Table II lists the endpoints defined for the REST API. The request and response formats indicated in this table are defined in the following subsection on payloads. The *ping* endpoint is intended to be a light-weight heartbeat message to check the status of the server. When the federation is starting, or when the client loses connection with the server, the *ping* message can be used to periodically check if the server is online. The *status* endpoint returns the current state of the server. Because the server implements the UCEF Gateway, it represents a federate in some federation, and its status contains information such as the current logical time and the most recent values for data exchanged in the federation. The *join* endpoint is used to tell the server that the client wants to join the federation, and contains some details about the client's identity and data model. The *dostep* endpoint is used to tell the server that the client is ready to advance to the next logical time step, and contains the set of client data that should be broadcast to the federation.

B. Payloads

JavaScript Object Notation (JSON) is used to define all the payload formats. The endpoints define two payloads called *ClientPost* and *FederateStatus*. However, these payloads contain HLA interactions and object instances. This subsection will first define the JSON format for these primitive HLA data structures, and then the formats used in Table II.

Listing 1 defines the JSON for object instances. An object in HLA can be thought of like a variable in a programming language. The user defines a data type (the object class) and a unique variable name (the instance name). The object class determines the structure of the data associated with the object instance in much the same way the data type determines the structure of a variable. The *classPath* field is the fully qualified path for the object class, and the *instanceName* field is the unique identifier of a particular object instance. The *attributes* array is a list of name-value pairs for the data associated with the specified object instance. All of the attribute values are encoded as strings, although the attribute could be any of the data types defined in the FOM. In the current implementation, the client and server are both pre-configured with the FOM so both sides can convert the string value into the correct data type. However, future work will have the client send the FOM to the server by embedding it into the payload of the *join* endpoint.

Listing 1
OBJECTINSTANCE JSON FORMAT

```
{
  "classPath": "ObjectRoot.ClassName",
  "instanceName": "ObjectInstanceName",
  "attributes": [
    {
      "name": "attrName",
      "value": "asString"
    }
  ]
}
```

The interpretation of Listing 1 depends on the direction of data flow. When the client sends an object instance to the server, it is a request to publish updated values for an object instance registered by the client. When the server sends an object instance to the client, it is a notification that the values for that object instance have changed in the federation.

Listing 2 shows the JSON format for interactions which is almost identical to the format for object instances. Because interaction instances are not assigned unique identifiers, as they have no persistent state that changes over logical time, the *instanceName* field has been dropped. In addition, to conform with the HLA naming conventions, the *attributes* field has been renamed to *parameters*. Otherwise, the format and use of this JSON payload is identical to object instances.

Listing 2
INTERACTION JSON FORMAT

```
{
  "classPath": "InteractionRoot.Class",
  "parameters": [
    {
      "name": "paramName",
      "value": "asString"
    }
  ]
}
```

Listing 3 shows the *ClientPost* JSON format that is sent from the client to the server. The client provides its internal state, represented with three boolean variables, as well as the list of interactions and object instances that should be published to the federation. *isJoining* is a boolean flag that indicates the client is ready to start the simulation, and *isLeaving* is a boolean flag that indicates the client is ready to stop the simulation. *isAdvancing* is a boolean flag that indicates the client has finished its current logical time step and is ready to advance logical time to the next iteration of execution. Not all permutations of values for these flags are valid, as a client cannot simultaneously join and leave. The valid permutations will be elaborated on in the following subsection on the state machine. The *interactions* and *objects* arrays contain updated values for all the interactions and object instances for the current logical time step. If an object instance has not changed from the previous time step, it can be omitted entirely from this array.

Listing 3
CLIENTPOST JSON FORMAT

```
{
  "isJoining": true/false,
  "isAdvancing": true/false,
  "isLeaving": true/false,
  "interactions": [ Interaction ],
  "objects": [ ObjectInstance ]
}
```

Of note is that the *ClientPost* payload provides no mechanism for the client to inform the server that it wants to register a new object instance. The server maintains a list of names for the client's registered object instances. When the client sends an object instance with an unknown *instanceName*, the server will automate the object registration process and update its internal list.

Listing 4 shows the *FederateStatus* JSON format that is sent from the server to the client. The server also provides its internal state using three boolean variables that will be further explained in the subsection on the state machine. *isSimulationActive* indicates the federation exists, and is either preparing to begin or has already begun logical time progression. *isDoStep* indicates the server is idle waiting on input from the client before it proceeds to the next logical time step. *isTerminating* indicates the simulation is over, and the client needs to prepare to exit. An additional *timeStep* value is provided to notify the client of the current logical time in the HLA federation. The *interactions* and *updatedObjects* arrays contain updated values received from the other federates. If an object instance has not been updated since the last status report, it is omitted entirely from this array. The *FederateStatus* JSON also contains a *newObjects* array that lists all the object instances that were registered by other federates since the last status update. If an object instance appears in the *newObjects* array for a given status report, it will not appear in the *updatedObjects* array.

Listing 4
FEDERATESTATUS JSON FORMAT

```
{
  "isSimulationActive": true/false,
  "isDoStep": true/false,
  "isTerminating": true/false,
  "timeStep": 0.0,
  "interactions": [ Interaction ],
  "newObjects": [ ObjectInstance ],
  "updatedObjects": [ ObjectInstance ]
}
```

C. State Machine

Figure 5 shows the state machine implemented by the REST server. This state machine does not show the exceptions that might cause the server to respond to the client with an error code. An exception would occur whenever the server receives a *join* or *dostep* request from the client in a state where there is no explicit transition labeled with that endpoint. The state transitions mirror the synchronization points identified in the gateway life cycle from Figure 4. The same labels are used for *JoinFederation*, *readyToPopulate*, *readyToRun*, *time advance grant*, and *readyToResign*. Three additional labels appear in the state machine transitions: two of the REST endpoints for *join* and *dostep*, and one transition labeled *exit condition*. Because the *ping* and *status* endpoints are valid in all states, they are not shown in the state machine.

The server has an internal state represented by the three boolean flags *isSimulationActive*, *isDoStep*, and *isTerminating*. These booleans have well-defined values for each state in the state machine as indicated in Figure 5. When the server produces a *FederateStatus* payload in response to a client request, the values of these booleans associated with the current

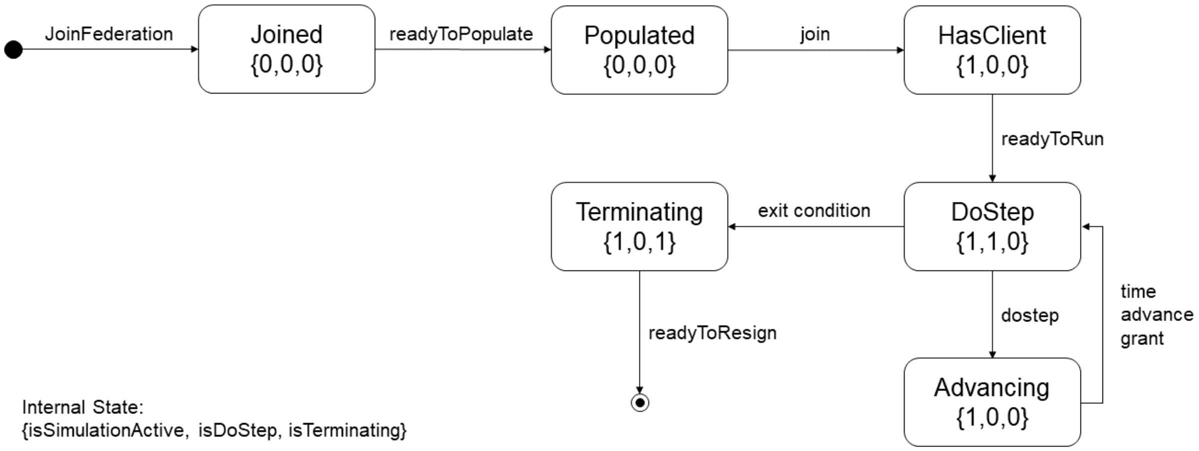

Fig. 5. State Machine of the REST Server

state are used to populate the contents of that payload. The remaining information is retrieved from the HLA federation.

VI. Conclusion

This paper provided a brief overview of UCEF and described two different approaches to tool integration for the platform. The first approach, an open-source Java library called the UCEF Gateway, is a mature implementation that has been used to integrate several new simulators into UCEF by different developers. The second approach, a REST server built using the gateway library, is a more recent development undergoing continuous refinement. Both approaches seek to simplify the tool integration challenge by providing default implementations for HLA services and exposing a reduced API that is more accessible for developers without co-simulation experience.

There are future plans to expand the REST server to support multiple simultaneous client sessions with the goal of creating something akin to an IoT gateway that integrates a large number of devices into a federation as a single federate. The server state machine will have to be updated to support multiple clients, and a session identifier will have to be inserted into the payloads so clients can be identified between calls to the different endpoints. During this process, it is likely the list of endpoints and the payload structure will undergo continuous refinement as the software matures.

One interesting research direction for this work is the performance characterization of different types of user applications using the two approaches. The REST server relies on socket communication rather than direct function calls and should be slower and more prone to bottlenecks than native UCEF Gateway implementations. However, the communication pattern of the user application — such as the frequency of communication and the size of the payloads — could result in vastly different performance profiles. It is likely that some types of user applications are ill-suited to using the REST server, while other types notice little to no performance degradation over a native gateway implementation. An investigation of these different performance characteristics would add another dimension beyond ease-of-use that must be considered when choosing to integrate a tool using one of the approaches.

***Abstract*—Modern electric grids that integrate smart grid technologies require different approaches to grid operations. There has been a shift towards increased reliance on distributed sensors to monitor bidirectional power flows and machine learning based load forecasting methods (e.g., using deep learning). These methods are fairly accurate under normal circumstances, but become highly vulnerable to stealthy adversarial attacks that could be deployed on the load forecasters. This paper provides a novel model-based Testbed for Simulation-based Evaluation of Resilience (*TeSER*) that enables evaluating deep learning based load forecasters against stealthy adversarial attacks. The testbed leverages three existing technologies, viz. *DeepForge*: for designing neural networks and machine learning pipelines, *GridLAB-D*: for electric grid distribution system simulation, and *WebGME*: for creating web-based collaborative metamodeling environments. The testbed architecture is described, and a case study to demonstrate its capabilities for evaluating load forecasters is provided.**

***Index Terms*—power grid, load forecasting, machine learning, security, resilience, adversarial attacks, model-based testbed**

I. Introduction

This work has been motivated by our NSA Science of Security Lablet research efforts to create executable simulation models and repeatable experiments for evaluating potential vulnerabilities and successful resilient strategies for complex Cyber-Physical Systems. To address these needs we developed a web-based, cloud-hosted design environment and integrated state-of-the-art simulation engines for multiple CPS domains (highway and railway transportation, power distribution). This paper focuses on the power grid domain of our multi-model testbed.

In electrical grids, the power generation is typically conducted on-demand, which requires utilities to continuously forecast the grid loads [1]. The loads are estimated for the long-term (LT) (i.e., more than a year), medium-term (MT) (i.e., a month to a year), and short-term (ST) (i.e., an hour to a week). LT forecasts are used for planning the necessary generation, transmission, and distribution equipment. MT forecasts are used for adjusting the LT plans. ST forecasts are used for real-time grid operations and operating both the grid and power markets in a safe, secure, and reliable manner.

ST and MT forecasting have become challenging due to the dynamic and distributed nature of modern electrical grids. In the traditional grid, power is centrally generated, and the power flow is unidirectional from generation to transmission to distribution network. Smart grid technologies enable the integration of distributed energy resources (DERs) that provide local sources and introduce bidirectional power flow into the system. Additionally, most DERs are variable sources such as wind turbine and solar photovoltaic (PV) that are not always available due to changing weather conditions such as storms. Because of capability for bidirectional power flow and the variable nature of DER, grid operations need to evolve from a deterministic to a stochastic model.

Smart grid with DER integration have enabled consumers to generate power locally and provide excess generated power back to the electric grid for a financial benefit. In addition, the potential dynamic pricing of electricity necessitates the use of transactive controllers and smart demand management to get the best pricing of power (e.g., move consumption to off-peak hours). This stochastic environment has made load forecasting significantly challenging where traditional demand-supply and failure modeling is no longer suitable.

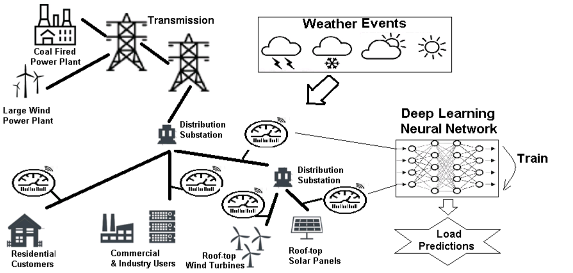

Figure 1: Deep Learning Based Load Forecasting in a Dynamic Power Grid with Distributed Energy Resources

To address the above challenges, smart grid deploys a large number of smart sensors that collect power flow readings at various points in the network. The measurements from these sensors can be used by deep learning based load forecasting systems to estimate the expected system loads. Figure 1 illustrates the variety of factors affecting ST load forecasting and how a deep learning system can be used to predict future loads. The sensor readings recorded by smart meters (generated by real system or a simulation) are stored in a time series database, which is used by a neural network to learn expected load on the system. Deep learning based forecasting is fairly accurate under normal circumstances, but, due to its complexity, becomes highly vulnerable to stealthy adversarial attacks. These

Neema, Himanshu; Volgyesi, Peter; Koutsoukos, Xenofon; Roth, Thomas; Nguyen, Cuong. "Online Testbed for Evaluating Vulnerability of Deep Learning Based Power Grid Load Forecasters." Paper presented at Modeling and Simulation of Cyber-Physical Energy Systems, Sydney, AU. April 21, 2020 - April 21, 2020.

attacks [2] subtly modify some of the sensor readings (by intercepting and forwarding modified data) such that not only the attacks remain undetectable by anomaly detection software, but also the accuracy of the load predictors is significantly reduced. As the adversarial attacks are not easily detected, they can result in cumulative disruptions leading to significant damage and loss before the system could be reverted to fallback methods.

Adversarial machine learning has been studied in many different categorization and estimation problems [2] [3]. Investigation of its use in cyber-physical systems (CPS) is recent, but is quickly emerging as an active research field [4]. The cyber-physical nature of smart grid makes it possible to attack specific cyber components such that the resulting failures cascade to a much wider region of the grid [5]. Further, attackers can exploit the growing networking capability of monitoring and control equipment to remotely attack specific components. Because the electric grid is one of the national critical infrastructures, it is crucial to study the vulnerability of different deep learning based forecasting methods earlier in the design cycle to avoid large-scale failures in a deployed system.

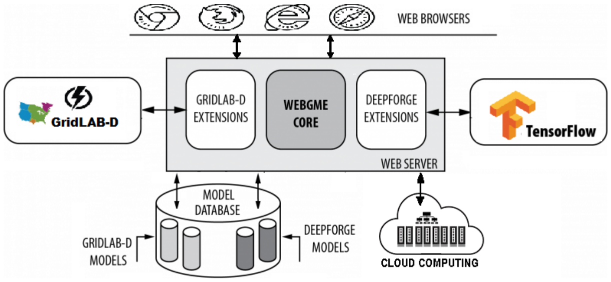

Figure 2: TeSER Testbed Architecture

In this paper, we describe a model-based Testbed for Simulation-based Evaluation of Resilience *(TeSER)* [6] that can analyze the resilience of load forecasters in the presence of stealthy adversarial attacks. As shown in Figure 2, the modeling front-end is built using the open-source Web-based Generic Modeling Environment (*WebGME*) [7] that supports creating web-based collaborative metamodeling environments. WebGME's plugin architecture enables interpretation of models and generation of system artifacts (e.g., source code, configuration files, and others), which can be used to execute experiments on a compute platform (e.g., desktop, server, or cloud). The stealthy adversarial attacks in this research were modeled using *DeepForge*, an open-source web-based environment for deep learning that enables collaborative modeling of neural networks and machine learning pipelines for reproducible deep learning experiments [8]. The testbed also utilizes an open-source power distribution system simulator, *GridLAB-D* [9], for simulating the electric grid and generating power flow data from smart sensors. In addition, the web-server contains an integrated *model database* that stores models of the electric grid, neural networks, and machine learning pipelines. TeSER executes the experiments on a connected *cloud computing* platform that enables the large-scale computations required by these experiments. The experiment results are collected and presented to the user as both raw data and digestible plots for analysis. The user is also provided with a full record of machine learning training iterations and console logs of the machine learning pipelines. We argue that by enabling earlier detection of the vulnerabilities in deep learning based load forecasting systems, our framework can help to both minimize the associated cost and make these systems more effective.

In the rest of the paper: Section II provides the motivation for analyzing vulnerabilities of load forecasters; Section III describes the core architectural components of TeSER; Section IV gives a case study to demonstrate TeSER's capabilities; and Section V concludes the paper and highlights future work. Note that a more detailed experiment—analyzing various attacker-defender games—is given in [10], this paper focuses on the architectural aspects of the testbed.

II. Motivation

Smart grid is a complex example of CPS [5] where the physical and computational components interact in specific ways to determine overall system functionality. For effective smart grid operations, a range of sensors are used to monitor aspects of the grid such as power flows at different locations, line continuity, equipment and device failures, actuator positions, and thermal characteristics. Load forecasting is essential for proper planning of the electrical system to determine the power equipment required and their arrangement, minimize system overloads, reduce power losses, manage operations effectively, and maintain the balance of supply and demand [1] [11].

Owing to bidirectional power flow and increases in DER integration, the smart grid has become highly dynamic, which directly affects the accuracy of load forecasts. The system dynamics are further affected by factors such as the variations in weather conditions and energy usage at different times of the day, price fluctuations in power markers, and a deeply integrated mix of residential, commercial, and industrial loads. Traditional methods of load forecasting use deterministic approaches (e.g., expert surveys and scenario-based assessment) and quantitative methods (e.g., time series analysis, smoothing averages and trend projections, least square estimates, and regression analysis). Since these methods tend to fit load expectations into a trending model, they do not work for highly dynamic variations in smart grid network topology (e.g., bidirectional power flow) and power supply and demand (e.g., DERs and time of use rate). Machine learning techniques can effectively handle these cases—where continuously updating the model is neither plausible nor pragmatic. The deep learning methods can be used for predicting loads in a more reliable manner while minimizing cost.

Deep learning methods, however, suffer from the *black box* problem, where there is no direct relation between inputs and outputs. Moreover, the electric grid has become more connected as the interactions between sensors, actuators, and controllers are largely enabled through a cyber communication network. This makes smart grids that use deep learning methods for load forecasting vulnerable to cyber-attacks and cascading failures. There are several examples where significant damage to the electric grid has occurred [12]. Therefore, the smart grid must be secured from potential cyber-attacks on deep learning based load forecasting methods. Stealthy adversarial attacks can intercept inputs of deep learning systems and subtly modify them to impact the system without being detected by anomaly detectors. These types of attacks on deep learning methods have been researched in the past, but as the deep learning methods are only recently being used in a CPS context, a testbed to enable such investigations is needed.

This paper describes a novel web-based and cloud-deployed testbed that can evaluate the vulnerability of deep learning models, that rely on a network of sensors for their inputs, to stealthy adversarial attacks. Specifically, the testbed is applied to load forecasters based on deep learning that use power flow readings from smart meters as their input. TeSER uses GridLAB-D for simulating an electric distribution system, and DeepForge for designing adversarial attack models and anomaly detectors. To avoid detection, the adversarial attacks are limited to modify the sensor readings within a given lower and upper threshold [13]. The testbed enables modeling of attacker-defender interactions as a *Stackelberg* game [4], where the defender uses a random subset of sensor readings and a neural network for load prediction, and then the attacker modifies some of those sensor readings within a configurable lower and upper bound. In addition, several load forecasters can be designed for introducing uncertainties that defend the load forecasting system against stealthy adversarial attacks.

III. TeSER Components & Features

The goal of TeSER is to provide a collaborative design and experimentation environment for evaluating the security and resilience of CPS amidst various cyber attack and defense strategies and the impact of these strategies on the physical infrastructure. The testbed leverages open-source technologies to build design tools that are reusable and configurable. It is web-based, cloud deployed, and supports real-time collaboration among researchers and analysts on models and experiments. In addition, it stores all input data, model parameters, and simulation results in the models, and version controls the models for experiment repeatability and provenance. This section provides an architectural overview of TeSER's core components and key features (as summarized in Figure 3).

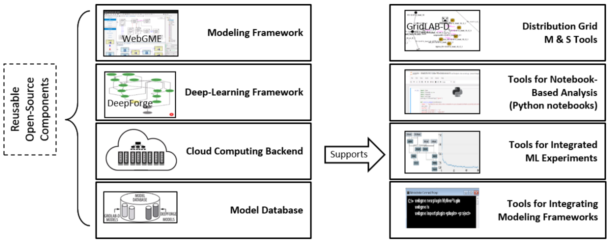

Figure 3: TeSER Core Components and Features

A. Modeling Framework

WebGME allows both the creation of rich, domain-specific modeling languages (DSMLs) and the use of those DSMLs to create domain models. It supports creating plugins that interpret the domain models, generate related system artifacts (e.g., source-code, scripts, configuration files), execute code on integrated compute platforms (e.g., cloud), collect experiment results, and display them to the users as digestible charts/plots and downloadable artifacts. For the modeling and experimentation front-end, WebGME's decorators and visualizers enable custom visualization of models, and the integrated console logging and feedback notifications allow users to get insights into long-running applications in the backend. A key aspect of WebGME is that it is web-based, highly scalable, and supports real-time collaboration among researchers and analysts who can edit the system and experiment models simultaneously from different locations using various web-browsers. WebGME stores all models in a MongoDB database and provides full version control and change tracking. Once designers create system models, analysts can use them to experiment with different designs. TeSER leverages WebGME for power distribution grid and deep learning models, but other CPS domains, such as transportation and healthcare, can also be supported using WebGME's extensible architecture.

B. Deep Learning Framework

DeepForge is built using WebGME and supports rapid development of neural-network and machine learning (ML) models. Modeling in DeepForge uses four main concepts, viz. *Operations*: atomic functions that accept named inputs and generate named outputs; *Pipelines*: specific ML activities such as training, data processing, and predicting; *Executions*: run-time instances of pipelines; and *Jobs*: run-time instances of operations along with associated execution metadata. As shown in Figure 4, the left side is a popular neural network model of a long-short term memory (LSTM) autoencoder for time series forecasting. The right side shows some of the reusable operations for creating ML pipelines (e.g., *GetLocalPredictor* implements a prediction routine and *PlotOperation* plots the time series data). A load forecasting processing pipeline is shown in the middle. Note, that the contents of some compound layers—most notably the LSTM blocks—are not modeled in DeepForge but directly mapped to classes in the Keras library.

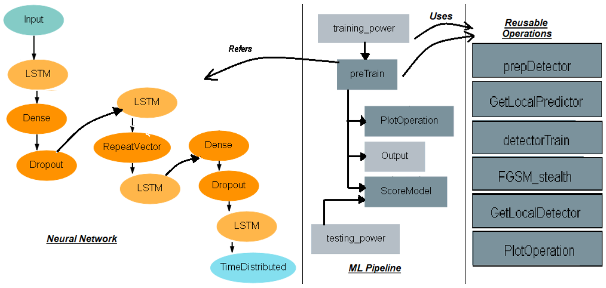

Figure 4: Deep Learning Framework

DeepForge allows users to add their own reusable operations in the library, and reuse pipeline models for creating variant or derived models. The neural network models are stored in a separate library for reuse. A neural network model can be used in multiple pipelines, and a single pipeline could use multiple neural network models. The integrated cloud backend is capable of executing several pipelines in parallel. DeepForge supports detailed views into pipeline execution progress by providing console logs that show the training iterations and by displaying integrated plots about training, testing, and prediction results. Another important feature of DeepForge is that it continuously aligns the Python code with corresponding pipeline models. The user can edit either the Python code or the pipeline model independently and DeepForge automatically synchronizes the other. In addition, all test data and models are stored in the connected artifacts store. With these comprehensive features and integrated experimentation support tools and compute infrastructure, DeepForge provides a powerful web-based environment for deep learning that TeSER leverages for creating its deep learning framework.

C. Distribution Grid Modeling & Simulation Tools

TeSER leverages a web-based platform from prior work [14] and WebGME for building its collaborative tools to support evaluation of distribution grids with integrated DER and their resilience against cyber and physical attacks. As shown in Figure 5, first a user either creates a new grid model or imports an existing GridLAB-D file and updates it as needed. Next, it provides *player* files (timestamped values of grid objects as input) and *recorder* files (specification of object values to collect as output). Finally, the *weather* files, if needed, can be supplied. The plugins are used to interpret the models and configurations to generate artifacts that are sent to a *Simulation Driver and Event Manager* module, which orchestrates the power grid simulation in the cloud accordingly, and gathers feedback from the executing experiments. The generated statistics specified in the recorder files are collected and returned to the user when the simulation completes. Continuous feedback is given while the simulation is running. TeSER uses this tool for simulating power distribution grid and generating smart meter recordings as input data for the deep learning models.

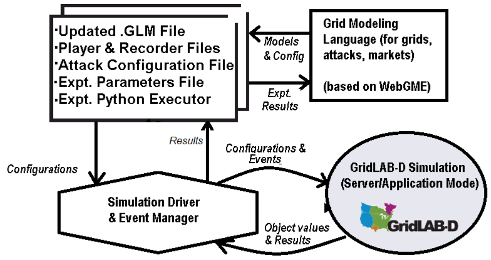

Figure 5: Distribution Grid Modeling & Simulation

D. Cloud Computing Backend

TeSER currently supports ML experiments in the power grid domain. The distribution grid simulation can take a long time for large grid models (e.g., with 1000+ nodes) or when multiple simulations are needed for different training inputs. The deep learning pipelines can also be computationally expensive, but multiple ML pipelines can be executed in parallel for faster responses. For these reasons, it is necessary to integrate a scalable and powerful compute platform. TeSER supports an integrated cloud computing backend that is hosted at Vanderbilt. The cloud also provides capability to store large datasets for ML pipelines and results of previous executions of pipelines. Users can login and inspect all of the executions ran previously (which could have taken hours or even days) including the console logs of all iterations, generated result files, and plots. Further, the user can investigate the execution results step-by-step and even re-execute any step (i.e., job).

E. Model Database

For web-based ML experimentation environments, it is crucial that models are version-controlled and accessible directly from the modeling frameworks. TeSER relies on the WebGME supported MongoDB object-oriented database. However, collaboration is highly challenging for large models (e.g., 1000+ node grid) as every small change in the interconnected graphical model can amount to a large update to be broadcasted. WebGME solves this issue by utilizing a Git-like commit architecture for model changes and only broadcasting deltas to all the modelers. The commits also enable fine-grained change tracking and allow relatively easier merging of models when a conflict arises. The WebGME model databse is used in TeSER to store not only the models of power grid, neural networks, machine learning pipelines, but also to store data and result artifacts. This greatly enhances the reproducibility and provenance of experiments. This database can also be queried using WebGME command-line tools, which enables automated experiments as well as testing.

F. Tools for Notebook-Based Analysis

CPS contain many interconnected physical and cyber components and their experimentation generates a large amount of data, which requires a rich framework for automated analysis. In the machine learning communities, Jupyter Notebooks are popular as they have integrated Python interpreter and analysis tools. TeSER has integrated Jupyter Notebooks in the WebGME front-end to facilitate analysis of data through Python scripts. As mentioned in Section III-B, DeepForge keeps the pipeline models and their corresponding Python code side-by-side and synchronized. The integration with Jupyter Notebooks allows embedding those Python scripts in Notebook cells and testing the corresponding pipeline models in an automated manner. For Notebook-based analysis, the user generates Jupyter Notebook files by executing TeSER plugins on a loaded model (or WebGME's Python libraries could be used to query the model from a user-created Notebook). TeSER also runs a Jupyter Notebook server besides the WebGME server and accesses it using a WebGME visualizer. The Notebook server enables users to develop scripts and algorithms for analyzing experiment results. As the Notebook server is accessed using WebGME visualizer, that can also update the model based on analysis results received from the Notebook server. Note that the notebook-based approach is optional for more advanced post-simulation analysis tasks.

G. Tools for Integrated ML Experiments

Experimentation with complex CPS not only requires parametric variations and cyber defense and attack combinations (i.e., design of experiments), but also an integrated deep-learning framework for analyzing ML algorithms. TeSER currently supports the power grid domain. It integrates GridLAB-D simulator for power distribution simulation and frameworks, such as Keras and TensorFlow, for creating deep-learning models. At present, the data from grid simulation is fed into deep learning models manually. However, we are working on integrating the two modeling environments into a single framework. This will support automated workflows of power grid simulation, generation of simulation data and its feed into corresponding ML pipelines. The pipeline execution results could also be fed back to update the grid model and close the loop. Figure 6 shows the overall architecture for integrated ML experiments. Here, the training operation in the ML pipeline refers to the corresponding grid model. The DeepForge code generator converts the pipeline model into an executable job script and the GridLAB-D Extension code generator generates templates to configure the simulation driver. We are developing an API for orchestrating the integrated ML experiments, which can execute grid simulations using an integrated simulation driver (like in III-C) and run the ML pipelines using the simulation data generated from grid simulations.

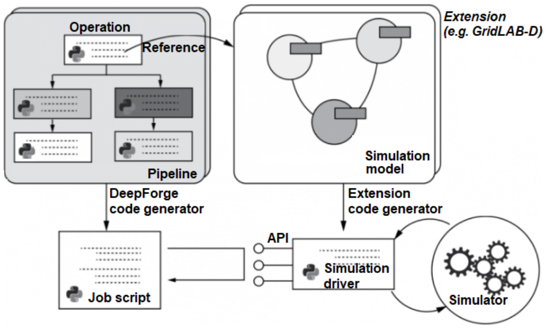

Figure 6: Integrated ML Experimentation in TeSER

H. Tools for Integrating Modeling Frameworks

Integrating modeling frameworks is needed in TeSER for connecting the power grid simulations and deep learning pipeline executions in a tight loop. We leverage WebGME's command-line interface for merging the corresponding DSML and creating an integrated modeling environment. In addition, we also leverage DeepForge's extension mechanism for integrating other modeling languages. The currently available support for creating Keras library based neural network models is an example of how DeepForge's extension mechanism works.

IV. Case Study

The collaborative model-based approach provided by TeSER enables rapid prototyping and experimentation with various neural network architectures and data processing, training and evaluation pipelines. Furthermore, tight integration with the CPS simulation tools—such as GridLAB-D—simplifies the process and shortens the time for input data generation for such models. Below we aim to illustrate how one can use the testbed to easily build and compare various ML-based predictors for load estimation in power distribution networks, and how this process is supported by the web-based design environment. For specific detailed analysis of prediction accuracy, its effects on load forecasting and of various attack and defend strategies, please refer to [10] [4].

A dataset has been generated with a realistic GridLAB-D model with 109 commercial and residential loads, where each endpoint reports its power usage on an hourly basis over a period of 90 days. Based on these reports the total power consumption in the distribution network is calculated. The case study aims to create and evaluate alternative regression models, which can predict the network-level (total) load for the next hour based on the previous 24 hours of data. The dataset was split into training and testing parts with 81 and 9 days of measurement data respectively.

We built a single generic data processing pipeline to train and evaluate the alternative ML models (see Figure 7). The testbed allows to (re)assign different ML architectures to the data processing pipeline. The current workflow loads the simulation results, implements the train/test split, drives the training (for a given number of epochs) and evaluates the model on the test data. It generates plot data for the training loss and summary statistics on the test results.

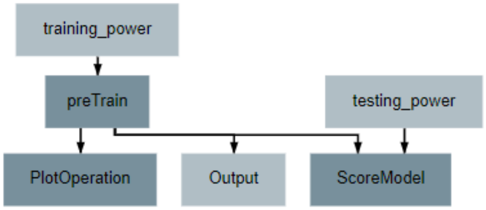

Figure 7: DeepForge generic pipeline model for training

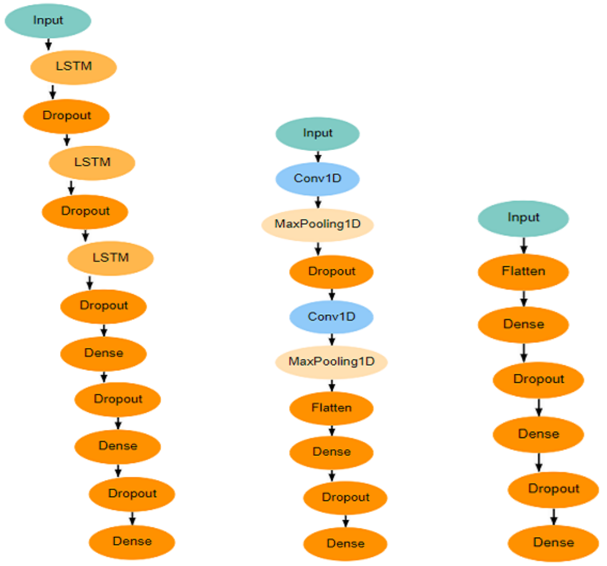
As shown in Figure 8, we selected three popular architectures for time series forecasting with neural networks. First, a multilayer perceptron (MLP) model with two hidden layers (64-nodes each) is built. The second model is a deep convolutional network (CNN) with two sets of 1-dimensional filters sweeping on the time axis. Last, a more complex long short-term memory (LSTM) model is created (three LSTM layers with two fully connected layers). All three models use simple Rectified Linear Unit (*RelU*) activation functions and dropout layers for regularization. The training loss figure (Figure 9) of the three alternatives is captured from the testbed's web interface.



(a) LSTM model (b) CNN model (c) MLP model

Figure 8: Alternative neural network architectures for regression

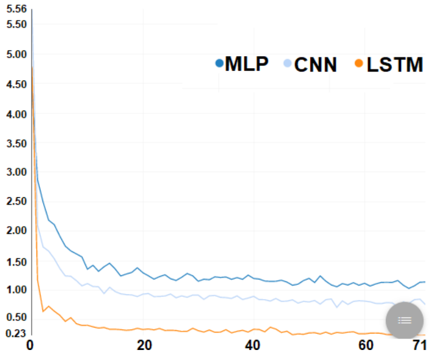


Figure 9: Training loss for MLP, CNN and LSTM

Evaluating the alternative predictors for the simulation data requires a single change in the pipeline–architecture assignment. The testbed takes care of input data generation, model versioning and tracing the analysis results back to the versioned model. This relatively simple experiment resulted in the prediction mean squared error (MSE) of 1.854 for MLP, 0.616 for CNN, and 0.106 for LSTM. As a baseline, the constant mean predictor has an MSE of 12.218. These results show the relative performances of the neural network models and agree with our assumptions on how 1-D convolutional and recurrent models can better learn and predict time series data.

V. Conclusions & Future Work

In this paper, we presented TeSER that is built using widely used open-source technologies. We presented its application in the power grid domain for evaluating deep learning based load forecasters. We described the testbed architecture and its core components and features and demonstrated it with a case study on load forecasters. TeSER uses a model-based approach and is web-based and cloud deployed. It provides strict version store for storing models (such as grid, neural network, and pipeline models), input datasets, and experiment results, thereby enabling experiments to be traceable and parameterizable.

We are working on integrating the power grid simulation and the deep learning framework into a single framework for end-to-end integrated workflows between them. This will support automated workflows of power grid simulation, generation of simulation data and its feed into corresponding ML pipelines. We are also extending our library of reusable and configurable cyber-attacks (modeled as ML pipelines), neural network models, and cyber-defense models of anomaly detectors that can mitigate the impact of stealthy adversarial attacks.

Abstract

This study examines the potential use of machine learning algorithms to build a model to forecast the flashover occurrence in a single-floor, multi-room compartment fire. Synthetic temperature data for heat detectors in different rooms are generated and more than 1000 simulation cases are considered and a total of 8 million data points are utilized for model development.

The development of P-Flash (Prediction model for Flashover occurrence) is presented. Two special treatments, sequence segmentation and learning from fitting, are proposed to overcome the temperature limitation of heat detectors in real-life fire scenarios and to enhance prediction capabilities to forecast the flashover occurrence even with situations where there is no temperature data from all detectors. Experimental evaluation shows that P-Flash offers reliable prediction. The model performance is approximately 83 % and 81 %, respectively, for current and future flashover occurrence, considering heat detector failure at 150℃. Results demonstrate that P-Flash, a new data-driven model, may provide fire fighters real-time, trustworthy, and actionable information to enhance situational awareness, operational effectiveness, and safety for firefighting.

Keywords: Machine learning, flashover occurrence prediction, synthetic temperature data, detector failure, smart firefighting.

Introduction

Several research efforts have been conducted to develop data-driven models to predict flashover conditions in a compartment fire. Richards et al. [1] established an empirical relationship based on a wide range of test data. Provided the estimated heat release rate (HRR), fire location and compartment size could be obtained. Yet, the prediction is only suitable for one-room compartments. Based on a generic algorithm, Neviackas and Trouvé [2] obtained a generalized HRR which can be used to

Wang, Jun; Tam, Wai Cheong; Reneke, Paul A.; Peacock, Richard D.; Cleary, Thomas; Fu, Eugene Yujun; Ngai, Grace; Leong, Hong Va. "On the Use of Machine Learning Models to Forecast Flashover Occurrence in a Compartment." Paper presented at 17th International Conference on Automatic Fire Detection (AUBE 20) & Suppression, Detection and Signaling Research and Applications Conference (SUPDET 2020), Mülheim an der Ruhr, DE. September 15, 2020 - September 17, 2020.

determine flashover conditions in multi-room geometries. Overholt and Ezekoye [3] also developed an inverse model using a predictor-corrected method to estimate the flashover occurrence. Based on smoke layer temperature measurements, the prediction accuracy of the model was shown to be within 60 s. However, a challenging problem exists in which all models [1-3] rely on a complete measurement dataset obtained from laboratory equipment. In practical situations, sensors such as heat and/or smoke detectors will stop functioning at a certain elevated temperature [4]. If the required temperature data is missing, the estimated HRR from these models will become highly uncertain and subsequently, the prediction of flashover based on the estimated HRR will be unreliable.

Unlike previous work [1-3], the temperature limitation for heat detectors is considered in this paper with the objective to develop a machine learning based model that can predict the current and the future flashover occurrence even with missing temperature data due to malfunctioning heat detectors.

Methodology

In this section, the development process of P-Flash (Prediction model for Flashover occurrence) is presented.

Data Generation

Consider a single-story building with three compartments as shown in Fig. 1. The dimensions of Room 1 are 3.5 m x 3.5 m and the dimensions of Room 2 and Corridor are 4.5 m x 4.5 m and 3.5 m x 1 m, respectively. The ceiling height is 2.5 m and it is identical for all compartments. For simplicity, the material of all walls, ceilings, and floors is gypsum wallboard. As seen in Fig. 1, there are 4 openings: 1) a window in Room 1, 2) a door between Room 1 and Corridor, 3) a door between Corridor and Room 2, and 4) an exit-door in Room 2. These openings are fully opened and their detailed geometric configurations are provided in [5]. There is one heat detector in each compartment and they are all located at the center of the compartment about 4.5 cm away from the ceiling. The outdoor conditions are typical with the temperature at 20 ˚C and atmospheric pressure of 101 kPa.

Given the geometric settings provided above, CFAST Fire Data Generator[1] (CData) [6] is used to execute 1000 simulation runs with a t-squared fire (which grows at a rate proportional to the time raised to the second power) at the center in Room 1 for a wide range of peak heat release rate (HRR) and time to HRR peak. Fig. 2 presents the mean temperature profiles as a function of time for three detectors. The dash

[1] CData is an in-house computer code that uses a validated fire simulation program, CFAST [7], as the simulation engine. One advantage of using CFAST is that synthetic data can be generated efficiently. In the future, more sophiscated fire simulation programs will be considered.

lines represent two times the standard deviation of detector temperature profiles over the 1000 different cases. It should be noted that more sophisticated building geometries and fires involving more complex stages (i.e. multi-floor buildings with ventilation controlled fires) can be considered in the future.

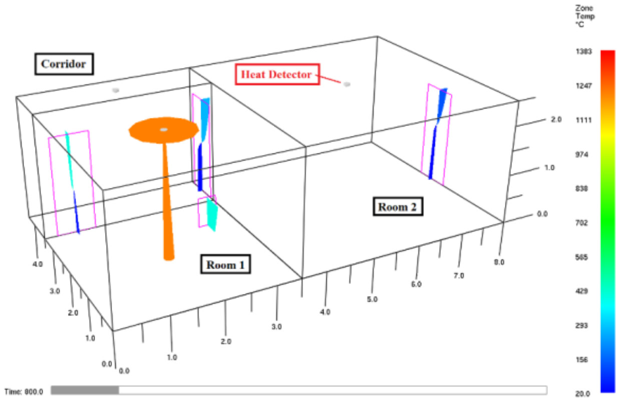

Fig 1. Schematic of the single-story multi-room compartment with a fire shown in the center of Room 1.

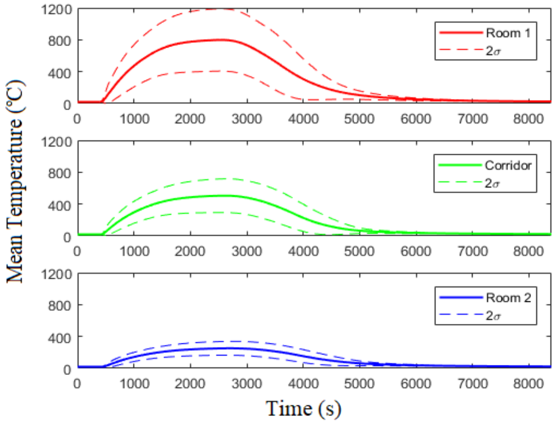

Fig. 2. Mean detector temperature profiles and two times its standard deviation in different compartments.

Sequence Segmentation for Detector Temperature Data

Loss of detector temperature signal is one of the major challenges for the development of a machine learning (ML) based flashover prediction model. For actual fire scenarios heat detectors cannot survive at elevated temperature [4] and would fail at temperatures well below flashover. In order to the overcome limited operating range, a special treatment to preprocess the detector temperature profiles is needed.

Assuming the detectors stop functioning at 150℃, Fig. 3 shows the detector ideal temperature profiles and those with a cut-off temperature at 150℃ for a simulation run with a fast-growth fire in Room 1. It can be seen that the available data for the Room 1 detector is very limited. In about 400 s, the temperature signal from Room 1 is lost and is artificially converted into a constant (i.e. a value of zero for simplicity). Yet, temperature signals from other compartments do exist. Given this observation, it is believed that the use of the available temperature data from other compartments will help to recover the detector temperature in Room 1 which can be used to determine the flashover condition from the room of fire origin.

Fig. 3 shows the implementation of sequence segmentation. The temperature profiles are divided into 4 phases. Each phase contains different available temperature signals. For example, signals from all detectors are present in Phase I. In Phase II, signals from the Corridor and Room 2 are available. In Phase III, only signals from Room 2 are left. Since it is well known that training a ML algorithm based on misleading data (i.e. zero temperature) jeopardizes the model accuracy, the use of sequence segmentation allows the ML algorithm to take advantage of the available signals from different phases. This treatment provides the basis for the model architecture of P-Flash.

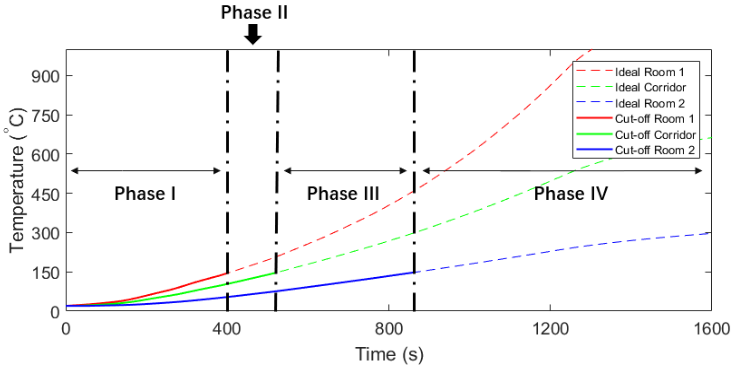

Fig. 3. Ideal detector and cut-off temperature for different phases.

P-Flash Architecture and Prediction Process

Fig. 4 depicts the model architecture and the prediction process of P-Flash. In general, P-flash consists of two regression models (R_{corr} and R_{R2}) and a memory component (M). Based on Fig. 3, the detector temperature in Room 1 is lost in Phase II and onward. For that, R_{corr} and R_{R2} are developed to predict/recover the temperature in Room 1 in different phases. The primary difference between the two models is that R_{corr} is trained based on the available information obtained from Corridor, and R_{R2} is trained based on Room 2. The memory component is a hybrid module: it performs as storage to contain outputs from R_{corr} and R_{R2} and to provide temperature prediction of Room 1 using the stored information. This architecture provides robust and flexible prediction capabilities to adapt to more complex cases with a larger number and different types of detectors. Since the prediction process of P-Flash requires a detailed explanation, the full description is provided in [5] due to the page limitations. However, key functions associated with procedures ① to ⑦ are highlighted below.

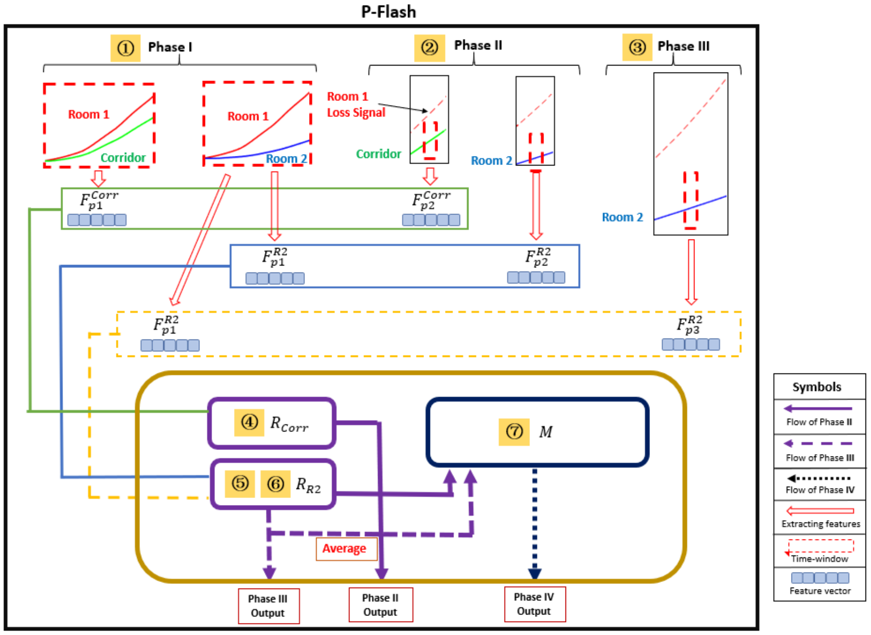

Fig. 4. Overview of P-Flash and the ML pipeline.

Feature Extraction (① to ③)

For development of the regression models, a set of features are needed. Typically, these properties are obtained based on feature extraction. As shown in Fig. 4, five different sets of features (*F*) are required to facilitate the model training process. It should be noted that one can use the original data as features (i.e. point-by-point temperature) to train a model. If the features are not extracted to relate data characteristics (i.e. rate of increase of temperature), it will be difficult for the model to learn any useful information (i.e. trends and/or patterns) for reliable predictions.

Given the sets of temperature data, feature vectors (F_{p1}^{Corr} and F_{p1}^{R2} in Phase I, F_{p2}^{Corr} and F_{p2}^{R2} in Phase II, and F_{p2}^{R2} in Phase III) are obtained based on delta and gradient[2]. Statistical features of delta and gradient are further extracted. In terms of notation, the superscript denotes the compartment that the features are used for training and the subscript denotes the phase from which the original data is being taken. For example, F_{p1}^{Corr} represents the feature vectors being used to train regression model, R_{corr}, based on temperature data obtained from Phase

[2] Delta refers to the overall temperature increase over the entire phase period and gradient refers to the rate of change of temperature increase through a time-window (see Fig. 4).

I. Readers can find the full list of features being obtained from Phase I, II, and III in [5].

Training and Testing (④ to ⑥)

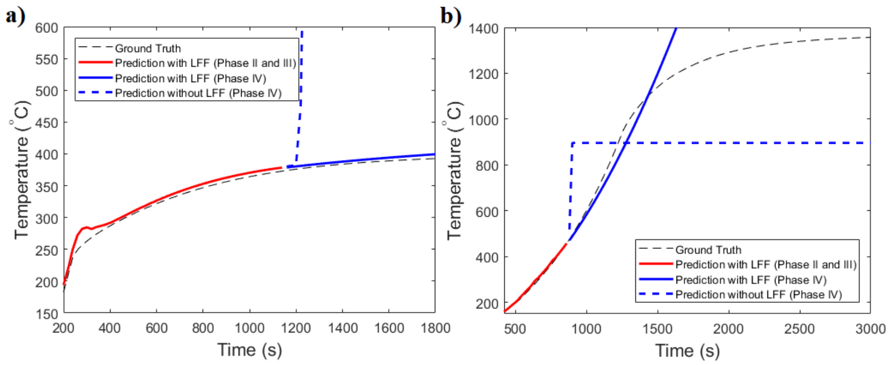
Support vector regression (SVR) [8] is used to develop the actual regression models (R_{corr} and R_{R2}). A 5-fold cross validation [8] method is applied to facilitate the training and testing process. In principle, the entire dataset from 1000 simulation runs is randomly divided into 5 subsets and each subset/fold contains 200 sessions. In general, one fold of data is being used as testing data and the remaining 4 folds are being used as training data. This process is carried out iteratively five times until all 5 different folds of data are being used as the testing set. The trained regression models provide Room 1 temperature predictions in Phase I to Phase III. Utilizing a grid search [8], the optimal configurations for SVR are C = 100 and Gamma = 0.05 with a radial basis function kernel.

Learning from Fitting (⑦)

In Phase IV, since all detectors are lost, no inputs are available and therefore no reliable predictions can be made from the regression models. In order to overcome this physical limitation, learning from fitting is implemented to facilitate the temperature prediction for Room 1 based on the historical temperature data of Room 1 (available temperature in Phase I and predicted temperature obtained in Phase II and III). As seen in Fig. 3, the increasing trend of the temperature in Room 1 is rather monotonic and follows similar behavior of a t-squared fire. Based on numerical experiment, a sigmoidal binding function is chosen for the fitting process. Mathematically, it is expressed as: $p_i = (b\sqrt{t_i})/(\sqrt{t_i} + a) + c$ where p_i is the prediction and t_i is the time associated with index *i*. Optimization is carried to obtain *a*, *b*, and *c* to produce a best fit to generalize the Room 1 temperature data in Phase I to III. Given the best fit, Room 1 temperature in Phase IV can be projected.

Results and Discussion

Figs. 5 show temperature predictions obtained from P-Flash for two selected cases: 1) a fast growth fire with low peak HRR case and 2) a medium growth fire with high peak HRR case. There are three sets of curves in each figure: i) ground truth, ii) prediction with learning from fitting (LFF), and iii) prediction without LFF. Each prediction curve is composed of up to two lines: a) the red line represents the Room 1 temperature predictions associated with Phase II and III and b) the blue line is for predictions in Phase IV. Since no prediction is needed for Phase I, the comparison is omitted. In Fig. 5a, P-Flash provides accurate temperature predictions of Room 1 in all phases and the benefit of using LFF is noticeable. After approximately 1150 s, when all detectors are lost, P-Flash is capable of providing predictions with similar trends and magnitudes. For P-Flash without LFF, the predictions rely on the regression models and it can be shown that the temperature prediction increases unrealistically to as high as 910℃. It is worth noting that the discrepancy observed at around 250 s is probably due to the change in temperature increase. Physically, it is the pivot point of its 2nd derivative where the rate of change of temperature increase changes from positive to negative. Additional work is under way to reduce such fluctuations.



Figs. 5. Comparison between ground truth and predictions obtained from P-Flash with and without LFF.

In Fig. 5b, it can be seen that the temperature of Room 1 being recovered from Phase II and III is in the fire growth stage. In the current version of P-Flash, it does not have additional information to predict the temperature decays. However, P-Flash is capable of predicting Room 1 temperature increase for flashover (i.e. temperature approaching 600℃). In order to evaluate the model performance over 1000 different cases, the mean absolute errors (MAE) are being calculated. Table 1 shows the MAE associated with different phases. It should be noted that the above results are denoted as "current prediction" and this prediction at time *t* is based on information obtained in time *t*.

Table 1. Performance summary for P-Flash with LFF.

	Phase II	**Phase III**	**Phase II & III**	**Phase IV**	**Overall Accuracy**
	MAE (℃)	**MAE (℃)**	**MAE (℃)**	**MAE (℃)**	**%**
Current Prediction	11.3	13.4	13.0	30.7	83.2
Future Prediction	12.9	15.5	13.4	37.6	81.7

In this work, it is important to evaluate the accuracy of the model in terms of classifying the occurrence of flashover. The overall accuracy is determined as the ratio of correct prediction within 20 s of the time of flashover to the total number of flashover occurrence in 1000 cases. As shown in Table 1, the model accuracy is approximately 83 % and 81 %, respectively, for the current and the future flashover occurrence.

On the fireground, knowing the room conditions of the fire origin is critical for optimizing rescue strategies and applying firefighting tactics. For that, P-Flash can forecast temperature in advance (i.e. 150 s) based on real-time information. As shown in Table 1, the MAE associated with future prediction only increases slightly with the same level of model accuracy.

Conclusion and Outlook

The development of P-Flash is presented. Based on experimental evaluation, P-Flash is capable of recovering required detector temperature for the determination of flashover in the room of fire origin. For practical use, P-Flash is under further development to handle more realistic and complicated cases. Our goal is that P-Flash will provide firefighters trustworthy and actionable information on the fireground to enable smart firefighting.

Abstract

This paper aims to facilitate the use of machine learning to carry out supervised classification/regression tasks for time series data in fire research. Specifically, a feature engineering tool, FAST (Feature extrAction and Selection for Time-series), is developed. Using hypothesis test method together with principal component analysis, relevant features with high significance to the prediction are selected. A study case is presented for the use of FAST. Results demonstrate the importance of obtaining effective features and its potential benefits. It is expected that the feature engineering tool can help scientists and engineers in the fire research community develop accurate machine learning based models.

Keywords: Time series; detection; feature extraction; feature selection; machine learning

Introduction

Machine learning (ML) paradigm is among the top methods that can be used to overcome real-time detection in many disciplines. Cao and his co-worker [1] provided a support vector machine being trained based on historical financial data for unusual trading detection in stock markets. Using streaming signals from vibration sensors in multiple locations, Anton et al. [2] developed a neural network-based model to detect potential intrusion on an industrial machine. It was reported that the model can provide early warning to schedule maintenance thus avoiding mechanical failure for large scale, high cost equipment. Recently, research efforts are made to implement ML paradigms to overcome detection problems that traditional approaches such as physics-based models [3] might not be able to handle in the fire research community. Although the studies [4] showed that the use of ML paradigm provides

Paper presented at 17th International Conference on Automatic Fire Detection (AUBE 20) and Suppression, Detection and Signaling Research and Applications Conference (SUPDET 20), Mülheim an der Ruhr, DE. September 15, 2020 - September 17, 2020.

improvement in detection performance with significant reduction to nuisance alarms, two technical difficulties were identified.

Foremost, relevant data is limited. In fire research community, it can be easily shown that acquiring the desired data, such as temperature, heat flux, velocity, and species concentration, is not trivial because a) the event of interest (i.e. fire ignition in a compartment) does not happen frequently, b) time series data associated with fire event are not available to the public data warehouse [5], and c) physically conducting fire experiments is costly and time-consuming. Although fire simulation programs (i.e. Fire Dynamic Simulator [3]) can be used to generate synthetic data for ML task, the physical models being used in these codes are simplified and will not capable the correct physics of fundamental processes such as gasification and pyrolysis. For that, mutual collaboration between laboratories might have to be established to resolve the data problem.

In additional to problems associated with data availability, another technical difficulty for the use of ML paradigms in fire research community is that the data is complex. Figures 1 show two sets of time series data from the cooktop ignition study reported in [6]. Three selected measurements are shown: velocity, carbon monoxide (CO), and volatile organic compounds (VOCs). Since the measurements are made with different devices, each of the time series is being normalized to its peak value obtained for a test for illustration purpose. As it is shown in the figures, different profiles are observed for the VOCs data. While the data associated with oil has a monotonic increasing trend, the food data has multiple peaks. Also, data such as VOCs and CO (refer to left figure) have unphysical negative values with a number of missing data. More than that, the value associated with CO has a rapid increasing trend and becoming significant towards the end of a test. For velocity data, they fluctuate around a mean value. Lastly, it is worth noting that these measurements (time series) are rather non-stationary and this implies that the absolute values of these measurements are sensitive to the surroundings. These complexities make the application of the use of the ML paradigm difficult.

In order to train an accurate ML model, it is well understood that features[1] are required. Typically, feature engineering is being carried out to obtain effective features and this process requires an exhaustive amount of work. Although one can use the existing ML packages (i.e. tsfresh [7] and tslearn [8]), the obtained features are often irrelevant and difficult to interpret. Consequently, none of these ML packages are being used in fire research community. In this paper, a feature engineering tool, FAST

[1] Features can be considered as the transformed data that better represents the underlying problem to the predictive models which helps to improve the model accuracy on unseen data.

(Feature extrAction and Selection for Time-series), is introduced to facilitate the implementation of ML paradigm in fire research. In order to demonstrate the effectiveness of the use of FAST for development of a ML model, a case study is provided.

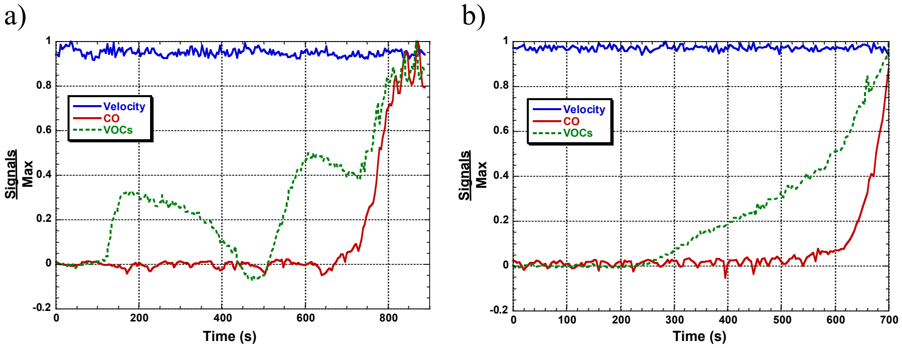

Figure 1. Time series data examples: a) measurements for a food and b) measurements for oil.

Development of FAST

The automated feature engineering tool, FAST, consists of two modules: 1) feature extraction and 2) feature selection. Figure 2 shows the overall structure of FAST and its operational procedures. In the following section,

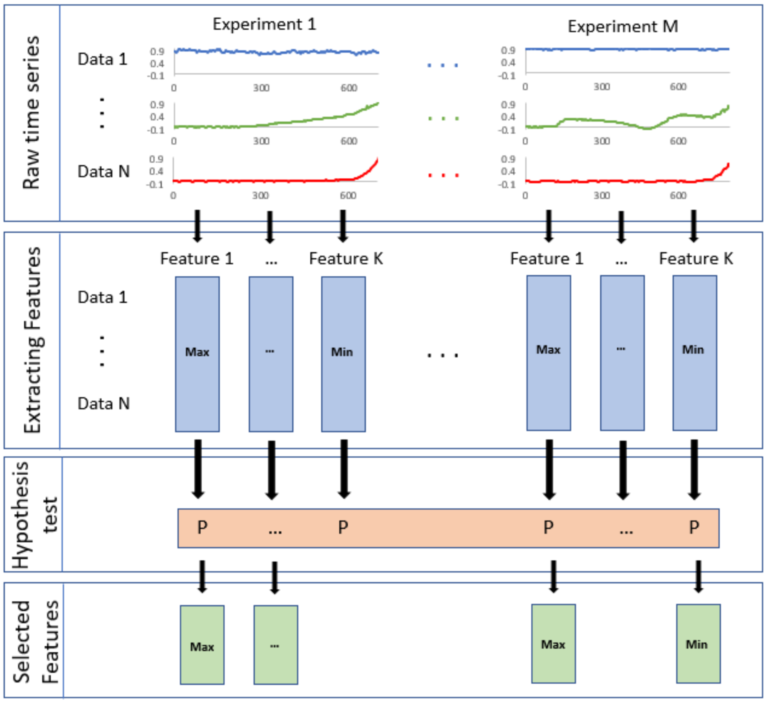

Figure 2. Overall structure of FAST and its operation procedures.

the details of each module and the descriptions of FAST operational procedures are presented. It should be noted that more effective features help to provide simpler models, better results, and higher numerical efficiency.

Feature extraction module (1 – 2)

In the current development of FAST, time series data, such as kitchen fire [6], smart firefighting technology [9], and wildland fire [10], are being considered. The behavior of these data varies significantly in which they can be either monotonic, periodic, or oscillatory. In order to capture the important tendency and/or pattern of these data, four types of feature extraction methods are being utilized and based on i) statistics, ii) trends, iii) its correlation, and iv) domain (i.e. frequency) of interest. In general, the application of statisticaly-based features such as mean or median over a sliding window[2] would help to obtain an average value and reduce the effect of data fluctuation due to outliers. For trend-based features, they provide information about the data with respect to time. In many regression problems, one might be interested in providing forecast of a future event and correlation-based features offer flexibility to obtain highly non-linear information. The last type of feature (frequency domain based) capture crucial information in frequency domain that is difficult to deduce in time domain. As shown in Fig. 2, the raw data will be separated into individual time series data in procedure 1. The data is then fed into the feature extraction module and a set of features (i.e. Min, Max, etc. as shown in procedure 2 in Fig. 2) are obtained. Table 1 provides a list of features that can be obtained in the feature extraction module. It should

Table 1. List of features being included in FAST.

Statistical based	Min	Max	Mean
	Median	Standard deviation	Sum
	Count above mean	Count below mean	Number of peaks
	Number of crossing		
Trend based	Delta	Rate of change	Acceleration
Correlation based	1st order regression	Max slope	Sinusoid
	2nd order regression	Exponential function	
Frequency domain based	Main frequency	Secondary frequency	
	Coefficients for discrete Fourier transform		

[2] A sliding window contains a specified length of time series data (i.e.30 seconds) and it moves over the data, sample by sample, and features are extracted over the data in the window.

be noted that since the module is written to perform the extraction procedure separately, additional features can be added if necessary.

Feature filtering module (3 – 4)

Two operations are carried out in the feature filtering module using hypothesis test and principal component analysis. The best 10 features are selected and they be readily used in training and testing of a ML algorithm.

Given the experimental dataset obtained in [7], which is partially being illustrated in Figs. 1, more than a hundred of features are obtained from the feature extraction module. The number of features would be 5 to 10 times more if methods from [9,10] are used. In general, having this large number of features is not ideal because the model can easily be overfitted and/or is hard to interpret. For that, a hypothesis test [12] is used to filter out the irrelevant features. In [7, 10, 11], the extracted features are usually continuous and labels can either be continuous and binary. For that, two test methods are adapted: i) Kolmogorov-Smirnov test [13] for cases where the features are continuous and the labels[3] are binary, and ii) Kendal rank test [14] for which both features and labels are continuous. Using either of the test methods, a p-value is obtained for each feature and the p-value quantifies the feature relevance to the prediction of the label. In principle, the smaller the p-value, the better/more relevant the features. Fig. 3 shows the top 10 selected features extracted from the kitchen fire dataset mentioned in [7] ranked by its p-value. In addition, two of the irrelevant features (most right) are also included in the figure. It can be seen that the velocity data is not useful and it can be understood based on the data behavior shown in Figs. 1.

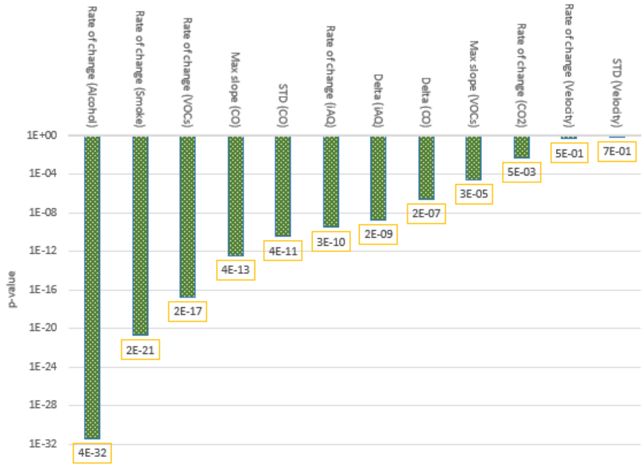

Figure 3. Selected features with small p-value.

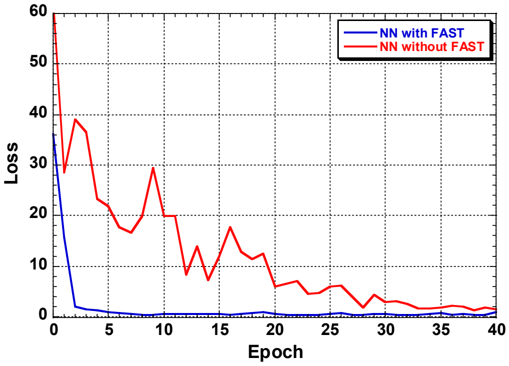
[3] Labels are referred to the targets for a classification/regression task.

Even though the hypothesis test helps to filter out a major portion of irrelevant features, there is still a high possibility that some of the selected features are redundant. For example, the features for median and mean are highly correlated in the absence of outliers in the time series. In order to avoid generating a group of highly correlated features, a principal component analysis (PCA) [15] is carried out and this step will help to select relevant features that are de-correlated.

Results and Discussion

In order to demonstrate the effectiveness of FAST, a case study is presented in this section. Given the set of time series obtained from [7], two sets of features are obtained: 1) one set with just the raw data and 2) one set using FAST. These two sets of features are used separately to facilitate the training of two individual 2-layer neural network (NN) models [15]. A holdout cross-validation [16] is used for training and testing. Approximately 60 % and 40 % of data is used as the training set and testing set, respectively. Similar to that of described in [7], the models attempt to classify abnormal cooking conditions based on the available sensor data.

For comparison, the two NN models are trained to have the same level of prediction accuracy[4]. Fig. 4 show the loss[5] as a function of epoch for two NN models. It can be seen that the model using FAST converges within 10 epochs and the model using raw data as features requires about four times more epochs to reach convergency. This highlights the benefits of obtaining relevant features for efficiency in training. Also, although both models are with 2-layer NN architecture, the NN model with FAST needs only 13 neurons for the first layer and 6 neurons for the second layer whereas the NN model without FAST requires 240 neurons in the first layer and 120 neurons in the second layer in order to achieve



Figs. 4. Loss for the two NN models during training.

[4] The accuracy is defined as the corrected predicted label over all possible labels.

[5] Loss value implies how well or poorly a certain model behaves after each iteration of optimization.

same level of prediction accuracy. It is worth noting that the prediction capability can generally be enhanced with the increasing number of layers and neuron. However, the model is highly possible to suffer from overfitting [17] in which the model is learning trends and patterns that are not used (i.e. the data oscillation as seen in Figs.1). Therefore, FAST can help model developers to avoid such training problems.

Conclusion and outlook

In this paper, the automated feature engineering tool, FAST (Feature extrAction and Selection for Time-series), is introduced. The overall structure of FAST and its operation procedure are described. Given a dataset similar to that of found in [7], 10 most-relevant features are obtained using FAST. The suggested features are then used in a case study to demonstrate its effectiveness. Results show that a machine learning model, such as a 2-layer neural network, trained using features obtained from FAST is more numerically efficient in terms of model training and has much simpler model structure. These observations highlight the importance of feature engineering. It is shown that the use of FAST will facilitate the development of an efficient and accurate machine learning model in fire research community.

Assessing Fire Smoke to Predict Backdraft and Smoke Explosion Potential

Ryan Falkenstein-Smith, Thomas Cleary
National Institute of Standards, Gaithersburg, USA

Abstract

The Fire Research Division at the National Institute of Standards and Technology is examining the ability to forecast backdraft or smoke explosions during a fire using a phi meter. Compared to other gas sensors, a phi meter can measure the global equivalence ratio under a broad spectrum of fuel-rich and fuel-lean conditions. Predetermined gas mixtures are fed into the phi meter wherein the equivalence ratio is measured. The measured and expected equivalence ratios for all gas mixtures are observed to be in substantial agreement. Concentration measurements are verified using the carbon to hydrogen ratio. Real-time temperature measurements are made at the inlet and outlet of the phi meter. The estimated enthalpy of the gas mixture from phi meter measurements is observed to increase as the gas mixture approaches stoichiometric conditions. The work demonstrates the potential to relate the estimated enthalpy in the phi meter with its oxygen consumption. The correlation can eventually be expanded to a variety of different fuels and conditions. Once established, the repository of data sets can be correlated to the bounding conditions for actual backdraft and smoke explosions of various strengths.

Keywords: Backdraft, Smoke Explosions, Phi Meter, Combustion Equivalence Ratio Meter, Flammability Limit, Gas Sampling

Introduction

The potential for backdrafts and smoke explosions to occur during fire events present a significant hazard to search and rescue teams, suppression teams, and other personnel in the surrounding area. Accurately assessing the condition of building spaces for potential smoke explosion or backdraft, before and during search and rescue and suppression activities, would improve situational awareness and lead to increased firefighter effectiveness and overall safety.

Falkenstein-Smith, Ryan; Cleary, Thomas. "Assessing Fire Smoke to Predict Backdraft and Smoke Explosion Potential." Paper presented at 17th International Conference on Automatic Fire Detection (AUBE 20) & Suppression, Detection and Signaling Research and Applications Conference (SUPDET 2020), Mülheim an der Ruhr, DE. September 15, 2020 - September 17, 2020.

A backdraft event is preceded by a change in the ventilation of a compartment filled with hot smoke that suddenly mixes with incoming Air through an opened door, broken window, or another venting source. Given the right conditions, the flammable gas mixture produced in the compartment ignites and expands, forcing fire gases out the opening, and subsequently erupting into a fireball or, with wind present, fire flower.

A smoke explosion is an event where a fuel-rich mixture of smoke (i.e., fuel vapors, carbon monoxide, and smoke particulate) located in an enclosed space mixes with oxygen (Air) that infiltrates the space. If a gas mixture is within the flammability limits while an ignition source is present, the mixture may explode with damaging deflagration overpressure. The fire service primarily relies on observations of smoke emanating from enclosures as evidence for the potential of backdraft or smoke explosions, such as puffing of the escaping smoke, color of the smoke, and other clues like darkened soot-covered window panes [1]. The fire service reliance on such indicators is not necessarily well-founded technically and is therefore not entirely reliable.

The full-scale backdraft experiments with No. 2 diesel fuel of Gottuk et al. [2] showed that the nominal fuel mass fraction (estimated from the fuel injection rate) correlated with the occurrence of backdraft and the resultant fireball size. The hypothesis proposed here is that the compartment gas temperature and the amount of fuel, oxygen, and non-combustible gases would allow the classification of the potential hazard. Furthermore, the potential hazard could be rated at varying strengths from no fireball or small overpressure, to large fireball extension or significant overpressure.

A significant hurdle to overcome in classifying backdraft is achieving gas measurements that accurately characterize the extracted sample. Extractive gas measurements with conventional catalytic bead flammable gas sensors are problematic for several reasons, some of which are: 1) the fuel composition is unknown which poses calibration issues; 2) the amount of particulate may play a role in these events and is not accounted for; and 3) these devices are typically limited to a range up to the lower flammability limit, they need sufficient oxygen to work, and poisoning or other loss of sensitivity is possible from the range of smoke exposures.

The idea proposed here is to measure the equivalence ratio, φ, using a phi meter operating under a new set of given conditions. The equivalence ratio is defined as the quotient of fuel to air ratio and the stoichiometric fuel to air ratio of the combustion process where fuel is initially un-combusted. Additional estimations and measurements include calculating the carbon to hydrogen ratio, an approximation of the fuel/oxygen ratio at the entrance of the phi meter, and the enthalpy increase from a combusted gas mixture. The measurements presented here lay the initial groundwork for developing a device that could predict potential backdrafts by quantifying certain conditions.

Experimental Method

In this work, the equivalence ratio is evaluated in real-time using a phi meter [3-7]. A phi meter has been constructed per the design of Babrauskas et al. [6] with the addition of thermocouples to measure the incoming and exiting flow temperatures. A flow diagram is provided in Fig.1. The phi meter operates by introducing extracted gas samples into a heated (900°C) plug flow reactor packed with platinum-coated beads as a combustion catalyst. An additional plug flow reactor placed within a furnace is available upstream to allow for the pre-combustion of fuel-air mixtures. Once the fuel/air mixture enters the phi meter, it is introduced to a counterflow of excess oxygen. Enough oxygen is supplied to the reactor such that the gas mixture is completely combusted.

Upon exiting the reactor, water is scrubbed from the gas stream using a chiller, resulting in a mixture primarily consisting of oxygen, carbon dioxide, and nitrogen. Assuming little to no nitrogen or oxygen in the fuel molecules, the known flow rates of the exit flow and added oxygen combined with a downstream measurement of the oxygen concentration allowed for a straightforward calculation of the equivalence ratio.

$$\varphi = \frac{{}^{Fuel}/_{Air}}{\left({}^{Fuel}/_{Air}\right)_{st}} = 1 + \left[\left(\frac{1 - X_{O_2,i}}{X_{O_2,i}\left(1 - X_{O_2,A} - X_{CO_2,A}\right)}\right)\left(\frac{n_{O_2}}{n_A} - X_{O_2,A}\right)\right] \quad \text{(Eq. 1)}$$

Here, n_{O_2} and n_A are the molar flow rates of oxygen introduced in the phi meter and total molar flow introduced into the analyzer, respectively. Additionally, $X_{O_2,i}$, $X_{O_2,A}$, and $X_{CO_2,A}$ are the volume fractions of oxygen in the Air (20.8%), and the dry oxygen and carbon dioxide introduced to the analyzer, respectively. A full derivation can be found in Ref. [6].

The upstream furnace is maintained at approximately 30°C, such that there is an un-combusted gas mixture entering the phi meter. The initial fuels of interest are methane and propane. The gas mixture varies within the flammability limits of the fuel [7] with φ_G ranging from approximately 0.5 to 2. The equivalence ratio is established from the predetermined fuel and air flows feeding into the upstream furnace. This work also has no additional air added to the flow stream past the upstream furnace (i.e., Air, 2=0, per Fig. 1). The fuel, Air, and oxygen volumetric flow rates are maintained using an Alicat Mass Flow Controller[1]. The volumetric flow rate exiting the chiller is measured using an Alicat Mass Flow Meter.

[1] Certain commercial products are identified in this report to specify adequately the equipment used. Such identification does not imply a recommendation by the National Institute of Standards and Technology, nor does it imply that this equipment is the best available for the purpose.

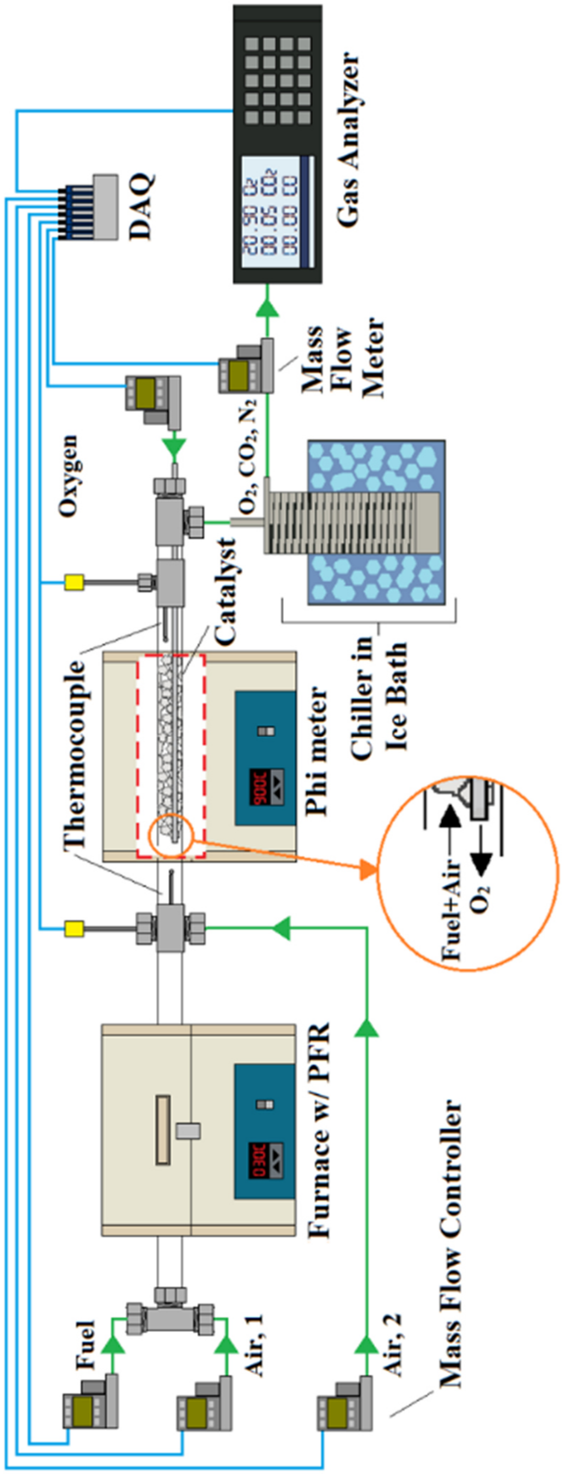

Fig. 1. A schematic of the phi meter experimental setup, including an additional furnace with a plug flow reactor (PFR) located upstream.

Oxygen and carbon dioxide concentrations are determined using a CAI 600 Series Gas Analyzer. Temperature measurements are made using two 20 gauge, 3 mm diameter, bare bead, Type K, low noise thermocouples positioned at the entrance and exit of the phi meter. The dataset is obtained approximately 10 min after the gas mixture composition entering the phi meter has been modified. All measurements are sampled at 2 Hz for approximately 2 min.

As a way to verify the accuracy of the result, the carbon to hydrogen mass ratio (C/H) is calculated for each analyzed sample using the equation below.

$$\frac{\mathrm{C}}{\mathrm{H}} = \frac{\mathrm{MW_C}}{\mathrm{MW_H}} \frac{\left(x_{\mathrm{CO_2}}\right) \frac{Y_{CO_2}}{\mathrm{MW}_{CO_2}}}{\left(y_{H_2O}\right) \frac{Y_{H_2O}}{\mathrm{MW}_{H_2O}}} \qquad \text{(Eq. 2)}$$

Here $\mathrm{x_{CO_2}}$ and $\mathrm{y_{H_2O}}$ are the number of carbon (1) and hydrogen (2) in carbon dioxide and water vapor, respectively. The molecular weight of carbon and hydrogen is denoted as $\mathrm{MW_C}$ and $\mathrm{MW_H}$, respectively. The mass fraction of species $\mathrm{CO_2}$, denoted as Y_{CO_2} is estimated from its measured volume fraction in the analyzer. The mass fraction of water vapor, Y_{H_2O}, is estimated from the difference between the total mass entering the phi meter and the total mass measured at the mass flow meter located past the chiller.

The uncertainties of all measurements are determined from a combined Type A and B evaluation of uncertainty. The Type A evaluation of uncertainty is estimated as the standard deviation of the measurement made during the sampling period. The Type B evaluation of uncertainty is estimated from the reported bias error in the instrumentation. The uncertainties presented in this work are expressed using a 95% confidence interval. For calculated values, the uncertainty was calculated using the law of propagation of uncertainty.

Results and Discussion

Fig. 2 presents a comparison between the expected and measured equivalence ratio. The expected equivalence ratio is calculated from the predetermined fuel and air flows feeding into the upstream furnace. The measured equivalence ratio is calculated using Eq. 1. As seen in Fig. 2, the measured values are equivalent, with some error, to their respective expected values for both fuel-rich and fuel-lean mixtures. The strong agreement indicates the validity of the phi meter set up, demonstrating a device that can measure the equivalence ratio of a fuel-air mixture.

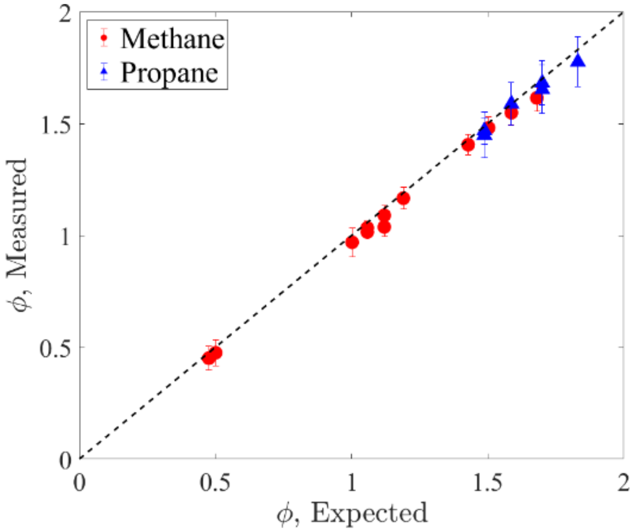

Fig. 2. A comparison between the expected and measured equivalence ratio. Note that the dotted line represents equivalency between the expected and measured values. The vertical bars are the estimated uncertainties of the measured equivalence ratio, calculated from the methods described in the previous section.

The limited propane data demonstrate a limitation of the phi meter design as conceived by the research engineer used in this work. The propane data presented here is limited by the flow capacity of the mass flow meter positioned downstream of the chiller. In this work, the maximum reading of the mass flow meter was 2 SLPM. In comparison to methane, propane requires a higher amount of Air to achieve stoichiometric combustion, which limited the investigation of propane to fuel-rich mixtures, given the mass flow meter constraint.

As previously stated, the carbon to hydrogen ratio is used to validate the accuracy of the measured volume fractions. As shown in Fig. 3, the estimated carbon to hydrogen ratio for each gas mixture is in strong agreement with the theoretical values of their respective fuels. This agreement validated the accuracy of the concentration measurements and the approximation of water concentration. These validation results suggest an additional feature of the phi meter; the calculated carbon to hydrogen ratio could be used to predict the composition of incoming fuels.

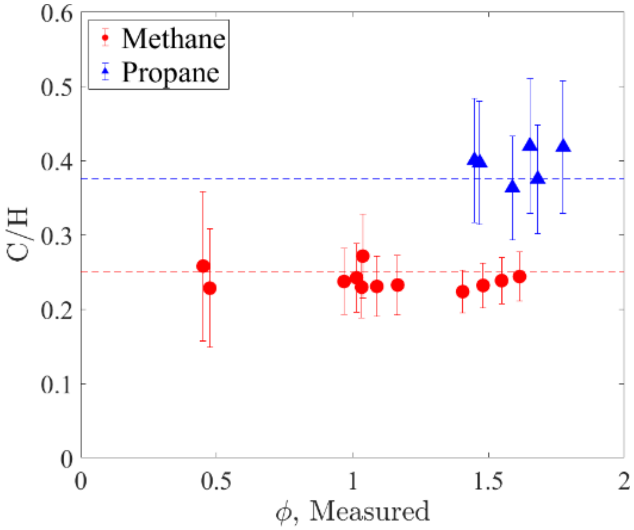

Fig. 3. Carbon to hydrogen ratio calculated from the product of all gas mixtures compared to the theoretical values at different equivalence ratios. The vertical bars on each data point represent the estimated uncertainty of the carbon to hydrogen ratio, calculated from the methods described in the previous section.

Fig. 4 presents the temperature difference across the phi meter for methane gas mixtures, maintained at a constant volumetric flow rate (2 SLPM), as a function of the total fuel to total oxygen ratio in the entire phi meter, (Fuel/O2) Tot. The temperature difference profile, as a function of the fuel/oxygen ratio, is not provided for propane since that obtained data is limited. The fuel/oxygen ratio is calculated from the un-combusted fuel and Air and the additional oxygen introduced to the mixture at the entrance of the phi meter. Since the objective of the phi meter is to completely combust the incoming fuel/air mixture, with the aid of additional oxygen, the combined gas mixture must always be lean such that $n_{\mathrm{Fuel}} < (n_{\mathrm{O_2}} + 0.21 \cdot n_{\mathrm{Air,1}})$. Based on that requirement, the fuel/oxygen ratio acts as an indicator of the operation of the phi meter. The fuel/oxygen ratio is calculated from the Eq.3, where $n_{\mathrm{Air,1}}$ is the molar flow rate of un-combusted Air flowing into the phi meter.

$$\left(\frac{\mathrm{Fuel}}{\mathrm{O_2}}\right)_{\mathrm{Tot.}} = \frac{n_{\mathrm{Fuel}}}{\left(n_{\mathrm{O_2}} + 0.21 \cdot n_{\mathrm{Air,1}}\right)} \qquad \text{(Eq. 3)}$$

The temperature difference across the phi meter as a function of the fuel/oxygen ratio is consistent for the methane fuel. The temperature is observed to increase as the fuel-lean gas mixture approaches stoichiometric conditions. For comparison to the calculated adiabatic flame temperatures, the temperature difference for each gas mixture is considerably less, indicating substantial heat loss within the reactor. Regardless, measuring the enthalpy increase of the reactor stream provides additional insight into the characteristics of the extracted gas mixture. The enthalpy measurement could be used to estimate the oxygen consumed internally based on the principle of oxygen consumption calorimetry.

The significance of the temperature measurement across the reactor is the additional information it can provide regarding the incoming fuel. As previously stated, the phi meter operation is based on the assumption that there is little to no oxygen and nitrogen in the fuel molecule. If the phi meter were to be used to investigate a fuel with a significant portion of oxygen or nitrogen in its composition, it could cause a significant error in the equivalence ratio measurement. The temperature measurements provide additional insight into the gas mixture introduced into the phi meter, which may prove useful when investigating unknown fuels.

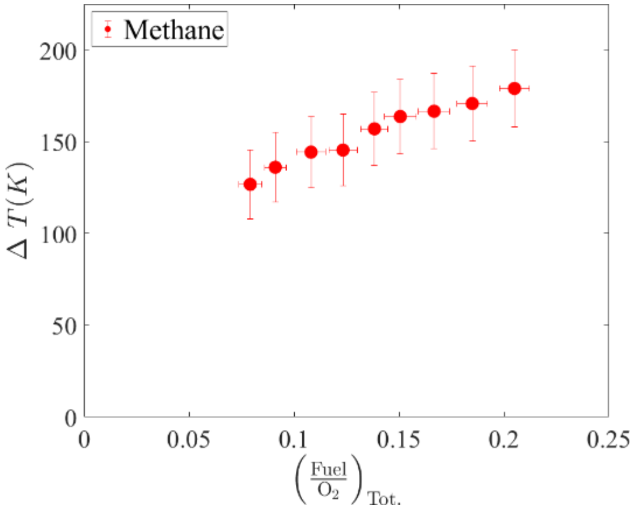

Fig. 4. The measured temperature difference across the phi meter as a function of the estimated fuel/oxygen ratio. It should be noted that the error of the temperature difference is determined from the measurement uncertainty derived from the uncertainty provided by the thermocouple manufacturer (±2% of the reading). The horizontal bars on each data point represent the uncertainty of the fuel to oxygen ratio within the phi meter and is calculated from the methods described in the previous section.

Conclusion and Future Work

This work highlights the application of a phi meter for measuring the equivalence ratio of methane and propane for fuel-rich and fuel-lean gas mixtures. This work demonstrates the phi meter's ability to measure the temperature rise across the reactor, which can be used if the future to infer the oxygen consumption within the phi meter and possibly provide additional information when dealing with fuels containing significant portions of oxygen and nitrogen. Future work will focus on expanding the library of fuels and gas mixtures to include gaseous fuels, with and without combustion gas diluents, and solid fuels like wood, plastics, and polyurethane foam combusted in low oxygen environments. Once an extensive library has been established, the phi meter will be applied to a 2/5 scale compartment, designed based on similar research [5,7,9], where backdraft and smoke explosions of various strengths can occur. The phi meter measurements can then be correlated to the bounding conditions for actual backdraft and smoke explosions of various strengths.

Acknowledgments

The authors would like to acknowledge Michael Selepak, who aided in the construction of the phi meter used for this work.

Abstract. We report on the concrete cryptanalysis of LEDAcrypt, a 2nd Round candidate in NIST's Post-Quantum Cryptography standardization process and one of 17 encryption schemes that remain as candidates for near-term standardization. LEDAcrypt consists of a public-key encryption scheme built from the McEliece paradigm and a key-encapsulation mechanism (KEM) built from the Niederreiter paradigm, both using a quasi-cyclic low-density parity-check (QC-LDPC) code. In this work, we identify a large class of extremely weak keys and provide an algorithm to recover them. For example, we demonstrate how to recover 1 in $2^{47.72}$ of LEDAcrypt's keys using only $2^{18.72}$ guesses at the 256-bit security level. This is a major, practical break of LEDAcrypt. Further, we demonstrate a continuum of progressively less weak keys (from extremely weak keys up to all keys) that can be recovered in substantially less work than previously known. This demonstrates that the imperfection of LEDAcrypt is fundamental to the system's design.

Keywords: NIST PQC, LEDAcrypt, McEliece, QC-LDPC, Cryptanalysis

1 Introduction

Since Shor's discovery [27] of a polynomial-time quantum algorithm for factoring integers and solving discrete logarithms, there has been a substantial amount of research on quantum computers. If large-scale quantum computers are ever built, they will be able to break many of the public-key cryptosystems currently in use. This would gravely undermine the integrity and confidentiality of our current communications infrastructure on the Internet and elsewhere.

In response, the National Institute of Standards and Technology (NIST) initiated a process [1] to solicit, evaluate, and standardize one or more quantum-resistant, public-key cryptographic algorithms. This process began in late 2017 with 69 submissions from around the world of post-quantum key-establishment mechanisms or KEMs (resp. public-key encryption schemes or PKEs), and digital signature algorithms. In early 2019, the list of candidates was cut from 69 to 26 (17 of which are PKEs or KEMs), and the 2nd Round of the competition began [2]. The conclusion of Round 2 is now rapidly approaching.

Apon, Daniel; Perlner, Ray; Robinson, Angela; Santini, Paulo. "Cryptanalysis of LEDAcrypt." Paper presented at Crypto 2020, Santa Barbara, CA, US. August 16, 2020 - August 20, 2020.

LEDAcrypt [16] is one of the 17 remaining candidates for standardization as a post-quantum PKE or KEM scheme. It is based on the seminal works of McEliece [20] in 1978 and Niederreiter [23] in 1986, which are based on the NP-complete problem of decoding an arbitrary linear binary code [5]. More precisely, LEDAcrypt is composed of a PKE scheme based on McEliece but instantiated with a particular type of codes (called QC-LDPC) and a KEM in the variant style of Niederreiter. The specific origins of LEDAcrypt – the idea of using QC-LDPC codes with the McEliece paradigm – dates back a dozen years to [15].

At a very high level, the private key of LEDAcrypt is a pair of binary matrices H and Q, where H is a sparse, quasi-cyclic, parity-check matrix of dimension $p \times p \cdot n_0$ for a given QC-LDPC code and where Q is a random, sparse, quasi-cyclic matrix of dimension $p \cdot n_0 \times p \cdot n_0$. Here p is a moderately large prime and n_0 is a small constant. The intermediate matrix $L = [L_0|...|L_{n_0-1}] = H \cdot Q$ is formed by matrix multiplication. The public key M is then constructed from L by multiplying each of the L_i by $L_{n_0-1}^{-1}$. Given this key pair, information can be encoded into codeword vectors, then perturbed by random error-vectors of a low Hamming weight.[1]

Security essentially relies on the assumption that it is difficult to recover the originally-encoded information from the perturbed codeword unless a party possesses the factorization of the public key as H and Q. To recover such matrices (or, equivalently, their product) one must find low-weight codewords in the public code (or in its dual) which, again, is a well-known NP-complete problem [5]. State-of-the-art algorithms to solve this problem are known as Information Set Decoding (ISD), and their expected computational complexity is indeed used as a design criteria for LEDAcrypt parameters.

The LEDAcrypt submission package in the 2nd Round of NIST's PQC process provides a careful description of the algorithm's history and specific design, a variety of concrete parameters sets tailored to NIST's security levels (claiming approximately 128-bit, 192-bit, and 256-bit security, under either IND-CPA or IND-CCA attacks), and a reference implementation in-code.

1.1 Our results

In this work, we provide a novel, concrete cryptanalysis of LEDAcrypt. Note that, in LEDAcrypt design procedure, the time complexity of ISD algorithms is derived by assuming that the searched codewords are uniformly distributed over the set of all n-uples of fixed weight. However, as we show in Section 3, for LEDAcrypt schemes this assumption does not hold, since it is possible to identify many families of secret keys, i.e., matrices H and Q, for which the rows of $L = HQ$ (which represent low weight codewords in the dual code) are characterized by a strong bias in the distribution of set bits. We define such keys as *weak* since, intuitively, in such a case an ISD algorithm can be strongly improved by taking into account the precise structure of the searched codeword. As a direct evidence, in Section 4 we consider a moderately-sized, very weak class

[1] We refer the reader to [3], A.1 for further technical details of the construction.

of keys, which can be recovered with substantially less computational effort than expected. This is a major, practical break of the LEDAcrypt cryptosystem, which is encapsulated in the following theorem.

Theorem 1.1 (Section 4). *There is an algorithm that costs the same as* $2^{49.22}$ *AES-256 operations and recovers* 1 *in* $2^{47.72}$ *of LEDAcrypt's Category 5 (i.e. claimed 256-bit-secure) ephemeral / IND-CPA keys.*

Similarly, there is an algorithm that costs the same as $2^{57.50}$ *AES-256 operations and recovers* 1 *in* $2^{51.59}$ *of LEDAcrypt's Category 5 (i.e. claimed 256-bit-secure) long-term / IND-CCA keys.*

While most key-recovery algorithms can exchange computational time spent vs. fraction of the key space recovered, this trade-off will generally be 1-to-1 against a secure cryptosystem. (In particular this trade off is 1-to-1 for the AES cryptosystem which is used to define the NIST security strength categories for LEDAcrypt's parameter sets.) However, we note in the above that both $49.22 + 47.72 = 96.94 \ll 256$ and $57.49 + 51.59 = 109.08 \ll 256$, making this attack quite significant. Additionally, we note that this class of very weak keys is present in every parameter set of LEDAcrypt.

While the existence of classes of imperfect keys is a serious concern, one might ask:

Is it possible to identify such keys during KeyGen, reject them, and thereby save the scheme's design?

We are able to answer this in the negative.

Indeed, as we demonstrate in Section 3, the bias in the distribution of set bits in L, which is at the basis of our attack, is intrinsic in the scheme's design. Our results clearly show that the existence of weaker-than-expected keys in LEDAcrypt is *fundamental* in the system's formulation and cannot be avoided without a major re-design of the cryptosystem.

Finally, we apply our new attack ideas to attempting key recovery without considering a weak key notion. Here we analyze the asymptotic complexity of attacking *all* LEDAcrypt keys.

Theorem 1.2 (Section 5). *The asymptotic complexity of ISD using an appropriate choice of structured information sets, when attacking* all *LEDAcrypt keys in the worst case, is* $\exp(\tilde{O}(p^{\frac{1}{4}}))$.

This gives a significant asymptotic speed-up over running ISD with uniformly random information sets, which costs $\exp(\tilde{O}(p^{\frac{1}{2}}))$. We note that simply enumerating all possible values of H and Q actually leads to an attack running in time $\exp(\tilde{O}(p^{\frac{1}{4}}))$, and indeed similar attacks were considered in LEDAcrypt's submission documents for the NIST PQC process. However, this type of attack had worse concrete complexity than ordinary ISD with uniformly random information sets for all of the 2nd Round parameter sets.

1.2 Technical Overview of Our New Attacks

Basic Approach: Exploiting the Product Structure. The typical approach to recovering keys for LEDAcrypt-like schemes is to use ordinary ISD algorithms, a class of techniques which can be used to search for low weight codewords in an arbitrary code. Generally speaking, these algorithms symbolically consider a row of an unknown binary matrix corresponding to the secret key of the scheme. From this row, they randomly choose a set of bit positions uniformly at random in the hope that these bits will (mostly) be zero. If the guess is correct and, additionally, the chosen set is an *information set* (i.e., a set in which all codewords differ at least in one position), then the key will be recovered with linear algebra computation. If (at least) one of the two requirements on the set is not met, then the procedure resets and guesses again.

For our attacks, intuitively, we will choose the information set in a non-uniform manner in order to increase the probability that the support of HQ, i.e. the non-zero coefficients of HQ, is (mostly) contained in the complement of the information set. At a high level, we will guess two sets of polynomials $H'_0, ..., H'_{n_0-1}$ and $Q'_{0,0}, ..., Q'_{n_0-1,n_0-1}$, then (interpreting the polynomials as $p \times p$ circulant matrices) group them into quasi-cyclic matrices H' and Q'. These matrices will be structured analogously to H and Q, but with non-negative coefficients defined over $\mathbb{Z}[x]/\langle x^p - 1\rangle$ rather than $\mathbb{F}_2[x]/\langle x^p + 1\rangle$. The hope is that the support of $H'Q'$ will (mostly) contain the support of HQ. It should be noted that a sufficient condition for this to be the case is that the support of H' contains the support of H and the support of Q' contains the support of Q. Assuming the Hamming weight of $H'Q'$ (interpreted as a coefficient vector) is chosen to be approximately W, then the information set can be chosen as the complement of the support of $H'Q'$ and properly passed to an ISD subroutine in place of a uniform guess.

Observe that the probability that the supports of H' and Q' contain the supports of H and Q, respectively, is maximized by making the Hamming weight of H' and Q' as large as possible while still limiting the Hamming weight of $H'Q'$ to W. An initial intuition is that this can be done by choosing the 1-coefficients of the polynomials $H'_0, ..., H'_{n_0-1}$ and $Q'_{0,0}, ..., Q'_{n_0-1,n_0-1}$ to be in a single, consecutive chunk. For example, by choosing the Hamming weight of the polynomials (before multiplication) as some value $B \ll W$, we can take $H'_0 = x^a + x^{a+1} + ... + x^{a+B-1}$ and $Q'_{0,0} = x^c + x^{c+1} + ... + x^{c+B-1}$.

Note that the polynomials H'_0 and $Q'_{0,0}$ (chosen with consecutive 1-coefficients as above) have Hamming weight B, while their product only has Hamming weight $2B - 1$. In the most general case, uniformly chosen polynomials with Hamming weight B would be expected to have a product with Hamming weight much closer to $\min(B^2, p)$. That is, for a fixed weight W required of $H'Q'$ by the ISD subroutine, we can guess around $W/2$ positions at once in H' and Q' respectively instead of something closer to $\sqrt{W}$ as would be given by a truly uniform choice of information set. As a result, each individual guess of H' and Q' that's "close" to this outline of our intuition will be more rewarding for searching the keyspace than the "typical" case of uniformly guessing information sets.

This constitutes the core intuition for our attacks against LEDAcrypt, but additional considerations are required in order to make the attacks practically effective (particularly when concrete parameters are considered). We enumerate a few of these observations next.

Different ring representations. The idea of choosing the polynomials within H' and Q' with consecutive nonzero coefficients makes each iteration of an information set decoding algorithm using such an H' and Q' much more effective than an iteration with a random information set. However there is only a limited number of successful information sets with this form. We can vastly increase our range of options by observing that the ring $\mathbb{F}_2[x]/\langle x^p+1\rangle$ has $p-1$ isomorphic representations which can be mapped to one another by the isomoprhism $f(x) \to f(x^\alpha)$. This allows us many more equally efficient choices of the information set, since rather than restricting our choices to have polynomials H'_0 and $Q'_{0,0}$ with consecutive ones in the standard ring representation, we have the freedom to choose them with consecutive ones in any ring representation (provided the same representation is used for H'_0 and $Q'_{0,0}$.)

Equivalent keys. For each public key of LEDAcrypt, there exist many choices of private keys that produce the same public key. In particular, the same public key $M = (L_{n_0-1})^{-1}L$ produced by the private key

$$H = [H_0, H_1, \cdots, H_{n_0-1}],$$

$$Q = \begin{bmatrix} Q_{0,0} & Q_{0,1} & \cdots & Q_{0,n_0-1} \\ Q_{1,0} & Q_{1,1} & \cdots & Q_{1,n_0-1} \\ \vdots & \vdots & \ddots & \vdots \\ Q_{n_0-1,0} & Q_{n_0-1,1} & \cdots & Q_{n_0-1,n_0-1} \end{bmatrix};$$

would also be produced by any private key of the form

$$H' = [x^{a_0}H_0, x^{a_1}H_1, \cdots, x^{a_{n_0-1}}H_{n_0-1}],$$

$$Q' = \begin{bmatrix} x^{b-a_0}Q_{0,0} & x^{b-a_0}Q_{0,1} & \cdots & x^{b-a_0}Q_{0,n_0-1} \\ x^{b-a_1}Q_{1,0} & x^{b-a_1}Q_{1,1} & \cdots & x^{b-a_1}Q_{1,n_0-1} \\ \vdots & \vdots & \ddots & \vdots \\ x^{b-a_{n_0}}Q_{n_0-1,0} & x^{b-a_{n_0}}Q_{n_0-1,1} & \cdots & x^{b-a_{n_0}}Q_{n_0-1,n_0-1} \end{bmatrix};$$

for any integers $0 < a_i, b < p, i \in \{0, \ldots, n_0-1\}$. These p^{n_0+1} equivalent keys improve the success probability of key recovery attacks as detailed in the following sections.

Different degree constraints for H' and Q'. While we have so far described H' and Q' as having the same Hamming weight B, this does not necessarily need to be the case. In fact, there are many, equivalent choices of H' and Q' which

Apon, Daniel; Perlner, Ray; Robinson, Angela; Santini, Paulo. "Cryptanalysis of LEDAcrypt." Paper presented at Crypto 2020, Santa Barbara, CA, US. August 16, 2020 - August 20, 2020.

produce the same product $H'Q'$ based on this observation. For example, the product of

$$H'_0 = x^a + x^{a+1} + ... + x^{a+B-1}$$
$$Q'_{0,0} = x^c + x^{c+1} + ... + x^{c+B-1}$$

is identical to the product of

$$H'_0 = x^a + x^{a+1} + ... + x^{a+B-1-\delta}$$
$$Q'_{0,0} = x^c + x^{c+1} + ... + x^{c+B-1+\delta}$$

for any integer $-B < \delta < B$. More generally, this relationship (that if H' shrinks and Q' proportionally grows, or vice versa, then the product $H'Q'$ is the same) is independently true for any set of $\{H'_i, Q'_{i,0}, ..., Q'_{i,n_0-1}\}$ for $i \in \{0, ..., n_0 - 1\}$.

Attacks for $n_0 = 2$ imply similar-cost attacks for $n_0 > 2$. Our attacks are more easily described (and more effective) in the case $n_0 = 2$. In this case, we apply ISD to find low-weight codewords in the row space of the public key $[M_0 \mid M_1]$ to recover a viable secret key for the system. Naively extending this approach for the case $n_0 > 2$ to the entire public key $[M_0 \mid ... \mid M_{n_0}]$ requires constraints on the support of $n_0 + n_0^2$ polynomials (n_0 polynomials corresponding to H' and n_0^2 polynomials corresponding to Q'), so the overall work in the attack would increase quadratically as n_0 grows. However, even in the case that $n_0 > 2$, we observe that it is sufficient to find low weight codewords in the row space of only $[M_0 \mid M_1]$ in order to recover a working key, implying that the attack only needs to consider $3n_0$ polynomials $H_i, Q_{j,0}, Q_{k,1}$. So, increasing n_0 will make all of our attacks less effective, but not substantially so. More importantly, any attack against $n_0 = 2$ parameters immediately implies a similar-cost attack against parameters with $n_0 > 2$. Therefore, we focus on the case of $n_0 = 2$ in the remainder of this work.

A Continuum of Progressively Less Weak Keys. The attacker can recover keys with the highest probability per iteration of ISD by using a very structured pattern for L'. As we will see in Section 4, in this pattern both L'_0 and L'_1 will have a single contiguous stretch of nonzero coefficients in some ring representation. The result is a practical attack, but one which is only capable of recovering weak keys representing something like 1 in 2^{40} or 1 in 2^{50} private keys.

However, if the attacker is willing to use a more complicated pattern for the information set, using different ring representations for different blocks of H' and Q', and possibly having multiple separate stretches of consecutive nonzero coefficients in each block, then the attacker will not recover keys with as high a probability per iteration, but the attack will extend to a broader class of slightly less weak keys. This may for example lead to a somewhat less practical attack that recovers 1 in 2^{30} keys, but still much faster than would be expected given the claimed security strength of the parameter set in question.

We do not analyze the multitude of possible cases here, but we show they must necessarily exist in Section 3 by demonstrating that bias is intrinsically present throughout the LEDAcrypt key space.

Improvements to Average-case Key Recovery. In Section 5 we will take the continuum of progressively weaker keys to its logical extreme. We show that the attacks in this paper are asymptotically stronger than the standard attacks not just for weak keys, but for all keys.

As we move away from the simpler information set patterns used on the weakest keys, the analysis becomes more difficult. To fully quantify the impact of our attack on average keys would require extensive case analysis of all scenarios that might lead to a successful key recovery given a particular distribution of information sets used by the attacker, which we leave for future work.

1.3 Related Work

The main attack strategies against cryptosystems based on QC-LDPC codes are known as information set decoding (ISD) algorithms. These algorithms are also applicable to a variety of other code-based cryptosystems including the NIST 2nd round candidates BIKE [22], HQC [8], Classic McEliece [9], and NTS-KEM [17]. Initiated by Prange [25] in 1962, these algorithms have since experienced substantial improvements during the years [4, 7, 12, 13, 18, 19, 28]. ISD algorithms can also be used to find low-weight codewords in a given, arbitrary code. ISD main approach is that of guessing a set of positions where such codewords contain a very low number of set symbols; when this set is actually an information set, then linear algebra computations yield the searched codeword (see [3], Appendix A.3). ISD time complexity is estimated as the product between the expected number of required information set guesses and the cost of testing each set. Advanced ISD algorithms improve Prange's basic idea by reducing the average number of required guesses, at the cost of increasing the time complexity of the testing phase. Quantum ISD algorithms take into account Grover's algorithm [10] to quadratically accelerate the guessing phase. A quantum version of Prange's algorithm [6] was presented in 2010, while quantum versions of more advanced ISD algorithms were presented in 2017 [11].

In the case of QC-MDPC and QC-LDPC codes, ISD key recovery attacks can get a speed-up which is polynomial in the size of the circulant blocks [26]. This gain is due to the fact that there are more than one sparse vector in the row space of the parity check matrix, and no modification to the standard ISD algorithms is required to obtain this speed-up. Another example of gains due to the QC structure is that of [14] which, however, works only in the case of the circulant size having a power of 2 among its factors (which is not the case we consider here).

ISD can generally be described as a technique for finding low Hamming-weight codewords in a linear code. Most ISD algorithms are designed to assume that the low-weight codewords are random aside from their sparsity. However, in some cryptosystems that can be cryptanalyzed using ISD, these short codewords are not random in this respect, and modified versions of ISD have been used to break these schemes [21, 24]. Our paper can be seen as a continuation of this line of work, since unlike the other 2nd Round NIST candidates where ISD is cryptanalytically relevant, the sparse codewords which lead to a key recovery of

LEDAcrypt are not simply random sparse vectors, but have additional structure due to the product structure of LEDAcrypt's private key.

2 Preliminaries

2.1 Notation

Throughout this work, we denote the finite field with 2 elements by $\mathbb{F}_2$. We denote the Hamming weight of a vector a (or a polynomial a, viewed in terms of its coefficient vector) as $\mathrm{wt}(a)$. For a polynomial a we use the representation $a = \sum_{i=0}^{p-1} a_i x^i$, and call a_i its i-th coefficient. We denote the support – i.e. the non-zero coordinates – of a vector (or polynomial) a by $\mathrm{S}(a)$. In similar way, we define the *antisupport* of a, and denote it as $\bar{\mathrm{S}}(a)$, as the set of positions i such that $a_i = 0$. Given a polynomial a and a set J, we denote as $a|_J$ the set of coefficients of a that are indexed by J. Given π, a permutation of $\{0, \cdots, n-1\}$, we represent it as the ordered set of integers $\{\ell_0, \cdots, \ell_{n-1}\}$, such that π places ℓ_i in position i. For a length-n vector a, $\pi(a)$ denotes the action of π on a, i.e., the vector whose i-th entry is a_{ℓ_i}. For a probability distribution $\mathcal{D}$, we write $X \sim \mathcal{D}$ if X is distributed according to $\mathcal{D}$.

2.2 Parameters

The parameter sets of LEDAcrypt that we explicitly consider in this work are shown in Table 1 (although similar forms of our results hold for all parameter sets). We refer the reader to [3], Appendix A.1 for further technical details of the construction.

NIST Category	Security Type	p	d_v	m_0	m_1	n_0
1 (128-bit)	IND-CPA	14,939	11	4	3	2
5 (256-bit)	IND-CPA	36,877	11	7	6	2
5 (256-bit)	IND-CCA	152,267	13	7	6	2

Table 1. LEDAcrypt parameter sets that we consider in this paper.

3 Existence of Weak Keys in LEDAcrypt

As we have explained in Section 1.3, key recovery attacks against cryptosystems based on codes with sparse parity-check matrices can be performed by searching for low weight codewords, either in the code or in its dual. For instance, such codewords in the dual correspond, with overwhelming probability, to the rows of the secret parity-check matrix, of weight $\omega \ll n$, where n denotes the code length. The most efficient way to solve this problem is to use ISD algorithms. To analyze the efficiency of such attacks, weight-ω codewords are normally modeled as independent random variables, sampled according to the uniform distribution of n-uples with weight ω, which we denote as $\mathcal{U}_\omega$. At each ISD iteration, the algorithm succeeds if the intersection between the chosen set T and the support of (at least) one of such codewords satisfies some properties. Regardless of the considered ISD variant, this intersection has to be small.

Let ϵ be the probability that a single ISD iteration can actually recover a specific codeword of the desired weight. When the code contains M codewords of weight ω, then the probability that a single ISD iteration can recover any of these codewords is $1-(1-\epsilon)^M$ which, if $\epsilon M \ll 1$, can be approximated as ϵM. This speed-up in ISD algorithm normally applies to the case of QC codes, where M corresponds to the number of rows in the parity-check matrix (that is, $M = n-k$).

In this section we show that the product structure in LEDAcrypt yields to a strong bias in the distribution of set symbols in the rows of the secret parity-check matrix $L = HQ$. As a consequence, the assumption on the uniform distribution of the searched codewords does not hold anymore, and this opens up for dramatic improvements in ISD algorithms. To provide evidence of this claim we analyze, without loss of generality, a simplified situation. We focus on the case $n_0 = 2$, and consider the success probability of ISD algorithms when applied on LEDAcrypt schemes, searching for a row of the secret L (say, the first row), with weight $\omega = 2d_v(m_0+m_1)$.

In this case we expect to have the usual speed-up deriving from the presence of multiple low-weight codewords. However, quantifying this speed-up is not straightforward and requires cumbersome computations, since it also depends on the particular choice of the chosen set in ISD. Thus, to keep the description as general as possible and easy to follow, in this section we only focus on a single row of L. Exact computations for these quantities are performed in Sections 4 and 5. Furthermore, we only consider the probability that a chosen set T does not overlap with the support of the searched codeword. With this choice, we essentially capture the essence of all ISD algorithms. An analysis on a specific variant, with optimized parameters and requirements on the chosen set, might significantly improve the results of this section which, however, are already significant for the security of LEDAcrypt schemes.

Let $T \subseteq \{0, \cdots, n-1\}$ be a set of dimension k: for $a \sim \mathcal{U}_\omega$, we have

$$\Pr\left[T \cap \mathrm{S}(a) = \varnothing \middle| \, a \sim \mathcal{U}_\omega\right] = \frac{\binom{n-\omega}{k}}{\binom{n}{k}}.$$

Note that this probability does not depend on the particular choice of T, but just on its size. When a purely random QC-MDPC code is used, as in BIKE [22], the first row of the secret parity-check matrix is well modeled as a random sample from $\mathcal{U}_\omega$. The previous probability can also be described as the ratio between the number of n-uples of weight ω whose support is disjoint with T, and that of all possible samples from $\mathcal{U}_\omega$; in schemes such as BIKE, this also corresponds to the probability that a secret key satisfies the requirement on an arbitrary set T.

As we show in the remainder of this section, in LEDAcrypt such a fraction can actually be made significantly larger, when T is properly chosen. To each choice, we can then associate a family of *weak keys*, that is, secret keys for which the corresponding first row of L does not overlap with T. We formally define the notion of weak keys in the following.

Definition 3.1. *Let $\mathcal{K}$ be the public key space of LEDAcrypt with parameters n_0, p, d_v, m_0, m_1. Let $T \subseteq \{0, \cdots, n_0p-1\}$ of cardinality $n-k=p$ and $\mathcal{W} \subseteq \mathcal{K}$ be the set of all public keys corresponding to secret keys $sk=(H,Q)$ such that the first row in the corresponding $L=HQ$ has support that is disjoint with T. Finally, we define $\omega = n_0(m_0+m_1)d_v$ and $\mathcal{U}_\omega$ as the uniform distribution of (n_0p)-tuples with weight ω. Then, we say that $\mathcal{W}$ is a set of* weak-keys *if*

$$\Pr\left[pk \in \mathcal{W} | (sk, pk) \leftarrow \mathsf{KeyGen}()\right] \gg \Pr\left[T \cap \mathrm{S}(a) = \varnothing | a \sim \mathcal{U}_\omega\right] = \frac{\binom{n_0p-\omega}{p}}{\binom{n_0p}{p}}.$$

Roughly speaking, we have a family of weak keys when, for a specific set choice, the number of keys meeting the requirement on the support is significantly larger than the one that we would have for the uniform case. Indeed, for all such keys, we will have a strongly bias in the matrix L, since null positions can be guessed with high probability; as we describe in Sections 4 and 5, this fact opens up for strong attacks against very large portions of keys.

3.1 Preliminary considerations on sparse polynomials multiplications

We now recall some basic fact about polynomial multiplication in the rings $\mathbb{F}_2[x]/\langle x^p+1\rangle$ and $\mathbb{Z}[x]/\langle x^p-1\rangle$, which will be useful for our treatment. Let $a, b \in \mathbb{F}_2[x]/\langle x^p+1\rangle$ and $c = ab$; we then have

$$c_i = \bigoplus_{z=0}^{p-1} a_z b_{z'}, \quad z' = i - z \mod p,$$

where the operator $\bigoplus$ highlights the fact that the sum is performed over $\mathbb{F}_2$. Taking into account antisupports, we can rewrite the previous equation as

$$c_i = \bigoplus_{\substack{z \notin \bar{\mathrm{S}}(a) \\ z'=i-z \mod p,\ z' \notin \bar{\mathrm{S}}(b)}}^{p-1} a_z b_{z'}. \tag{1}$$

Let $N(a,b,i)$ denote the set of terms that contribute to the sum in Eq. (1), i.e.

$$N(a,b,i) = \left\{z \text{ s.t. } z \notin \bar{\mathrm{S}}(a) \text{ and } i - z \mod p \notin \bar{\mathrm{S}}(b)\right\}.$$

We now denote with $\tilde{a}$ and $\tilde{b}$ the polynomials obtained by lifting a and b over $\mathbb{Z}[x]/\langle x^p-1\rangle$ i.e., by mapping the coefficients of a and b into $\{0,1\} \subset \mathbb{Z}$. Let $\tilde{c} =$

$\tilde{a}\tilde{b}$: we straightforwardly have that $c \equiv \tilde{c} \mod 2$, $|N(a,b,i)| = \tilde{c}_i$ and $\sum_{i=0}^{p-1} \tilde{c}_i = \mathrm{wt}(a) \cdot \mathrm{wt}(b)$. Let $a' \in \mathbb{Z}[x]/\langle x^p + 1\rangle$ with coefficients in $\{0, 1\}$, such that $\mathrm{S}(a') \supseteq \mathrm{S}(a)$, i.e., such that its support contains that of a (or, in another words, such that its antisupport is contained in that of a); an analogous definition holds for b'. Indeed, we can write $a' = \tilde{a} + s_a$, where $s_a \in \mathbb{Z}[x]/\langle x^p + 1\rangle$ and whose i-th coefficient is equal to 0 if $a'_i = a_i$, and equal to 1 otherwise; with analogous notation, we can write $b' = \tilde{b} + s_b$. Then

$$c' = a'b' = (\tilde{a} + s_a)(\tilde{b} + s_b) = \tilde{a}\tilde{b} + s_a\tilde{b} + s_b\tilde{a} + s_a s_b = \tilde{c} + s_a\tilde{b} + s_b\tilde{a} + s_a s_b.$$

Since $s_a\tilde{b}$, $s_b\tilde{a}$ and $s_a s_b$ have all non-negative coefficients, we have

$$c'_i \geq \tilde{c}_i = |N(a,b,i)| \geq 0, \forall i \in \{0, \cdots, p-1\}. \tag{2}$$

We now derive some properties that link the coefficients of c' to those of c; as we show, knowing portions of the antisupports of a and b is enough to gather information about the coefficients in their product.

Lemma 3.2. *Let $a, b \in \mathbb{F}_2[x]/\langle x^p + 1\rangle$, and $J_a, J_b \subseteq \{0, \cdots, p-1\}$ such that $J_a \supseteq \mathrm{S}(a)$ and $J_b \supseteq \mathrm{S}(b)$. Let $a', b' \in \mathbb{Z}[x]/\langle x^p - 1\rangle$ be the polynomials whose coefficients are null, except for those indexed by J_a and J_b, respectively, which are set as 1. Let $c = ab \in \mathbb{F}_2[x]/\langle x^p + 1\rangle$ and $c' = a'b' \in \mathbb{Z}[x]/\langle x^p - 1\rangle$; then*

$$c'_i = 0 \implies c_i = 0.$$

Proof. The result immediately follows from (2) by considering that if $c'_i = 0$ then necessarily $|N(a,b,i)| = 0$ and, subsequently, $c_i = 0$. □

When the weight of $c = ab$ is maximum, i.e., equal to $\mathrm{wt}(a) \cdot \mathrm{wt}(b)$, the probability to have null coefficients in c_i can be related to the coefficients in c'_i; in analogous way, we can also derive the probability that several bits are simultaneously null. These relations are formalized in the following Lemma.

Lemma 3.3. *Let $a, b \in \mathbb{F}_2[x]/\langle x^p + 1\rangle$, with respective weights ω_a and ω_b, such that $\omega = \omega_a\omega_b \leq p$, and $c = ab$ has weight ω. Let $J_a, J_b \subseteq \{0, \cdots, p-1\}$ such that $J_a \supseteq \mathrm{S}(a)$ and $J_b \supseteq \mathrm{S}(b)$. Let $a', b' \in \mathbb{Z}[x]/\langle x^p - 1\rangle$ be the polynomials whose coefficients are null, except for those indexed by J_a and J_b, respectively, which are set as 1; finally, let $M = |J_a| \cdot |J_b|$.*

i) Let c'_i be the i-th coefficient of $c' = a'b'$; then

$$\Pr\left[c_i = 0 | c'_i\right] = \gamma(M, \omega, c'_i) = \left(1 + \omega \cdot \frac{c'_i}{M + 1 - \omega - c'_i}\right)^{-1}.$$

ii) For $V = \{v_0, \cdots, v_{t-1}\} \subseteq \{0, \cdots, p-1\}$, we have

$$\Pr\left[\mathrm{wt}(c|_V) = 0 \mid c'\right] = \zeta(V, c', \omega) = \prod_{\ell=0}^{t-1} \gamma\big(M - \textstyle\sum_{j=0}^{\ell-1} c'_{v_j}, \omega, c'_{v_\ell}\big).$$

Proof. The results follow from a combinatorial argument. See [3], Appendix B.3 for details. □

3.2 Identifying families of weak keys

We are now ready to use the results presented in the previous section to describe how, in LEDAcrypt, families of weak keys as in Def. 3.1 can be identified. We base our strategy on the results of Lemmas 3.2 and 3.3. Briefly, we guess "containers" for each polynomial in the secret key, i.e., polynomials over $\mathbb{Z}[x]/\langle x^p - 1\rangle$ whose support contains that of the corresponding polynomials in $\mathbb{F}_2[x]/\langle x^p + 1\rangle$. We then combine such containers, to find positions that, with high probability, do not point at set coefficient in the polynomials in $L = HQ$. Assuming that the initial choice for the containers is right, we can then use the results of Lemmas 3.2 and 3.3 to determine such positions. For the sake of simplicity, and without loss of generality, we describe our ideas for the practical case of $n_0 = 2$.

Operatively, to build a set T defining an eventual set of weak keys, we rely on the following procedure.

1. Consider sets J_{H_i} such that $J_{H_i} \supseteq \mathrm{S}(H_i)$, for $i = 0, 1$; the cardinality of J_{H_i} is denoted as B_{H_i}. In analogous way, define sets $J_{Q_{i,j}}$, for $i = 0, 1$ and $j = 0, 1$, with cardinalities $B_{Q_{i,j}}$.
2. To each set J_{H_i}, associate a polynomial $H'_i \in \mathbb{Z}[x]/\langle x^p - 1\rangle$, taking values in $\{0, 1\}$ and whose support corresponds to J_{H_i}; in analogous way, construct polynomials $J_{Q_{i,j}}$ from the sets $J_{Q_{i,j}}$. Compute
$$L'_{i,j} = H'_j Q'_{j,i} \in \mathbb{Z}[x]/\langle x^p - 1\rangle, \ \ (i, j) \in \{0, 1\}^2.$$
3. Compute
$$L'_i = L'_{i,0} + L'_{i,1} = H'_0 Q'_{0,i} + H'_1 Q'_{1,i} \in \mathbb{Z}[x]/\langle x^p - 1\rangle.$$
Let π_i, with $i = 0, 1$, be a permutation such that the coefficients of $\pi_i\big(L'_i\big)$ are in non decreasing order. Group the first $\left\lfloor \frac{p}{2} \right\rfloor$ entries of π_0 in a set T_0, and the first $\left\lceil \frac{p}{2} \right\rceil$ ones of π_1 in a set T_1. Define T as $T = T_0 \cup \{p + \ell |\, \ell \in T_1\}$.

A visual representation of the above constructive method to search for weak keys is described in [3], Appendix C.

Essentially, our proposed procedure to find families of weak keys starts from the sets J_{H_i} and $J_{Q_{i,j}}$, which we think of as "containers" for the secret key, i.e., sets containing the support of the corresponding polynomial in the secret key. Their products yield polynomials $L'_{i,j}$, which are containers for the products $H_i Q_{j,i}$. Because of the maximum weight requirement in LEDAcrypt key generation, each $L'_{i,j}$ matches the hypothesis required by the Lemma 3.3: the lowest entries in $L'_{i,j}$ correspond to the coefficients that, with the highest probability, are null in $H'_i Q'_{j,i}$. We remark that, because of Lemma 3.2, a null coefficient in $L'_{i,j}$ means that the corresponding coefficients in $H_j Q_{j,i}$ must be null. Finally, we need to combine the coefficients of the polynomials $L'_{i,j}$, to identify positions that are very likely to be null in each L_i. The approach we consider consists in choosing the positions that correspond to coefficients with minimum values in the sums $L'_{i,0} + L'_{i,1}$. This simple criterion is likely to be not optimal, but allows to avoid cumbersome notation and computations; furthermore, as we show next, it already detects significantly large families of weak keys.

The number of secret keys that meet the requirements on T, i.e., keys leading to polynomials L_0 and L_1 that do not overlap with the chosen sets T_0 and T_1, respectively, clearly depends on the particular choice for the containers. In the remainder of this section, we describe how such a quantity can be estimated. For the sake of simplicity, we analyze the case in which the starting sets for the containers have constant size, i.e., $B_{H_i} = B_H$ and $B_{Q_{i,j}} = B_Q$, for all i and j; furthermore, we choose $J_{H_0} = J_{H_1}$, $J_{Q_{0,0}} = J_{Q_{1,1}}$ and $J_{Q_{1,0}} = J_{Q_{0,1}}$.

First of all, let $\mathcal{J}$ be the set of secret keys whose polynomials are contained in the sets J_{H_i} and $J_{Q_{i,j}}$; the cardinality of this set can be estimated as

$$|\mathcal{J}| = \eta\left(\binom{B_H}{d_v}\binom{B_Q}{m_0}\binom{B_Q}{m_1}\right)^2,$$

where η is the acceptance ratio in key generation, i.e., the probability that a random choice of matrices H and Q leads to a matrix L with full weight.

We now estimate the number of keys in $\mathcal{J}$ that produce polynomials L_0 and L_1 corresponding to a correct choice for T_0 and T_1, i.e., such that their supports are disjoint with T_0 and T_1, respectively. For each product $H_iQ_{i,j}$, we know i) that it has full weight, not larger than p, and ii) that sets J_{H_i}, $J_{Q_{i,j}}$ are containers for H_i and $Q_{i,j}$, respectively. Then, Lemma 3.3 can be used to estimate the portion of valid keys. For instance, we consider the polynomial $L_0 = H_0Q_{0,0} + H_1Q_{1,0}$: the coefficients that are indexed by T_0 will be null when both the supports of $H_0Q_{0,0}$ and $H_1Q_{1,0}$ are disjoint with T_0. If we neglect the fact that these two products are actually correlated (because of the full weight requirement on L_0), then the probability that L_0 does not overlap with T_0, which we denote as $\Pr\left[\texttt{null}(T_0)\right]$, is obtained as

$$\Pr\left[\texttt{null}(T_0)\right] = \zeta\big(T_0, L'_{0,0}, m_0d_v\big) \cdot \zeta\big(T_0, L'_{0,1}, m_1d_v\big),$$

where ζ is defined in Lemma 3.3. The above quantity can then be used to estimate the fraction of keys in $\mathcal{J}$ for which the support of L_0 does not overlap with T_0; we remark that, as highlighted by the above formula, this quantity strongly depends on the choices on J_{H_0}, J_{H_1}, $J_{Q_{0,0}}$, $J_{Q_{1,0}}$.
With the same reasoning, and with analogous notation, we compute $\Pr\left[\texttt{null}(T_1)\right]$; because of the simplifying restrictions on $J_{Q_{i,j}}$, this probability is equal to $\Pr\left[\texttt{null}(T_0)\right]$.

Then, if we neglect the correlation between L_0 and L_1 (since H_0 and H_1 are involved in the computation of both polynomials), the probability that a random key from $\mathcal{J}$ is associated to a valid L, i.e., that it leads to polynomials L_0 and

L_1 that respectively do not overlap with T_0 and T_1, can be estimated as

$$\begin{aligned}\Pr\left[\texttt{null}(T)\right] &= \Pr\left[\texttt{null}(T_0)\right] \cdot \Pr\left[\texttt{null}(T_1)\right] \\ &= \big(\Pr\left[\texttt{null}(T_0)\right]\big)^2 \\ &= \Big(\zeta\big(T_0, L'_{0,0}, m_0 d_v\big) \cdot \zeta\big(T_0, L'_{0,1}, m_1 d_v\big)\Big)^2.\end{aligned}$$

Thus we conclude that the number of keys whose polynomials are contained by the chosen sets, and such that the corresponding L does not overlap with T, can be estimated as $|\mathcal{J}| \cdot \Pr[\texttt{null}(T)]$.
Then, for the set of secret keys where T does not intercept the first row of L, which we denote with $\mathcal{W}$, we have

$$|\mathcal{W}| \geq |\mathcal{J}| \cdot \Pr[\texttt{null}(T)]. \tag{3}$$

The inequality comes from the fact the right term in the above formula only counts keys with polynomials contained by the initially chosen sets; even if such property is not satisfied, it may still happen that the resulting L does not overlap with T (thus, we are underestimating the cardinality of $\mathcal{W}$).

3.3 Results

In this section we provide practical examples on choices for containing sets, leading to actual families of weak keys. To this end, we need to define clear criteria on how the sets J_{H_i} and $J_{Q_{i,j}}$ can be selected. For the sake of simplicity, we restrict our attention to the cases $J_{H_0} = J_{H_1} = J_H$ and $J_{Q_{0,0}} = J_{Q_{0,1}} = J_{Q_{1,0}} = J_{Q_{1,1}} = J_Q$. We here consider two different strategies to pick these sets.

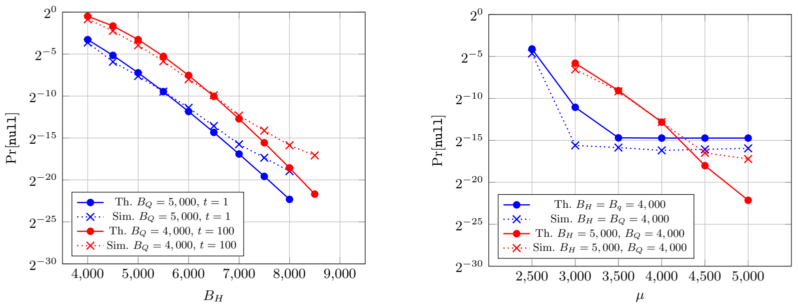
- *Type I*: for $i = 0, 1$, $\delta \in \{0, \cdots, p-1\}$ and $t \in \{1, \cdots, p-1\}$, we choose

$$\begin{aligned} J_H &= \{\ell t \mod p \,|0 \leq \ell \leq B_H - 1\}, \\ J_Q &= \{\delta + \ell t \mod p \,|0 \leq \ell \leq B_Q - 1\}.\end{aligned}$$

- *Type II*: for $i = 0, 1$, we choose $J_{H_0} = J_{H_1}$ as the union of disjoint sets, formed by contiguous positions. Analogous choice is adopted for J_Q.

To provide numerical evidences for our analysis, in Figure 1 we compare the simulated values of $\Pr[\texttt{null}(T)]$ with the ones obtained with theoretical expression, for parameters of practical interest and for some Types I and II choices. The simulated probabilities have been obtained by generating random secret keys from $\mathcal{J}$ and, as our results show, are well approximated by the theoretical expression. This shows that Eq. 3 provides a good estimate for the fraction of keys in $\mathcal{J}$ that meet the requirement on the corresponding set T.

Tables 2, 3 display results testing various weak key families of Type I and II, for two different LEDAcrypt parameters sets. According to the reasoning in the previous section, the values reported in the last column can be considered as a rough (and likely conservative) estimate for the probability that a random key belongs to the corresponding set $\mathcal{W}$. Our results show that the identified families of keys meet Definition **??**, so can actually be considered weak.



(a) Type I

(b) Type II

Fig. 1. Comparison between simulated and theoretical values for Pr[`null`], for $p = 14939$, $d_v = 11$, $m_0 = 4$, $m_1 = 3$. The values reported in Figure (a) are all referred to the case $\delta = 0$. In Figure (b), the blue curves correspond to the choice $J_H = J_Q = \{0, \cdots, 1999\} \cup \{\mu, \cdots, \mu + 1999\}$, while the red curves correspond to $J_H = \{0, \cdots, 2499\} \cup \{\mu, \cdots, \mu + 2499\}$ and $J_Q = \{0, \cdots, 3999\}$.

Type	Family Parameters	$\frac{\lvert\mathcal{J}\rvert \cdot \Pr[\texttt{null}(T)]}{\lvert\mathcal{K}\rvert}$
I	$B_H = B_Q = 7470$ $\delta = 0, t = 1$	$2^{-99.88}$
I	$B_H = 8000, B_Q = 4000$ $\delta = 2000, t = 1$	$2^{-85.25}$
I	$B_H = 8500, B_Q = 4000$ $\delta = 0, t = 127$	$2^{-90.23}$
II	$J_H = \{0, \cdots, 4499\} \cup \{7000, \cdots, 11499\}$ $J_Q = \{0, \cdots, 2499\} \cup \{8000, \cdots, 10499\}$	$2^{-101.53}$

Table 2. Fraction of weak keys, for LEDAcrypt instances designed for 128-bit security, with parameters $n_0 = 2$, $p = 14939$, $d_v = 11$, $m_0 = 4$, $m_1 = 3$, for which $\eta \approx 0.7090$. For this parameter set, probability of randomly guessing a null set of dimension p, in a vector of length $2p$ and weight $2(m_0 + m_1)d_v$, is $2^{-154.57}$.

Remark 1. The results we have shown in this section only represent a qualitative evidence of the existence of families of weak keys in LEDAcrypt. There may exist many more families of weak keys, having a complete different structure from the ones we have studied. Additionally, the parameters we have considered for types I and II may not be the optimal ones, but already identify families of weak keys. In the next sections we provide a detailed analysis for families of keys of type I and II, and furthermore specify the actual complexity of a full cryptanalysis exploiting such a key structure.

Type	Family Parameters	$\frac{\lvert\mathcal{J}\rvert\cdot\Pr[\texttt{null}(T)]}{\lvert\mathcal{K}\rvert}$
I	$B_H = 18000, B_Q = 9000$ $\delta = 9000, t = 1$	$2^{-125.18}$
I	$B_H = 24000, B_Q = 12000$ $\delta = 0, t = 1$	$2^{-184.21}$
I	$B_H = 18000, B_Q = 9000$ $\delta = 0, t = 5$	$2^{-125.18}$
II	$J_H = \{0, \cdots, 20999\}$ $J_Q = \{0, \cdots, 3999\} \cup \{10000, \cdots, 13999\} \cup \{20000, \cdots, 23999\}$	$2^{-270.30}$

Table 3. Fraction of weak keys, for LEDAcrypt instances designed for 256-bit security, with parameters $n_0 = 2$, $p = 36877$, $d_v = 11$, $m_0 = 7$, $m_1 = 6$, for which $\eta \approx 0.614$. For this parameter set, probability of randomly guessing a null set of dimension p, in a vector of length $2p$ and weight $2(m_0 + m_1)d_v$, is $2^{-286.80}$.

4 Explicit Attack on the Weakest Class of Keys

In the previous section we described how the product structure in LEDAcrypt leads to an highly biased distribution in set positions in L. As we have hinted, this property may be exploited to improve cryptanalysis techniques based on ISD algorithms. In this section, we present an attack against a class of weak keys in LEDAcrypt's design. We begin by identifying what appear to be the weakest class of keys (though large enough in number to constitute a serious, practical problem for LEDAcrypt). It is easily seen that the class of keys we consider in this section corresponds to a particular case of type I, introduced in Section 3.3. We proceed to provide a simple, single-iteration ISD algorithm to recover these keys, then analyze the fraction of all of LEDAcrypt's keys that would be recovered by this attack. Afterward, we show how to extend the ISD algorithm to more than one iteration, so as to enlarge the set of keys recovered by a similar enough of effort per key. We conclude by considering the effect of advanced ISD algorithms on the attack as well as the relationship between the rejection sampling step in LEDAcrypt's KeyGen and our restriction to attacking a subspace of the total key space.

4.1 Attacking an example (sub)class of ultra-weak keys

The simplest and, where it works, most powerful version of the attack dramatically speeds up ISD for a class of ultra-weak keys chosen under parameter sets where $n_0 = 2$. One example (sub)class of ultra-weak keys are those keys where the polynomials L_0 and L_1 are of degree at most $\frac{p}{2}$. Such keys can be found by a single iteration of a very simple ISD algorithm. We describe this simple attack as follows.

The attacker chooses the information set to consist of the last $\frac{p-1}{2}$ columns of the first block of M and the last $\frac{p+1}{2}$ columns of the second block. If the key being attacked is one of these weak keys, the attacker can correctly guess the top row of L as being identically zero within the information set and linearly solve for the nonzero linear combination of the rows of M meeting this condition. The cost of the attack is one iteration of an ISD algorithm.

A sufficient condition for this class of weak key to occur is for the polynomials H_0, H_1, $Q_{0,0}$, $Q_{0,1}$, $Q_{1,0}$, and $Q_{1,1}$ to have degree no more than $\frac{p}{4}$. Since each of the $2m_0+2m_1+2d_v$ nonzero coefficients of these polynomials has a $\frac{1}{4}$ probability of being chosen with degree less than $\frac{p}{4}$, these weak keys represent at least 1 part in $4^{2m_0+2m_1+2d_v}$ of the key space.

4.2 Enumerating ultra-weak keys for a single information set

In fact, there are significantly more weak keys than this that can be recovered by the basic, one-iteration ISD algorithm using the information set described above. Intuitively, this is for two reasons:

1. **Equivalent keys:** There are p^2 private keys, not of this same, basic form, which nonetheless produce the same public key.
2. **Different degree constraints:** The support of the top row of L will also fall entirely outside the information set if the degree of H_0 is less than $\frac{p}{4} - \delta$ and the degrees of $Q_{0,0}$ and $Q_{0,1}$ are both less than $\frac{p}{4} + \delta$ for any $\delta \in \mathbb{Z}$ such that $-\frac{p}{4} < \delta < \frac{p}{4}$. Likewise for H_1 and $Q_{1,0}$ and $Q_{1,1}$, for a total of p keys.

Concretely, we derive the number of distinct private keys that are recovered by the one-iteration ISD algorithm in the following theorem.

Remark 2. There are p columns of each block of M. For the sake of simplicity, instead of referring to pairs of $\frac{p-1}{2}$ and $\frac{p+1}{2}$ columns, we instead use $\frac{p}{2}$ for both cases. This has a negligible effect on our results.

Theorem 4.1. *The number of distinct private keys that can be found in a single iteration of the decoding algorithm described above (where the information set is chosen to consist of the last $\frac{p}{2}$ columns of each block of M) is*

$$\begin{aligned}
&p^3 \cdot \sum_{A_0=d_v-1}^{\frac{p}{2}} \sum_{A_1=d_v-1}^{\frac{p}{2}} \left(\binom{A_0-1}{d_v-2} \binom{A_1-1}{d_v-2} \right. \\
&\cdot \left(\binom{\frac{p}{2}-A_0-2}{m_0-1} \binom{\frac{p}{2}-A_0-1}{m_1} \binom{\frac{p}{2}-A_1-1}{m_1} \binom{\frac{p}{2}-A_1-1}{m_0} \right. \\
&+ \binom{\frac{p}{2}-A_0-1}{m_0} \binom{\frac{p}{2}-A_0-2}{m_1-1} \binom{\frac{p}{2}-A_1-1}{m_1} \binom{\frac{p}{2}-A_1-1}{m_0} \\
&+ \binom{\frac{p}{2}-A_0-1}{m_0} \binom{\frac{p}{2}-A_0-1}{m_1} \binom{\frac{p}{2}-A_1-2}{m_1-1} \binom{\frac{p}{2}-A_1-1}{m_0} \\
&\left. \left. + \binom{\frac{p}{2}-A_0-1}{m_0} \binom{\frac{p}{2}-A_0-1}{m_1} \binom{\frac{p}{2}-A_1-1}{m_1} \binom{\frac{p}{2}-A_1-2}{m_0-1} \right) \right) \\
&\cdot \left(1 - O\left(\frac{m}{p} \right) \right).
\end{aligned} \tag{4}$$

Proof. We count the number of ultra-weak keys as follows. By assumption, all nonzero bits in each block of an ultra-weak key are contained in some consecutive stretch of size $\leq \frac{p}{2}$. Thus these ultra-weak keys contain a stretch of at least $\frac{p}{2}$ zero bits. This property applies directly to the polynomials $H_0Q_{0,0} + H_1Q_{1,0}$ and $H_0Q_{0,1} + H_1Q_{1,1}$, and must also hold for H_0 and H_1. We index the number of ultra-weak keys according to the first nonzero coefficient of these polynomials after the stretch of zero bits in cyclic ordering.

We begin by considering H, Q though not requiring HQ to have full weight. We are using an information set consisting of the same columns for both $H_0Q_{0,0}+ H_1Q_{1,0}$ and $H_0Q_{0,1} + H_1Q_{1,1}$. Therefore we count according the first nonzero bit of the sum $H_0Q_{0,0} + H_1Q_{1,0} + H_0Q_{0,1} + H_1Q_{1,1}$. Let l be the location of the first nonzero bit of this sum.

Let j_0, j_1 be the locations of the first nonzero bit of H_0, H_1, respectively. Suppose that the nonzero bits of H_0, H_1 are located within a block of length A_0, A_1, respectively.

By LEDAcrypt's design, $d_v \leq A_i, i \in \{0, 1\}$ and by assumption on the chosen information set, $A_i \leq \frac{p}{2}, i \in \{0, 1\}$. Once j_0 is fixed, there are $\sum_{A_0=d_v-1}^{\frac{p}{2}} \binom{A_0-1}{d_v-2}$ ways to arrange the remaining bits of H_0. Thus there are

$$\sum_{j_0=1}^{p-1} \sum_{A_0=d_v-1}^{\frac{p}{2}} \binom{A_0-1}{d_v-2} \sum_{j_1=1}^{p-1} \sum_{A_1=d_v-1}^{\frac{p}{2}} \binom{A_1-1}{d_v-2} \tag{5}$$

many bit arrangements of H_0, H_1.

Once j_0, j_1 are fixed, there are four blocks of Q which may influence the location l. We compute the probability that only one block of Q may influence l at a time.

If l is influenced by $Q_{0,0}$, there are $\binom{\frac{p}{2}-A_0-2}{m_0-1}$ ways the remaining bits of $Q_{0,0}$ can fall, $\binom{\frac{p}{2}-A_0-1}{m_1}$ arrangements of the bits of $Q_{0,1}$, $\binom{\frac{p}{2}-A_1-1}{m_1}$ arrangements of the bits of $Q_{1,0}$, and $\binom{\frac{p}{2}-A_1-1}{m_0}$ arrangements of the bits of $Q_{1,1}$. If l is influenced by $Q_{0,1}$, there are $\binom{\frac{p}{2}-A_0-2}{m_0}$ arrangements of the bits of $Q_{0,0}$, $\binom{\frac{p}{2}-A_0-1}{m_1-1}$ ways the remaining bits of $Q_{0,1}$ can fall, $\binom{\frac{p}{2}-A_1-1}{m_1}$ arrangements of the bits of $Q_{1,0}$, and $\binom{\frac{p}{2}-A_1-1}{m_0}$ arrangements of the bits of $Q_{1,1}$. Similar estimates hold for $Q_{1,0}$, or $Q_{1,1}$.

We sum over the l locations considering each of the blocks of Q and their respective weights. Then the overall sum is

$$\begin{aligned}
&\sum_{j_0=0}^{p-1}\sum_{A_0=d_v-1}^{\frac{p}{2}}\binom{A_0-1}{d_v-2}\sum_{j_1=0}^{p-1}\sum_{A_1=d_v-1}^{\frac{p}{2}}\binom{A_1-1}{d_v-2}\\
&\cdot\sum_{l=0}^{p-1}\left(\binom{\frac{p}{2}-A_0-2}{m_0-1}\binom{\frac{p}{2}-A_0-1}{m_1}\binom{\frac{p}{2}-A_1-1}{m_1}\binom{\frac{p}{2}-A_1-1}{m_0}\right.\\
&+\binom{\frac{p}{2}-A_0-1}{m_0}\binom{\frac{p}{2}-A_0-2}{m_1-1}\binom{\frac{p}{2}-A_1-1}{m_1}\binom{\frac{p}{2}-A_1-1}{m_0}\\
&+\binom{\frac{p}{2}-A_0-1}{m_0}\binom{\frac{p}{2}-A_0-1}{m_1}\binom{\frac{p}{2}-A_1-2}{m_1-1}\binom{\frac{p}{2}-A_1-1}{m_0}\\
&\left.+\binom{\frac{p}{2}-A_0-1}{m_0}\binom{\frac{p}{2}-A_0-1}{m_1}\binom{\frac{p}{2}-A_1-1}{m_1}\binom{\frac{p}{2}-A_1-2}{m_0-1}\right)\\
&\cdot\left(1-O\left(\frac{m}{p}\right)\right).
\end{aligned} \tag{6}$$

Failure to impose full weight requirements on HQ introduces double-counting. This occurs when more than one block of Q influences l, though the probability of this event will not exceed $O(\frac{m}{p})$. The constant sums yield the factor of p^3. □

We can now estimate the percentage of these recovered, ultra-weak keys out of all possible keys.

Theorem 4.2. *Let $m = m_0 + m_1, x = \frac{A_0}{p}, y = \frac{A_1}{p}$. Out of $\binom{p}{d_v}^2\binom{p}{m_0}^2\binom{p}{m_1}^2$ possible keys, we estimate the percentage of ultra-weak keys found in a single iteration of the decoding algorithm above as*

$$d_v{}^2(d_v-1)^2 m\int_{x=0}^{\frac{1}{2}}\int_{y=0}^{\frac{1}{2}}(xy)^{d_v-2}\left(\left(\frac{1}{2}-x\right)\left(\frac{1}{2}-y\right)\right)^m\left(\frac{1}{\frac{1}{2}-x}+\frac{1}{\frac{1}{2}-y}\right)\mathrm{d}y\mathrm{d}x.$$

Proof. Note that the lines $2-5$ of (4) are approximately

$$\binom{\frac{p}{2}-A_0}{m_0}\binom{\frac{p}{2}-A_0}{m_1}\binom{\frac{p}{2}-A_1}{m_1}\binom{\frac{p}{2}-A_1}{m_0}\left(\frac{m_0+m_1}{\frac{p}{2}-A_1}+\frac{m_0+m_1}{\frac{p}{2}-A_0}\right). \tag{7}$$

For $b, c \in \{0, 1\}$,

$$\binom{\frac{p}{2}-A_b}{m_c}\approx\binom{p}{m_c}\left(\frac{1}{2}-\frac{A_b}{p}\right)^{m_c} \tag{8}$$

and

$$\binom{A_b-1}{d_v-2}\approx\binom{p}{d_v-2}\left(\frac{A_b}{p}\right)^{d_v-2} \tag{9}$$

since p is much larger than m_0, m_1, d_v. We rewrite (4) using the approximations of expressions (7,8) as

$$p^3 \sum_{A_0=d_v-1}^{\frac{p}{2}} \binom{A_0-1}{d_v-2} \sum_{A_1=d_v-1}^{\frac{p}{2}} \binom{A_1-1}{d_v-2} \binom{p}{m_0}^2 \left(\frac{1}{2}-\frac{A_0}{p}\right)^{m_0+m_1} \tag{10}$$

$$\binom{p}{m_1}^2 \left(\frac{1}{2}-\frac{A_1}{p}\right)^{m_0+m_1} \left(\frac{m_0+m_1}{\frac{p}{2}-A_1}+\frac{m_0+m_1}{\frac{p}{2}-A_0}\right). \tag{11}$$

Applying approximation (9) further reduces expression (10) to

$$\begin{aligned}
&p^3 \binom{p}{m_0}^2 \binom{p}{m_1}^2 \binom{p}{d_v-2}^2 \sum_{A_0=d_v-1}^{\frac{p}{2}} \left(\frac{A_0}{p}\right)^{d_v-2} \sum_{A_1=d_v-1}^{\frac{p}{2}} \left(\frac{A_1}{p}\right)^{d_v-2} \\
&\quad \left(\frac{1}{2}-\frac{A_0}{p}\right)^{m_0+m_1} \left(\frac{1}{2}-\frac{A_1}{p}\right)^{m_0+m_1} \left(\frac{m_0+m_1}{\frac{p}{2}-A_1}+\frac{m_0+m_1}{\frac{p}{2}-A_0}\right) \\
=&p^2 \binom{p}{d_v-2}^2 \binom{p}{m_0}^2 \binom{p}{m_1}^2 m \sum_{A_0=d_v-1}^{\frac{p}{2}} \sum_{A_1=d_v-1}^{\frac{p}{2}} \left(\frac{A_0}{p}\frac{A_1}{p}\right)^{d_v-2} \left(\frac{1}{2}-\frac{A_0}{p}\right)^{m} \\
&\quad \left(\frac{1}{2}-\frac{A_1}{p}\right)^{m} \left(\frac{1}{\frac{1}{2}-\frac{A_0}{p}}+\frac{1}{\frac{1}{2}-\frac{A_1}{p}}\right).
\end{aligned}$$

Letting $x=\frac{A_0}{p}, y=\frac{A_1}{p}$, this is approximated by

$$\begin{aligned}
&p^2 \binom{p}{d_v}^2 \binom{p}{m_0}^2 \binom{p}{m_1}^2 m \frac{{d_v}^2(d_v-1)^2}{(p-d_v+2)^2(p-d_v+1)^2} \\
&\cdot p^2 \int_{x=0}^{\frac{1}{2}} \int_{y=0}^{\frac{1}{2}} (xy)^{d_v-2} \left(\frac{1}{2}-x\right)^m \left(\frac{1}{2}-y\right)^m \left(\frac{1}{\frac{1}{2}-x}+\frac{1}{\frac{1}{2}-y}\right) \mathrm{d}y\mathrm{d}x.
\end{aligned}$$

Dividing by $\binom{p}{d_v}^2\binom{p}{m_0}^2\binom{p}{m_1}^2$, the result follows. □

Evaluating this percentage with the claimed-256-bit ephemeral (CPA-secure) key parameters of LEDAcrypt — $d_v = 11, m = 13$ — we determine that 1 in $2^{72.8}$ ephemeral keys are broken by one iteration of ISD. Similarly for the long-term (CCA-secure) key setting, we evaluate with the claimed 256-bit parameters — $d_v = 13, m = 13$ — and conclude the number of long-term keys broken is 1 in $2^{80.6}$.

This result merely determines the number of keys that can be recovered given that the information set of both blocks of M is chosen to be the last $\frac{p}{2}$ columns.[2] In the following, we turn to demonstrating a class of additional information sets that are as effective as this one.

[2] For the reader, we point out that if, hypothetically, we had a sufficiently large number of *totally independent* information sets that were equally "rewarding" in recovering keys, this would straightforwardly imply $\approx 2^{72.8}$-time and $\approx 2^{80.6}$-time "full" attacks against LEDAcrypt's claimed-256-bit parameters rather than weak-key attacks.

Remark 3. We remind the reader that instead of referring to the pairs of $\frac{p-1}{2}$, $\frac{p+1}{2}$ columns of blocks of M, we use $\frac{p}{2}$ in both cases. This has a negligible effect on our results.

4.3 Enumerating ultra-weak keys for all information sets

Now we will demonstrate a multi-iteration ISD attack that is effective against the class of all ultra-weak keys. To set up the discussion, we begin by highlighting two, further "degrees of freedom," which will allow us to find additional, relevant information sets to guess:

1. **Changing the ring representation:** Contiguity of indices depends on the choice of ring representation. The large family of ring isomorphisms on $\mathbb{Z}[x]/\langle x^p - 1\rangle$ given by $f(x) \to f(x^t)$ for $t \in [0, p]$ preserves Hamming weight. For example, we can use the family of polynomials

   $$H'_i = Q'_{i,j} = 1 + x^t + x^{2t} + ... + x^{\lfloor \frac{p}{4} \rfloor t}$$

   in this attack, since there exists one t such that H'_i has consecutive nonzero coefficients. Choices of $t \in \{1, \ldots, \frac{p-1}{2}\}$ yield independent information sets (noting that choices of t and $-t \mod p$ yield equivalent information sets).

2. **Changing the relative offset of the two consecutive blocks:** We can also change the beginning index of the consecutive blocks produced within L'_0 or L'_1 (by modifying the beginning indices of H'_i and $Q'_{i,j}$ to suit). Note that shifting both L'_0 and L'_1 by the same offset will recover equivalent keys. However, if we fix the beginning index of L'_0 and allow the beginning index of L'_1 to vary, we can find more, mostly independent information sets in order to recover more, distinct keys. The exact calculation of how far one should shift L'_1's indices for a practically effective attack is somewhat complex; we perform this analysis below in the remainder of this subsection.

Recall that in the prior 1-iteration attack, we considered *one* example class of ultra-weak keys – namely, those keys where the polynomials L_0 and L_1 are of degree at most $\frac{p}{2}$. Here, we will now take a broader view on the weakest-possible keys.

Definition 4.3. *We define the* **class of ultra-weak keys** *to be those where, in some ring representation, both* $H_0Q_{0,0} + H_1Q_{1,0}$ *and* $H_0Q_{0,1} + H_1Q_{1,1}$ *have nonzero coefficients that lie within a block of* $\frac{p-1}{2}$*-many consecutive (modulo p) degrees.*

Our goal will be now to find a multi-iteration ISD algorithm — by estimating how far to shift the offset of L'_1 per iteration — that recovers as much of the class of ultra-weak keys as possible without "overly wasting" the attacker's computational budget. Toward this end, recall that we have a good estimate in Theorem 4.2 of the fraction of keys ($2^{-72.8}$, resp. $2^{-80.6}$) recovered by the best-case, single iteration of our ISD algorithm. In what follows, we will first calculate the fraction of ultra-weak keys as a part of the total key space.

Let 2^{-X} be the fraction of all keys recovered by the best-case, single iteration of our previous ISD algorithm. Let 2^{-Y} be the fraction of ultra-weak keys among all keys. On the assumption that every ring representation leads to independent information sets (chosen uniformly for each invocation of ISD) and on the assumption that independence of ISD key-recovery is maximized by shifting "as far as possible," we will compute an estimate of the number of index-shifts that should be performed by the optimal ultra-weak-key attacker as $2^Z = 2^{X-Y}$. Beyond 2^Z shifts per guess (but not until), the attacker should begin to experience diminishing returns in how many keys are recovered per shifted guess.

Therefore, given an index beginning at 1 out of p positions, the attacker will shift by $\frac{p(\frac{p-1}{2})}{2^Z}$ indices at each invocation (where the factor $\frac{p-1}{2}$ accounts for the effect of the different possible ring representations). By assumption, each such guess will be sufficiently independent to recover as many keys in expectation as the initial, best-guess case described by the 1-iteration algorithm. We note that additional, ultra-weak keys will certainly be obtained by performing more work — specifically by shifting less than $\frac{p(\frac{p-1}{2})}{2^Z}$ per guess — but necessarily at a reduced rate of reward per guess.

Toward this end, we now calculate the number of ultra-weak keys then the fraction of ultra-weak keys among all keys following the format of the previous calculation.

Theorem 4.4. *The total number of ultra-weak keys is*

$$\frac{p-1}{2}p^2 \sum_{A_0=d_v-1}^{\frac{p}{2}} \sum_{A_1=d_v-1}^{\frac{p}{2}} \binom{A_0-1}{d_v-2}\binom{A_1-1}{d_v-2} \tag{12}$$

$$\cdot \sum_{l_0=0}^{p-1} \left(\binom{\frac{p}{2}-A_0-1}{m_0-1}\binom{\frac{p}{2}-A_1-1}{m_1} + \binom{\frac{p}{2}-A_0-1}{m_0}\binom{\frac{p}{2}-A_1-1}{m_1-1} \right) \tag{13}$$

$$\cdot \sum_{l_1=0}^{p-1} \left(\binom{\frac{p}{2}-A_0-1}{m_0}\binom{\frac{p}{2}-A_1-1}{m_1-1} + \binom{\frac{p}{2}-A_0-1}{m_0-1}\binom{\frac{p}{2}-A_1-1}{m_0} \right). \tag{14}$$

Proof. The proof technique follows as in Theorem 4.1. Details are found in [3], B.1. □

Theorem 4.5. *Let $m = m_0 + m_1, x = \frac{A_0}{p}, y = \frac{A_1}{p}$. The fraction of ultra-weak keys out of all possible keys is*

$$\frac{p-1}{2}{d_v}^2(d_v-1)^2 \int_{x=0}^{\frac{1}{2}} \int_{y=0}^{\frac{1}{2}} x^{d_v-2}y^{d_v-2}\left(\frac{1}{2}-x\right)^m\left(\frac{1}{2}-y\right)^m$$
$$\left(\frac{{m_0}^2+{m_1}^2}{(\frac{1}{2}-x)(\frac{1}{2}-y)} + \frac{m_0m_1}{(\frac{1}{2}-x)^2} + \frac{m_0m_1}{(\frac{1}{2}-y)^2}\right) \mathrm{d}y\mathrm{d}x.$$

Proof. Similar techniques apply. See [3], B.2 for details. □

We evaluate the fraction of weak keys using the claimed CPA-secure parameters $p = 36877, m = 13, d_v = 11$ and determine that 1 in $2^{54.1}$ ephemeral keys are broken. Evaluating with one of the CCA-secure parameter sets $p = 152267, m = 13, d_v = 13$, approximately 1 in $2^{59.7}$ long-term keys are broken.

Given the above, we can make an estimate as to the optimal shift-distance per ISD invocation as $\frac{36{,}877(\frac{36{,}876}{2})}{2^{72.8-54.1}} \approx 1597 \approx 2^{10.6}$ for the ephemeral key parameters and $\frac{152{,}267(\frac{152{,}266}{2})}{2^{80.6-59.7}} \approx 5925 \approx 2^{12.5}$ for the long-term key parameters.

The multi-iteration ISD algorithm against the class of ultra-weak keys, then, makes its first guess (except, one in each ring representation) as in the case of the 1-iteration ISD algorithm. It then shifts the relative offset of the two consecutive blocks by the values calculated above and repeats (again, in each ring representation).

This will not recover all ultra-weak keys, but it will recover a significant fraction of them. In particular, if the support of each block of L, rather than fitting in $\frac{p}{2}$ consecutive bits fits in blocks that are smaller by at least $\frac{1}{4}$ of the shift distance. We can therefore lower bound the fraction of recovered keys by replacing factors of $\frac{1}{2}$ with factors of $\frac{p}{2}$ minus half or a quarter of the offset, all divided by p, to find the sizes of sets of private keys of which we are guaranteed to recover all, or at least half of respectively.

The multi-iteration ISD algorithm attacking the ephemeral key parameters will make $2^{72.8-54.1} \approx 2^{18.7}$ independent guesses and recover at least 1 in $2^{56.0}$ of the total keys. The multi-iteration ISD algorithm attacking the long-term key parameters will make $2^{80.6-59.7} \approx 2^{20.9}$ independent guesses and recover at least 1 in $2^{61.6}$ of the total keys.

4.4 Estimating the effect of more advanced information-set decoding

Our attempts to enumerate all weak keys were based on the assumption that the adversary was using an ISD variant that required a row of L to be uniformly 0 on all columns of the information set. The state of the art in information set decoding still allows the adversary to decode provided that a row of L has weight no more than about 6 on the information set. For example, Stern's algorithm [28] with parameter 3 would attempt to find a low weight row of L as follows.

The information set is divided into two disjoint sets of $\frac{p}{2}$ columns. The first row of L to be recovered should have weight at most 3 within each of the two sets. Further, the same row of L should have have $\Omega(\log(p))$ many consecutive 0's in column-indices that are disjoint from those of the information set. If both of these conditions occur, then a matrix inversion is performed (even though 6 non-zero bits were contained in the information set).

Note that for reasonably large p, nearly a third of the sparse vectors having weight 6 in the information set will meet both conditions. The most expensive steps in the Stern's algorithm iteration are a matrix inversion of size p and a claw finding on functions with logarithmic cost in p and domain sizes of $\binom{\frac{p}{2}}{3}$. The claw finding step is similar in cost to the matrix inversion, both having computational cost $\approx p^3$. The matrix inversion step is present in all ISD algorithms. Therefore with Stern's algorithm we can recover in a single iteration with similar cost to a single iteration of a simpler ISD algorithm, $O(1)$ of the private keys where a row of L has weight no more than 6 on the information set columns.

Recall that we choose the information set to be of size $\approx \frac{p}{2}$ in L'. The distribution of the non-zero coordinates within a successful guess of information set will be more heavily weighted toward the middle of the set and approximately triangular shaped (since these coordinates are produced by convolutions of polynomials). In particular, we will *heuristically* model both of the tails of the distribution as small triangles containing 3 bits on the left side and three bits on the right that are missed by the choice of information set.

Let $W = 2d_v(m_0 + m_1)$ denote the number of non-zero bits in L'. Then the actual fraction ϵ that the information set (in the context of advanced information set decoding) should target within L, rather than $1/2$, can be estimated by geometric area as

$$\epsilon \cdot \left(1 - \sqrt{\frac{3}{W/2}}\right) = \frac{1}{2}$$

or, re-writing:

$$\epsilon = \frac{1}{2\left(1 - \sqrt{\frac{3}{W/2}}\right)}.$$

For the claimed-256-bit ephemeral key parameters, we have $W_{\mathsf{CPA}} = 286$. For the claimed-256-bit long-term key parameters, we have $W_{\mathsf{CCA}} = 338$. Therefore,

$$\epsilon_{\mathsf{CPA}} = \frac{1}{2\left(1 - \sqrt{\frac{3}{286/2}}\right)} \approx 0.585.$$

$$\epsilon_{\mathsf{CCA}} = \frac{1}{2\left(1 - \sqrt{\frac{3}{338/2}}\right)} \approx 0.577.$$

So – heuristically – we can model the effect of using advanced information set decoding algorithms by replacing the $\frac{1}{2}$'s in the calculations of the theorems earlier in this section by ϵ_{CPA} or ϵ_{CCA} respectively.

4.5 Rejection sampling considerations

We recall that LEDACrypt's KeyGen algorithm explicitly requires that the parity check matrix L be *full weight*. Intuitively full weight means that no cancellations occur in the additions or the multiplications that are used to generate L from H and Q. Formally, the full weight condition on L can be stated as:

$$\forall i \in \{0, \ldots, n_0 - 1\},\ \ \mathsf{weight}(L_i) = d_v \sum_{j=0}^{n_0-1} m_j.$$

When a weak key notion causes rejections to occur significantly more often for weak keys than non-weak keys, we will effectively reduce the probability of weak key generation compared to our previous analysis. As an extreme example, if, for a given weak key notion, rejection sampling rejects all weak keys, then no weak keys will ever be sampled. We therefore seek to measure the probability of key rejection for both weak keys and keys in general in order to determine whether the effectiveness of this attack is reduced via rejection sampling.

Let $\mathcal{K}$, $\mathcal{W} \subset \mathcal{K}$, and KeyGen be the public key space, the weak key space, and the key generation algorithm of LEDACrypt, respectively. Let $\mathcal{K}'$, $\mathcal{W}' \subset \mathcal{K}'$, and $\mathsf{KeyGen'}$ be the associated objects if rejection sampling were omitted from LEDACrypt. We observe that since KeyGen samples uniformly from $\mathcal{K}$,

$$\Pr\left[pk \in \mathcal{W} | (pk, sk) \leftarrow \mathsf{KeyGen}()\right] = \frac{|\mathcal{W}|}{|\mathcal{K}|}.$$

This equality additionally holds when rejection sampling does not occur. Since, until now, all of our analysis has ignored rejection sampling we have effectively been measuring $|\mathcal{W}'|/|\mathcal{K}'|$. We therefore seek to find a relation that allows us determine $|\mathcal{W}|/|\mathcal{K}|$ from $|\mathcal{K}'|$ and $\mathcal{W}'|$. We observe that

$$\frac{|\mathcal{W}|}{|\mathcal{K}|} = \frac{|\mathcal{W}|}{|\mathcal{K}|}\frac{|\mathcal{W}'|}{|\mathcal{W}'|}\frac{|\mathcal{K}'|}{|\mathcal{K}'|} = \frac{|\mathcal{W}'|}{|\mathcal{K}'|}\frac{|\mathcal{W}|}{|\mathcal{W}'|}\frac{|\mathcal{K}'|}{|\mathcal{K}|}.$$

Therefore it holds that the probability of generating a weak key when we consider rejection sampling for the first time in our analysis changes by exactly a factor of $(|\mathcal{W}|/|\mathcal{W}'|) \cdot (|\mathcal{K}'|/|\mathcal{K}|)$. This is precisely the probability that a weak key will not be rejected due to weight concerns divided by the probability that key will not be rejected due to weight concerns.

We note that as long as the rejection probabilities for both keys and weak keys is not especially close to 0 or 1, then it is sufficient to sample many keys according to their distributions and observe the portion of these keys that would be rejected.

In order to practically measure the security gained by rejection sampling for the 1-iteration ISD attack against the ephemeral key parameters, we sample 10,000 keys according to $\mathsf{KeyGen'}$ and we sample 10,000 weak keys according to $\mathsf{KeyGen'}$ and we observe how many of them are rejected. We observe that approximately 39.2% of regular keys are rejected while approximately 67.4% of weak keys are rejected. We therefore conclude for this attack and this parameter set, $\frac{|\mathcal{W}|}{|\mathcal{K}|} = 0.582\frac{|\mathcal{W}'|}{|\mathcal{K}'|}$. Therefore, rejection sampling grants less than 1 additional bit of security back to LEDACrypt.

This attack analysis can be efficiently reproduced for additional parameter sets and alternative notions of weak key with the same result.

4.6 Putting it all together

Finally, we re-calculate the results of Section 4.2 using Theorems 4.2 and 4.5, but accounting for the attack improvement of using advanced information set decoding from Section 4.4 and accounting for the security improvement due to rejection sampling issues in Section 4.5. We re-write the formulas with the substitutions of ϵ_{CPA} (resp. ϵ_{CPA}) for the constant $\frac{1}{2}$ for the reader, and note that the definition of ultra-weak keys has been implicitly modified to have more liberal degree constraints to suit the advanced ISD subroutine being used now.

Let x, y, m be defined as in Theorem 4.5. For the case of claimed-256-bit security for ephemeral key parameters, the fraction of ultra-weak keys recovered by a single iteration of the advanced ISD algorithm is

$$d_v{}^2(d_v-1)^2 m \int_{x=0}^{\epsilon}\int_{y=0}^{\epsilon} (xy)^{d_v-2}\left((\epsilon-x)(\epsilon-y)\right)^m \left(\frac{1}{\epsilon-x}+\frac{1}{\epsilon-y}\right) \mathrm{d}y\mathrm{d}x,$$

and the fraction of these ultra-weak keys out of all possible keys is

$$(\epsilon p)d_v{}^2(d_v-1)^2 \int_{x=0}^{\epsilon}\int_{y=0}^{\epsilon} x^{d_v-2}y^{d_v-2}(\epsilon-x)^m(\epsilon-y)^m \left(\frac{m_0{}^2+m_1{}^2}{(\epsilon-x)(\epsilon-y)}+\frac{m_0m_1}{(\epsilon-x)^2}+\frac{m_0m_1}{(\epsilon-y)^2}\right)\mathrm{d}y\mathrm{d}x.$$

Evaluating these formulae with ephemeral key parameters $d_v = 11, m_0 = 7, m_1 = 6, p = 36,877$ and substituting $\epsilon_{\mathsf{CPA}} = .585$ yields 1 key recovered in $2^{62.62}$ per single iteration, and 1 ultra-weak key in $2^{43.90}$ of all possible keys. This yields an algorithm making $2^{62.62-43.90} = 2^{18.72}$ guesses and recovering 1 in $2^{47.72}$ of the ephemeral keys (accounting for the loss due to rejection sampling and the limited number of iterations).

Substituting $\epsilon_{\mathsf{CCA}} = .577$ similarly and evaluating with long-term key parameters $d_v = 13, m_0 = 7, m_1 = 6, p = 152,267$ yields 1 key recovered in $2^{70.45}$ per single iteration and 1 ultra-weak key in $2^{49.55}$ of all possible keys. This yields an algorithm making $2^{70.45-49.55} = 2^{20.90}$ guesses and recovering 1 in $2^{52.54}$ of the long-term keys (accounting for the loss due to rejection sampling and the limited number of iterations).

To conclude, we would like to compare this result against the claimed security level of NIST Category 5. Formally, these schemes should be as hard to break as breaking 256-bit AES. Each guess in the ISD algorithms leads to a cost of approximately p^3 bit operations (due to linear algebra and claw finding operations combined). This is $2^{45.5}$ bit operations for the ephemeral key parameters and $2^{51.6}$ bit operations for the long-term key parameters. A single AES-256 operation costs approximately 2^{15} bit operations. This yields the main result of this section.

Theorem 4.6 (Main). *There is an advanced information set decoding algorithm that costs the same as $2^{49.22}$ AES-256 operations and recovers 1 in $2^{47.72}$ of LEDAcrypt's Category 5 ephemeral keys.*

Similarly, there is an advanced information set decoding algorithm that costs the same as $2^{57.50}$ AES-256 operations and recovers 1 in $2^{52.54}$ of LEDAcrypt's Category 5 long-term keys.

Remark 4. Note that $49.22+47.72 = 96.94 \ll 256$, $57.50+52.54 = 110.03 \ll 256$.

Remark 5. Finally, we recall that we used various heuristics to approximate the above numbers, concretely. However, these simplifying choices can only affect at most one or two bits of security compared to a fully formalized calculation (which would come at the expense of making the analysis significantly more burdensome to parse for the reader).

5 Attack on All Keys

To conclude, we briefly analyze the asymptotic complexity of our new attack strategy in the context of recovering keys in the average case. We first note that, assuming the LEDAcrypt approach is parameterized in a balanced way – that is, H and Q are similarly sparse, and further assuming that n_0 is a constant – the ordinary ISD attack (with a randomly chosen information set) has a complexity of $\exp(\tilde{O}(p^{\frac{1}{2}}))$. To see this, observe that all known ISD variants using a random information set to find an asymptotically sparse secret parity check matrix constructed like the LEDAcrypt private key, have complexity $O\left(\frac{n_0}{n_0-1}\right)^w$, where $w = n_0 d_v m$ is the row weight of the secret parity check matrix. Efficient decoding requires $w = O(p^{\frac{1}{2}})$. By inspection this complexity is $\exp(\tilde{O}(p^{\frac{1}{2}}))$

However, we obtain an improved asymptotic complexity when using structured information sets as follows.

Theorem 5.1. *The asymptotic complexity of ISD using an appropriate choice of structured information sets, when attacking* all *LEDAcrypt keys in the worst case, is* $\exp(\tilde{O}(p^{\frac{1}{4}}))$.

Proof. We analyze the situation with structured information sets. Imagine we are selecting the nonzero coefficients of H' and Q' completely at random, aside from a sparsity constraint. The sparsity constraint needs to be set in such a way that the row weight of the product $H'Q'$ (restricted to two cyclic blocks) has row weight no more than p. This further constrains the row weight of each cyclic block of H' and Q' to be approximately $\left(\frac{p\ln(2)}{n_0}\right)^{\frac{1}{2}} = O(p^{\frac{1}{2}})$. The probability of success per iteration is then at least $O\left(\left(\frac{\ln(2)}{pn_0}\right)^{\frac{1}{2}\cdot(\sum_{i=0}^{n_0-1} m_i+n_0d_v)}\right)$. With balanced parameters, d_v and the m_i are $O(p^{\frac{1}{4}})$, thus the total complexity is indeed $\exp(\tilde{O}(p^{\frac{1}{4}}))$. Note that when H' and Q' are random aside from the sparsity constraint, the probability that the supports of H' and Q' contain the supports of H and Q respectively does not depend on H and Q, so the structured ISD algorithm is asymptotically better than the unstructured ISD algorithm, even when we ignore weak keys. □

Remark 6. The fact that there exists an asymptotically better attack than standard information set decoding against keys structured like those of LEDAcrypt is not itself particularly surprising. Indeed, the very simple attack that proceeds by enumerating all the possible values of H and Q is also asymptotically

$\exp(\tilde{O}(p^{\frac{1}{4}}))$. However, this simple attack does not affect the concrete parameters presented in the Round 2 submission of LEDAcrypt.

In contrast, we strongly suspect, but have not rigorously proven, that our attack significantly improves on the complexity of standard information set decoding against typical keys randomly chosen for some of the submitted parameter sets of LEDAcrypt. In particular, our estimates suggest that the NIST category 5 parameters with $n_0 = 2$ can be attacked with an appropriately chosen distribution for H' and Q' (e.g. with each polynomial block of H' and Q' chosen to have 5 or 6 consecutive chunks of nonzero coefficients in some ring representation) and that typical keys will be broken at least a few hundred times faster than with ordinary information set decoding.

If it were the case that we were attacking an "analogously-chosen" parameter set for LEDAcrypt targeting higher security levels (512-bit security, 1024-bit security, and so on), we believe a much larger computational advantage would be obtained and (importantly) be very easy to rigorously demonstrate.

6 Conclusion

In this work, we demonstrated a novel, real-world attack against LEDAcrypt – one of 17 remaining 2nd Round candidates for standardization in NIST's Post-Quantum Cryptography competition. The attack involved a customized form of Information Set Decoding, which carefully guesses the information set in a non-uniform manner so as to exploit the unique product structure of the keys in LEDAcrypt's design. The attack was most effective against classes of weak keys in the proposed parameter sets asserted to have 256-bit security (demonstrating a trade-off between computational time and fraction of the key space recovered that was better than expected even of a 128-bit secure cryptosystem), but the attack also substantially reduced security of all parameter sets similarly.

Moreover, we demonstrated that these type of weak keys are present throughout the key space of LEDAcrypt, so that simple "patches" such as rejection sampling cannot repair the problem. This was done by demonstrating a continuum of progressively larger classes of less weak keys and by showing that the same style of attack reduces the average-case complexity of certain parameter sets.

Acknowledgements. We thank Corbin McNeill for his contributions to our analysis of rejection sampling on the weak key attack. We also thank the anonymous reviewers for very thorough editorial feedback. This work is funded in part by NSF grant award number 1906360.

***Abstract*—A co-simulation may comprise several heterogeneous federates with diverse spatial and temporal execution characteristics. In an iterative time-stepped simulation, a federation exhibits the Bulk Synchronous Parallel (BSP) computation paradigm in which all federates perform local operations and synchronize with their peers before proceeding to the next round of computation. In this context, the lowest performing (i.e., slowest) federate dictates the progression of the federation logical time. One challenge in co-simulation is performance profiling for individual federates and entire federations. The computational resource assignment to the federates can have a large impact on federation performance. Furthermore, a federation may comprise federates located on different physical machines as is the case for cloud and edge computing environments. As such, distributed profiling and resource assignment to the federation is a major challenge for operationalizing the co-simulation execution at scale. This paper presents the Execution Performance Profiling and Optimization (EXPPO) methodology, which addresses these challenges by using execution performance profiling at each simulation execution step and for every federate in a federation. EXPPO uses profiling to learn performance models for each federate, and uses these models in its federation resource recommendation tool to solve an optimization problem that improves the execution performance of the co-simulation. Using an experimental testbed, the efficacy of EXPPO is validated to show the benefits of performance profiling and resource assignment in improving the execution runtimes of co-simulations while also minimizing the execution cost.**

I. Introduction

Cyber-physical systems (CPS) such as smart city, smart manufacturing, and transactive energy systems must make time-sensitive control decisions to ensure their safe operations. However, such CPS are an amalgamation of multiple dynamic systems such as transportation systems, vehicle dynamics, control systems, and power systems with different interconnected networks of different scales and properties. The assurance that such complex systems are safe and trustworthy requires simulation capabilities that can rapidly integrate tools from multiple domains in different configurations. Co-simulation is an attractive option for interlinking such multiple simulators to simulate higher-level, complex system behaviors.

The IEEE 1516-2010 High Level Architecture (HLA) defines the standardized set of services offered to a process in a distributed co-simulation [1]. A co-simulation in HLA comprises individual simulators called federates that are grouped into a logical entity called a federation. Each federate can have diverse computation and networking resource requirements, which must be considered when assigning resources to the simulators when the federation is deployed to cloud-fog-edge computation environments. The wall-clock execution time required for each federate's computation step varies based on this resource allocation. The variation in execution times can result in some federates waiting on others before they can proceed to the next stage of computation. Federates that require more wall-clock time for their computation steps (the low performing federates) increase the overall completion time (or *makespan*) of the entire simulation. This can potentially violate the simulation completion deadline. Thus, resource allocation and resource configuration selections are very important for the overall performance of distributed simulations.

Although co-simulations have traditionally been hosted in high-performance computing (HPC) clusters, there has been an increasing trend towards the adoption of cloud computing for simulation jobs. It is in this context that the Docker container run-time platform [2] provides a solution for running federates across different computation platforms by providing a unified packaging of simulation code with its software dependencies. But recent research [3] has shown that there are operational challenges, such as performance aware resource assignments, that need to be considered for running simulations in cloud environments. Furthermore, there are several infrastructure-related complexities that must be considered to run these distributed simulations in a cloud environment.

This work presents a performance profiling, simulation run-time optimization and resource configuration platform called EXPPO - (***EX**ecution **P**erformance **P**rofiling and **O**ptimization*). EXPPO uses distributed tracing [4] to assess federate level performance for each computational step. These performance characteristics are used at runtime to determine whether changes to the resource allocation of the federation

Barve, Yogesh; Neema, Himanshu; Kang, Zhuangwei; Sun, Hongyang; Gokhale, Aniruddha; Roth, Thomas. "EXPPO: EXecution Performance Profiling and Optimization for CPS Co-simulation-as-a-Service." Paper presented at the 23rd International Symposium on Real-Time Distributed Computing, Nashville, TN, US. May 19, 2020 - May 21, 2020.

could enable shorter makespan for the simulation run. To enable distributed tracing, EXPPO utilizes the *opentracing* [5] specification for measuring the wall-clock time spent in each computational step of the simulation. To shield the developers from complexities when embedding tracing code in the simulation application logic, EXPPO leverages generative aspect of Model Driven Engineering (MDE) to auto-generate source-code snippets and configuration files for the simulation run. To provide resource recommendations for the individual federates, EXPPO uses the tracing information to build a resource-performance model and solves an optimization problem to find the resource allocation with the lowest makespan and cost for the co-simulation.

The main contributions of EXPPO are:

1) Demonstration that the default resource configuration for a federation has scenarios where a federate with a longer wall-clock execution time for its computational step increases the makespan of the co-simulation;
2) Development of an approach to generate tracing probes inside the source code of the simulation logic, which is required to perform distributed simulation profiling;
3) Development of a new resource recommendation engine which uses an optimization algorithm for finding the resource configuration for a federation that minimizes its overall makespan and cost; and
4) Validation of EXPPO showing its benefits on the performance of distributed simulation execution.

The rest of the paper is organized as follows. Section II provides a motivating use-case for EXPPO and lists its key requirements. Section III provides an overview of the EXPPO framework. Section IV describes the key EXPPO components and its resource configuration and optimization algorithms. EXPPO 's cloud architecture and co-simulation framework are described in Section V. The experiment evaluation results are described in Section VI, related works are described in Section VII and Section VIII concludes the paper.

II. Motivation and Solution Requirements

The computation pattern of many time-stepped co-simulations follows the Bulk Synchronous Parallel (BSP) model [6]. In this model, every participating simulation completes its computation for a given time step, waits for the other participating simulations to complete their computations, exchanges new state information with its peers, and only then proceeds to the next time step. Thus, if one simulation takes more time to execute, the other simulations are forced to wait for it and remain idle. This is illustrated in Figure 1 which shows an HLA federation with three federates. Each federate executes one computation task repeated each time step. Federate 1 takes the longest to execute, and the other two federates are waiting for Federate 1 to complete before moving to the next computation step. This increases the makespan of the entire simulation, thereby decreasing the performance of the simulation execution.

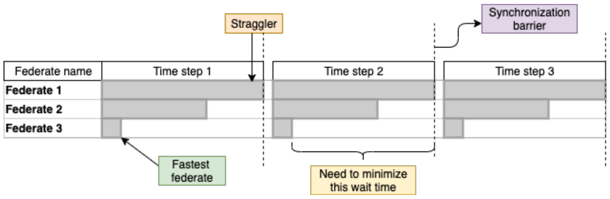

Fig. 1: Performance visualization of an example federation.

Recently, co-simulations have been deployed using container management solutions [7] [8], such as Docker Swarm [9], Kubernetes [10], Mesos [11]. However, these solutions use queue-based scheduling, wherein the containers are allocated to machines one at a time. Hence, there could be instances where there may not be enough resources available in the cluster to schedule all the federates of the federation. However, a few federates may still get deployed while the remaining federates are stuck in the scheduler queue until more resources are available. This will cause the entire simulation to stall, since all the federates are required to participate in the simulation to progress. For instance, from Figure 1, if there are resources to deploy Federate 1 and Federate 3, and not sufficient resources to deploy Federate 2, the job scheduler should not deploy any federates and should wait until more resources are available. Hence, there is a need for bag-of-tasks scheduling mechanism for deploying these federates on the cloud computing environments.

The resource configuration also plays an important role in the execution time of the federates. Figure 2(a) depicts the performance of a federate when assigned different numbers of cores for executing a computation step. This federate is running a Freqmine application from the Princeton Application Repository for Shared-Memory Computers (PARSEC) benchmark [12] as its computation task. This figure shows that the execution time generally decreases with the increasing amount of resources assigned to the federate. Thus, there is a potential for minimizing the wait time by appropriately configuring the resources assigned to the federates. Minimizing the wait time can be done either by providing the highest resource configuration for all the federates, or finding a resource configuration that considers the cost of assigning the resources to the federates. However, deciding what resource configuration to select for a given computation is a non-trivial task for a simulation developer who may not have the domain expertise of configuring and running applications in cloud computing environments. Performance profiling of the federates can help in understanding the relation between the resource assignment and the execution performance. However, these simulations might be deployed across different physical and/or virtual host environments when running in cloud computing platforms; performance profiling for such distributed simulations can be very challenging.

Building on the above use-case, below are the four key requirements EXPPO aims to satisfy:

- **Requirement R1.** *Conduct distributed performance tracing of the federates:* To understand the bottlenecks in federation performance, there is a need for logging and

Barve, Yogesh; Neema, Himanshu; Kang, Zhuangwei; Sun, Hongyang; Gokhale, Aniruddha; Roth, Thomas. "EXPPO: EXecution Performance Profiling and Optimization for CPS Co-simulation-as-a-Service." Paper presented at the 23rd International Symposium on Real-Time Distributed Computing, Nashville, TN, US. May 19, 2020 - May 21, 2020.

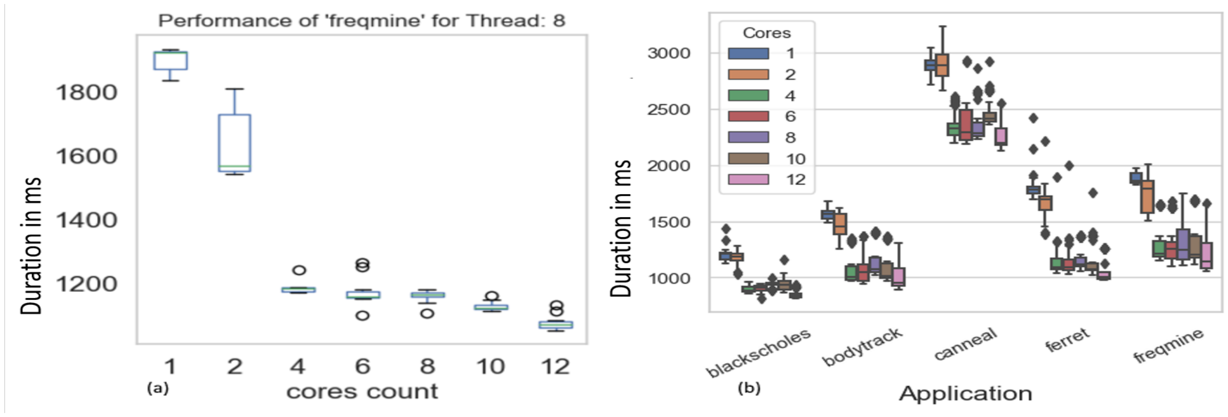

Fig. 2: (a) Performance of the federate running the PARSEC Freqmine application using 8 threads for different resource configuration selections. (b) Performance of five PARSEC benchmark applications for different resource configuration selections.

gathering execution performance traces of the federates. The tracing infrastructure needs to handle federates which are distributed across multiple physical hosts. Hence, the tracing infrastructure should be able to correlate traces from different federates of a federation.

- **Requirement R2.** *Reduce complexity in provisioning software probes:* Requiring the developer to manually write source code for performance tracing for the federation can result in complexities and errors which need to be minimized. The developer needs to understand the tracing software and write code which adheres to the tracing software requirements. This is tedious for the developer, who now apart from writing the simulation logic must also setup and configure the tracing infrastructure. EXPPO should reduce the manual configuration of the tracing information, thereby reducing repeated effort by the developer.
- **Requirement R3.** *Recommend resource configuration to minimize the co-simulation makespan and cost:* It can be challenging for an end user to determine the resource requirements for a federation because each federate can be configured differently. A bad resource configuration can have inadvertent effect on the completion time of the simulation. However, the choice of resource configuration also has an associated cost. Hence, the configuration must be chosen such that it satisfies both quality of service (QoS) and cost factors.
- **Requirement R4.** *Provide a gang-scheduling algorithm for executing simulations:* The runtime platform should support deployment of multiple federate using bag-of-tasks scheduling (or gang scheduling) algorithm.

III. Overview of EXPPO

Figure 3(a) shows the workflow and components of EXPPO. The *design phase* requires the developer to model the federation using the federation development toolkit. This toolkit is based on the Web-based Generic Modeling Environment (WebGME) [13]. To measure the execution time of a federate in a time step, the simulator needs to embed a tracing code initializer and logger to record the execution time completion of the computation step. The tracing initialization code and the tracer configuration files are auto-generated by the custom WebGME model interpreters. Once the required code is generated and the user has implemented the necessary simulation logic, the federate is compiled into an executable image, which is then packaged inside a Docker container.

During the *profiling phase*, each federate is executed and profiled under different resource configurations. The execution time for each federate is logged using the tracing information, and this tracing information is stored in a centralized database. The resource configuration tuner uses the recorded logs together with user provided objectives to optimize the resource configuration for each federate. Finally, the optimized resource configuration is used to configure the co-simulation deployment accordingly.

During the *runtime phase*, the simulation job information for the federates in the co-simulation is submitted to the deployment manager. The job information includes the name of the federate Docker image, resource configuration requirements, etc. The deployment manager submits the scheduling information to the job scheduler, which handles the execution of the jobs on the co-simulation runtime execution platform.

IV. Design Elements of EXPPO

EXPPO allows users to design and deploy co-simulations on distributed compute infrastructures supported by Docker-based virtualization. Its generative capabilities simplify the auto-generation of performance monitoring instrumentation, configuration and probing for the different federates. Its resource configuration tuner optimizes resource allocations to federates to lower the makespan and execution cost for the federation execution. Its runtime platform supports parallel execution of different federations on its shared compute infrastructure. This section details each of the EXPPO components.

```

Fig. 3: (a) Workflow of EXPPO illustrating the connections between different components of the system. (b) Profiling code snippet in Java language generated leveraging the MDE techniques.

A. *Performance Profiling of Federates*

Understanding the performance characteristics of the co-simulation execution is of paramount importance when deciding how to run federates in runtime execution environments. Individual federates have different resource needs, and their execution performance will vary depending on how the resources are assigned. Thus, understanding the performance profiles of each federate is critical to the problem of optimizing the resource allocation and thereby lowering the makespan and execution cost of the federation execution. EXPPO leverages distributed tracing to assist in the logging of time stamps of distributed events generated in the federation (Requirement **R1**). It leverages Opentracing instrumentation [5] to track execution time spent during each computation time step of the federate. The execution time is then logged into a timeseries database for conducting performance analysis. It leverages MDE technologies [14] such as Domain Specific Modeling Language (DSML), code generators and model interpreters to synthesize performance profiling software artifacts which can be used for performance profiling of federates (Requirement **R2**). An example code snippet is shown in Figure 3(b).

B. *Federation Resource Configuration Optimization*

When running a federate in a Docker container, cloud providers usually have multiple resource configurations from which the user can select for their application. However, without analyzing the resource dependency of the application, it may be challenging for the user to select the resource configuration that meets the application's quality of service (QoS) requirement while at the same time minimizing the execution cost in terms of the cost of resources utilized. Figure 2(b) shows how the different resource configuration impacts the execution time of the federate which is running applications from the PARSEC benchmark. Furthermore, in a co-simulation, the resource selection becomes critical as every federate's execution time will contribute to the co-simulation's performance. To address this issue (Requirement **R3**), EXPPO provides a resource configuration recommendation system that selects the resource assignment which optimizes the application's QoS performance and user's budget requirements.

Consider the following optimization problem: Suppose the system has a set of homogeneous machines, each with k processing cores. Let $F = \{f_1, f_2, \ldots, f_n\}$ denote a federation (co-simulation) that consists of a set of n federates. Given a resource assignment $R = [r_1, r_2, \ldots, r_n]$ to each federate, the execution time of federate $f_j \in F$ can be expressed as $t_j(r_j)$ when assigned r_j cores. For performance reasons, assume a federate cannot be split among two or more machines, so we have $1 \leq r_j \leq k$. The makespan M for every computation step for the entire federation F is dictated by the slowest running federate (i.e., the straggler), and is defined as $M = \max_j t_j(r_j)$. The execution cost C is given by the total resource used by all the federates over the makespan duration. Since the cores will be reserved for the federation until the slowest federate is done executing, the cost is defined as $C = M \cdot \sum_j r_j$. The resource configuration recommender needs to find a resource assignment R^* that minimizes $G = \alpha M + \beta C = M(\alpha + \beta \sum_j r_j)$, where α and β denote the user-defined weights to the application's QoS and the execution cost, respectively.

Two additional assumptions are made to solve this optimization problem: (1) federate execution time does not increase with the amount of resources (number of cores) assigned, i.e., $r_j \leq r'_j$ implies $t_j(r_j) \geq t_j(r'_j)$; (2) federate execution cost does not decrease with the amount of resources assigned, i.e., $r_j \leq r'_j$ implies $c_j(r_j) \leq c_j(r'_j)$, where $c_j(r) = r \cdot t_j(r)$. These are realistic assumptions as many practical applications have *monotonically increasing and sublinear* speedup functions [15], [16], such as those that follow Amdahl's law [17]. As such, the optimization problem can be solved by examining all possible makespan values while guaranteeing the minimum cost. Algorithm 1 presents the pseudocode of this solution with a time complexity of $O(n \log n)$ by maintaining a priority queue for all jobs. Similar approaches can be applied to

Algorithm 1: Resource Configuration Tuner

```
Input  : Execution time $t_j(r)$ for each federate $f_j$ in
         federation $F$ when allocated different amounts of
         resources $r$, where $1 \le r \le k$.
Output: A resource assignment $R^* = [r_1, r_2, \dots, r_n]$ for
         each federate in the federation that minimizes a
         linear combination of makespan and cost.
Initialize $r_j \leftarrow 1$ for all $1 \le j \le n$;
Compute $G \leftarrow (\max_j t_j(r_j)) \cdot (\alpha + \beta \sum_j r_j)$;
$R^* \leftarrow [r_1, r_2, \dots, r_n]$ and $G^* \leftarrow G$;
while $\sum_j r_j < nk$ do
    $j \leftarrow$ Index of a federate with longest execution time;
    if $r_j = k$ then
        break;
    else
        Increment $r_j$ to the next higher profiled resource
         amount;
        Update $G \leftarrow (\max_j t_j(r_j)) \cdot (\alpha + \beta \sum_j r_j)$;
        if $G < G^*$ then
            $R^* \leftarrow [r_1, r_2, \dots, r_n]$ and $G^* \leftarrow G$;
```

find the minimum makespan subject to a cost budget or the minimum cost for a target makespan.

C. Federation Machine Scheduling Heuristics

A custom scheduler is required to deploy all the federates in the federation to their respective distributed computing environments. Since the federates cannot run independently of the federation, the scheduling scheme must simultaneously run all of the federates of the federation (Requirement **R4**). This is referred to as *Gang scheduling* or *Bag-of-tasks scheduling* in the literature. To achieve this, EXPPO supports two heuristics to simultaneously schedule the federates on a fixed number m of available machines while utilizing the resource configuration results obtained from Section IV-B. These approaches handle the case where some of the machines are loaded with other compute tasks unrelated to the federation.

The first heuristic is inspired by the First-Fit Decreasing (FFD) algorithm for bin packing and is described in Algorithm 2. The heuristic first sorts all the federates in decreasing order of resource assignment and then tentatively allocates each one of them in order onto the first available machine. If all federates in the federation can be successfully allocated, then the schedule is finalized; otherwise, the entire federation will be temporarily put in a waiting queue to be scheduled later. The time complexity of the heuristic is $O(n(\log n + m))$. The other heuristic is based on the Best-Fit Decreasing (BFD) algorithm that works similarly to FFD, except that it finds, for each federate, a best-fitting machine (i.e., with the least remaining resource after hosting the federate). Note that since finding the optimal schedule (or bin packing) is an NP-complete problem, these heuristics may not always find a feasible allocation for a federation even if one exists. However, once an allocation has been found, it is guaranteed to produce the optimal makespan and cost for the federation by using the resource configuration from Section IV-B.

Algorithm 2: First Fit Decreasing (FFD)

```
Input  : Resource assignment $R = [r_1, r_2, ..., r_n]$ for all
         federates in a federation. Current available
         resource $A = [a_1, a_2, ..., a_m]$ of all $m$ machines
         in the system.
Output: Machine allocation $L = [\ell_1, \ell_2, \dots, \ell_n]$ of all
         federates in the system.
Sort all resource assignments in decreasing order, i.e.,
  $r_1 \ge r_2 \ge \cdots \ge r_n$;
Initialize $\ell_j \leftarrow 0, \ \forall 1 \le j \le n$;
for $j = 1, 2, \dots, n$ do
    $fit \leftarrow false$;
    for $i = 1, 2, \dots, m$ do
        if $r_j \le a_i$ then
            Update $a_i \leftarrow a_i - r_j$;
            Set $\ell_j \leftarrow i$;
            $fit \leftarrow true$;
            break;
    if $fit = false$ then
        // revert allocations done so far
        for $k = 1, 2, \dots, j-1$ do
            $i \leftarrow \ell_k$;
            $a_i \leftarrow a_i + r_k$;
            $\ell_k \leftarrow 0$;
        break;
```

V. Co-simulation as a Service Middleware

Figure 4 shows the different components and workflow of the EXPPO co-simulation framework. It is called the Co-simulation-as-a-Service (CaaS) middleware because it enables users to automatically deploy groups of service-based applications to a cloud environment without any concern of resource allocation, application lifecycle monitoring, and cluster management. The functionality of each component is described below.

In ①, the FrontEnd component allows a user to submit a simulation job descriptor in JavaScript Object Notation (JSON) using a Representational State Transfer (REST) Application Programming Interface (API). Each simulation job contains a list of federates, and each federate is run on an individual Docker container. The simulation job descriptor also includes meta-information for each federate, for example, resources required, running status, container image details, etc. The FrontEnd creates a record in a database ④ for each incoming job, then relays the job identifier to JobManager ② which handles resource management. Instead of deploying jobs immediately, the JobManager stores received jobs in a local queue and consults the database about the latest status of cluster resources. It then periodically transfers the information of pending jobs and available resources to JobScheduler ③, which is a pluggable component that implements multiple scheduling algorithms. The JobScheduler either replies with a scheduling decision if the submitted jobs are deployable, or returns a KeepWaiting signal to notify the JobManager that resources are insufficient. The JobManager then forwards deployable jobs to GlobalManager ⑤, synchronizes job status

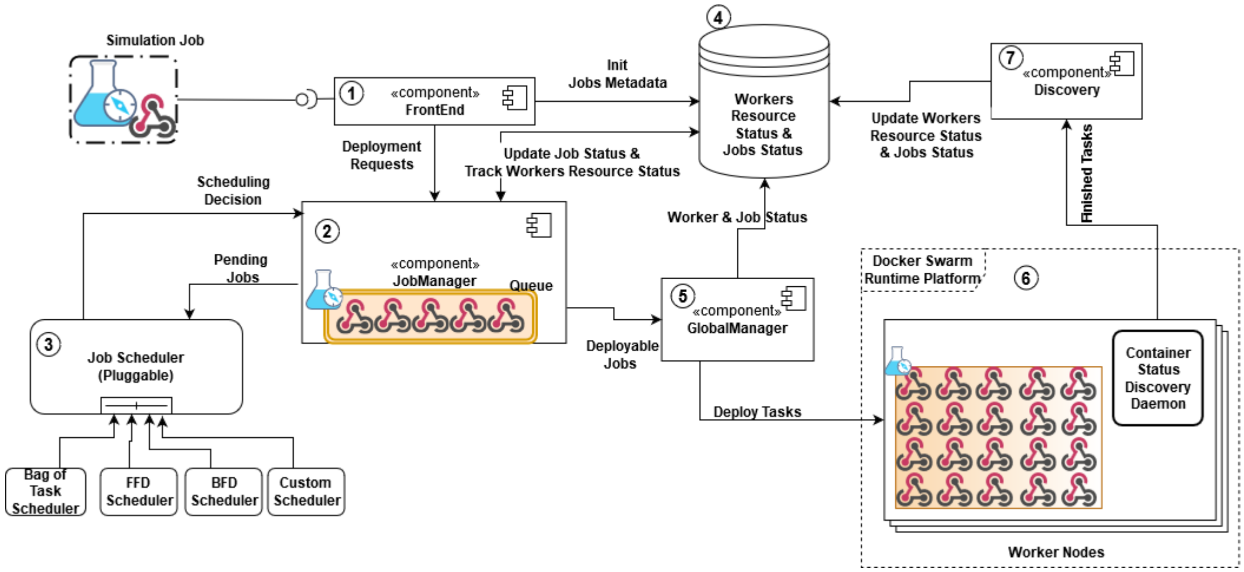

Fig. 4: Co-simulation-as-a-Service.

with the database, and deletes the deployed jobs from its queue. The GlobalManager is responsible for managing participants of the Docker Swarm Runtime Platform ⑥. It launches the master node of the Docker Swarm cluster and accepts registration requests sent from worker nodes. Every joined Worker Node runs a CaaS-Worker daemon that is used to receive and perform commands sent from the GlobalManager. The GlobalManager parses received deployment requests and spawns containers in specific Worker Nodes. Additionally, the Worker Nodes employ a CaaS-Discovery daemon to track the status of containers, and reports a StatusChanged signal to the Discovery component ⑦ when a task is completed.

VI. Experimental Evaluation

A. Experimental Setup

EXPPO was validated using seven homogeneous compute servers with a configuration of 12-core 2.1 GHz AMD Opteron central processing units, 32 GB memory, 500 GB disk space, and the Ubuntu 16.04 operating system. The runtime platform was based on Docker engine version 19.0.5 with swarm mode enabled. There was one client machine that submitted simulation job requests. The front end, job manager, job scheduler and the global manager components were running on a single shared compute server, and five compute worker servers were deployed for running the simulation jobs.

The simulation job consisted of three federates each running a unique application from the PARSEC benchmark: freqmine, blackscholes and ferret. These applications were chosen as they are realistic representations of real-world simulation tasks [12]. During the federation execution, each federate executed its application at every logical time step, for a total number of 100 logical time steps. The implementation of the co-simulation federation was done using Portico HLA [18]. The BFD scheduler was used in the experiments (as it was found to have better performance than FFD). The weights for the QoS and the cost were set to $\alpha = 1$ and $\beta = 0.5$. These weights are chosen so that they correspond to a specific brand of QoS that prioritizes low makespan over resource usage, which is representative of CPS applications.

B. Experimental Results

EXPPO recommended a resource configuration of 4 cores for freqmine federate, 4 cores for ferret federate and 1 core for blackscholes federate. Two baseline approaches were used to compare the performance of resource configuration selection of EXPPO. In the first approach (*least configuration*), all the federates were assigned the lowest possible configuration of 1 core each. In the second approach (*max configuration*), all the federates were assigned the highest possible configuration of 10 cores each. The performance data was collected over 10 simulation jobs.

Figure 5(a) shows the cumulative distribution function (CDF) of the execution time of EXPPO compared to the other two approaches. The resource configurations selected by EXPPO for the federation had a 90*th* percentile execution time of around 230 seconds, which was significantly better than the 320 seconds for the *least configuration*. Its performance was close to that of the *max configuration* (90*th* percentile execution time of around 200 seconds), with the difference due to its lower resource allocation to conserve the cost.

Figure 5(b) shows the cost analysis of the three strategies using the cost function defined in Section IV-B. As can be seen, resource configuration selected by EXPPO incurred a larger cost than the *min configuration* due to the higher resource allocation to reduce execution time, but it had a substantially lower cost compared to the *max configuration*.

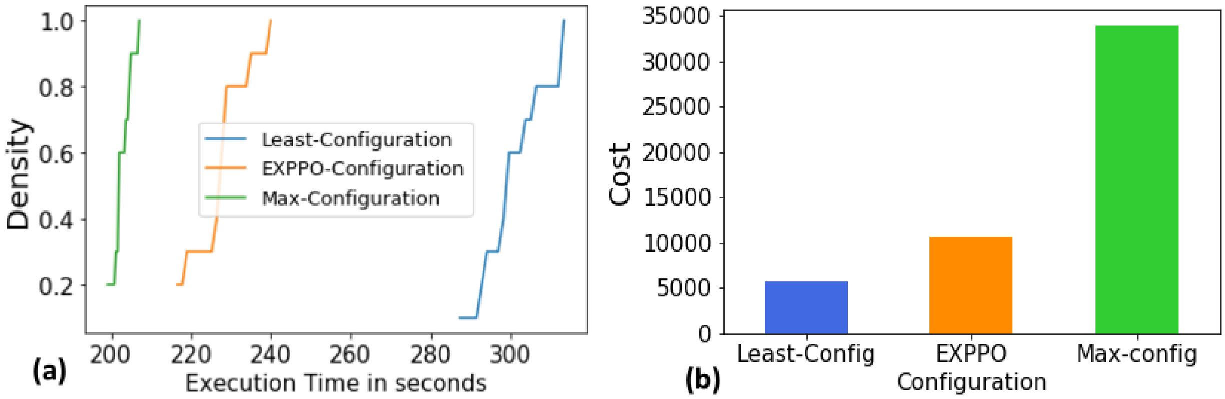

Fig. 5: (a) Execution time for the EXPPO resource configuration compared to other strategies. (b) Cost for the EXPPO resource configuration compared to other strategies.

Overall, the results show that EXPPO is able to select resource configurations and schedule the federates in such a way that minimizes the combination of execution time and cost of the simulation successfully.

VII. Related Work

In [7], the authors presented a Kubernetes co-simulation execution platform for cloud computing environments. Similarly, [8] presented a Docker swarm co-simulation platform for running mixed electrical energy systems simulations. However, these platforms do not use a gang-scheduling based simulation deployment strategy.

For resource recommendation, [19] presented a data-driven approach for selecting the best resource configuration for a virtual machine from a set of different configuration options. [20] explored the cost-sensitive allocation of independent tasks to cloud computing environments. However, these approaches are different from EXPPO as they focus on a single task rather than a pool of BSP tasks.

In [21], the authors proposed a scientific workflows scheduling algorithm to minimize the execution time under budget constraints for deploying to cloud computing environments. [22] proposed an advance-reservation scheduling strategy for message passing interface (MPI) applications. Similarly, [23] presented an approach for gang-scheduling of jobs with different resource needs, such as a compute intensive task paired with a network or I/O intensive task. In [24], the authors present scheduling of multiple container workloads on shared cluster as a minimum cost flow problem (MCFP) constraint satisfaction problem. In [25], the authors proposed a locality-based process placements for parallel and distributed simulation. The evaluation of the proposed framework was carried out using the OMNET++ network simulator.

Compared to related work, EXPPO provides a resource recommendation engine which tries to minimize the makespan and cost for the entire federation (BSP tasks) rather than a single task. EXPPO uses a gang scheduling scheme based on heuristic bin packing techniques to deploy the entire federation on Docker container platform as one batch job. Furthermore, EXPPO provides automatic code generation of distributed tracing probes for performance profiling of the federates which maybe deployed on a distributed infrastructure, thereby relieving the developers from incurring complexities in writing code for the profiling of federates [26].

VIII. Conclusion & Future Works

Resource allocation plays a critical role in co-simulation performance. However, the end user is not necessarily well-equipped to determine what resource allocations work best for their co-simulation jobs given the various resource configuration options (and associated costs) available from the cloud provider. To address these challenges, this paper presents EXPPO, which is a Co-simulation-as-a-Service (CaaS) platform for executing distributed co-simulations in cloud computing environments. EXPPO provides performance profiling capabilities for federates which help in the understanding of the relationship between resource allocations and the simulation performance. Similarly, it addresses performance profiling challenges for a simulation job comprising heterogeneous computation tasks or federates deployed across distributed systems. Furthermore, EXPPO selects the resource configurations for these federates in a way that not only minimizes the makespan of the co-simulation, but also satisfies the cost budget of the user.

Future work will address the following:

- The assumption that federate computations have identical wall-clock execution times across all iterations restricts the generality of the approach to a subset of application use cases. For hybrid simulations or simulations with non-linear dynamics, the execution times of the involved simulation steps will vary at each iteration. Future work must explore dynamic resource allocation for federates which have different work loads for different computation steps. Reinforcement learning approaches which can monitor the federates and dynamically adjust resource allocations based on the varying demand of a federate over time offer a promising approach that remains to be explored.

- EXXPO only considers workloads that are CPU bound. It assumes constant communication costs during each computation step for all the federates. Future work must consider the different communication costs for simulations which may need to be constantly updating states or sending messages for triggering discrete events.
- When other applications are co-located in the cluster environments, the effects of noisy-neighbors [27], [28] can also affect federation performance. Thus, future work could consider the effect of noisy-neighbors for resource scheduling and simulation placement in the cluster.
- EXPPO assumes the use of homogeneous servers for running simulations to simplify its algorithms, and could be extended to include heterogeneous systems. Also, with the growing relevance of edge computing and digital twin techniques, efficient resource allocation and scheduling of the simulations at the edge will be necessary.

ABSTRACT

Melt pool size is a critical intermediate measure that reflects the outcome of a laser powder bed fusion process setting. Reliable melt pool predictions prior to builds can help users to evaluate potential part defects such as lack of fusion and over melting. This paper develops a layer-wise Neighboring-Effect Modeling (L-NBEM) method to predict melt pool size for 3D builds. The proposed method employs a feedforward neural network model with ten layer-wise and track-wise input variables. An experimental build using a spiral concentrating scan pattern with varying laser power was conducted on the Additive Manufacturing Metrology Testbed at the National Institute of Standards and Technology. Training and validation data were collected from 21 completed layers of the build, with 6,192,495 digital commands and 118,928 in-situ melt pool coaxial images. The L-NBEM model using the neural network approach demonstrates a better performance of average predictive error (12.12%) by leave-one-out cross-validation method, which is lower than the benchmark NBEM model (15.23%), and the traditional power-velocity model (19.41%).

Keywords: Melt pool size, powder bed fusion, additive manufacturing, machine learning, layer-wise, track-wise

1 INTRODUCTION

Laser powder bed fusion (LPBF) additive manufacturing (AM) uses a laser to melt and fuse spread powder on a build plate. An LPBF machine can precisely scan thin layers of powder to form a designed geometry. The laser delivers thermal energy to the powder to create melt pools once it reaches the melting temperature. Under ideal conditions, the laser should remelt the nearby solidified part to bond the newly melted part [1]. This process occurs both horizontally (track-wise) and vertically (layer-wise) [2,3].

Melt pool size is a generalized term that represents a group of values such as depth, width, and length. These measurements closely correlate to the part quality [4]. Melt pool width, for example, working closely with hatch distance, can predict void type defects between two adjacent tracks. Melt pool depth, on the other hand, determines the fusion between layers [5]. Figure 1(a) shows an ideal melting condition where the melted areas are well connected between tracks and layers. However, the un-melted powders would appear when the melt pool size doesn't reach the hatch distance and layer thickness. Figure 1(b) shows a lack-of-fusion defect created by insufficient overlap between two melt pool tracks, which leaves track-wise un-melted powders. Figure 1(c) shows the layer-wise un-melted powder between the current and previous layers caused by an insufficient melt pool depth. Either condition could increase porosity in the final part.

Figure 1 shows the defects due to small melt pool sizes. Nevertheless, oversized melt pools may lead to a different type of defects called over melting [6]. If a laser beam frequently re-melts an area with oversized melt pools, this area can be overheated and develops keyholing [7]. Keyhole is a defect that affects both current and future layers. Keyholing creates voids in the current layer, which can significantly affect the powder spreading of the next layer [8,9].

Though melt pool size is not a property of AM parts, it is a critical process measurement with salient features associated with part quality. Many process parameters can directly or indirectly affect melt pool size. For example, instant energy density has been proved being a major factor in manipulating melt pool size [10,11]. Melt pool formation is highly sensitive to energy density-related variables such as laser power, scan speed,

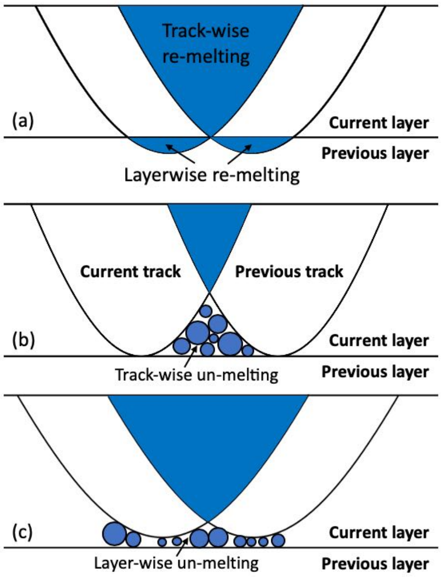

FIGURE 1: The cross-sectional view of two parallel melt pool tracks under three melting conditions. The solid blue area represents the re-melted area. The circles are the un-melted powder particles.

and hatch distance [12]. Energy density determines the maximum thermal input to the powder. Material properties such as heat absorption efficiency determine the actual thermal energy received by the powder [13]. Scan pattern, defining how a laser beam travels, is another important element that affects melt pool size. Experimental studies indicate that part built with the same process parameters but different scan patterns can have distinct thermal fields [14, 15].

If the melt pool size can be predicted before a part is built, users can modify the part design and process setting timely. Physics-based simulation approaches such as finite element analysis (FEA) and computational fluid dynamics (CFD) methods are mature and popular in AM research to predict melt pool size. Pioneer modeling works also reveal that melt pool formation is sensitive to both process parameters and scan patterns [14, 16]. An advantage of the FEA and CFD modeling methods is that they can simulate the effects of any physical parameter [17, 18], for example, various scan patterns. However, the high computational cost is hindering the use of physics-based modeling approaches. A single layer FEA simulation at millimeter-scale may take hours to calculate the interactions between multiple scan tracks. CFD models may be more expensive. This issue becomes noticeable when solving large scale AM problems. The computational cost also prevents the use of these simulations in model-based optimization, because it requires iterative runs to approach the optimal solution.

The data-driven modeling approach becomes a substitute for the physics-based modeling methods to achieve fast predictions. In general, data-driven modeling methods create black-box surrogate models based on experimental data. The computational time may vary from method to method but generally faster than complex simulations [19]. The prediction from surrogate model can usually be made within seconds [11, 20]. However, for data-driven methods, it could be very challenging to characterize process settings and formulate them into a model. For example, scan pattern involves long time series, numerous moving vectors, and dynamic laser spot locations. It is challenging to represent these features using a few variables. And from the perspective of data availability, most AM machines don't export the exact scan path of a build to the users [21].

The authors' previous works developed a data-driven method called Neighboring-Effect Modeling (NBEM) method which was able to address the challenge and predict the melt pool size for a single-layer [14]. However, there were multiple obstacles to further improvement of the model accuracy by extending the single layer to the multi-layers approach. First, it requires multi-layers in-situ melt pool monitoring data, which was not available. Besides, the NBEM factors that designed to capture the features of the single-layer scan strategy cannot quantify the variation between layers.

This study aims to address the research obstacles by developing a novel Layer-wise NBEM (L-NBEM) approach. The L-NBEM method introduces five additional input variables to predict melt pool size using the scan and exposure setting data from the previous layer. An experiment was conducted to collect build commands and melt pool images for multiple layers of one part. This data was used for model construction and validation. The following section mainly introduces the L-NBEM approach, including the physical hypothesis, the modeling variables, and the machine learning method for model training. Section 3 lists the details about the experiment and data. Section 4 presents the results of the L-NBEM model compared to other models. Section 5 discusses the result and future research plan.

2 LAYER-WISE NEIGHBORING-EFFECT MODELING METHOD

This section introduces the background, hypothesis, and modeling variables and method for the L-NBEM approach. The original NBEM method focuses on predicting the melt pool size for a single layer from the process parameters and scan pattern. The fundamental idea is to characterize the neighboring area process settings into two simplified NBEM variables. The proposed L-NBEM method builds on the previous method by introducing more variables to characterize the layer-wise features of process settings for multi-layers AM build.

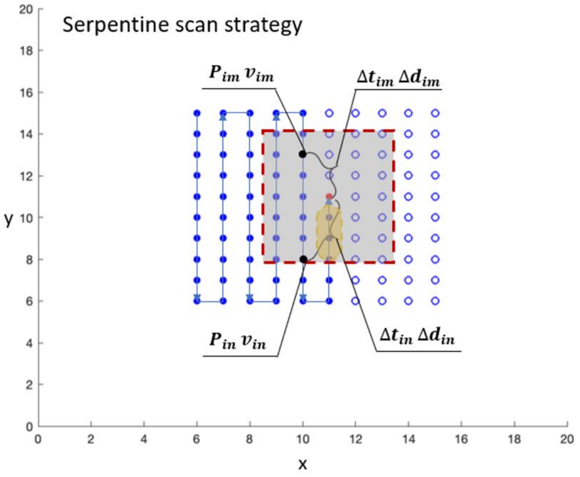

FIGURE 2: Neighboring points in serpentine scan strategy. [14]

2.1 Neighboring-Effect Modeling Method

The fundamental idea of the NBEM method is to use a minimum number of variables to characterize complex scan patterns and the corresponding process parameters. It assumes the melt pool at current laser spot is affected by the nearby region with a neighboring effect, which is a function of the scan pattern. Different scan patterns would visit the neighboring area of a laser scan spot differently. Thus, the time differences and the spatial differences between the previous spots and the current laser spot can be used to characterize the scan pattern.

Figure 2 shows an example of constructing an Ω matrix [14] to capture all the factors affecting the melt pool size within a neighbor region. The red, solid blue, and unfilled blue points in the figure represent the current, previous, and future scan points, respectively. The arrow marks the scan direction of the serpentine scan strategy. The gray area is the neighboring-effect zone enclosed by the red dashed box. This study investigates the neighboring area as a $0.1mm \times 0.1mm$ square. The solid blue points in the gray area are the neighboring points to be included in the Ω matrix. In this work, the points located on the same straight track of the current focal spot are not included in the matrix (dashed yellow area) to avoid over-estimation. It assumes that the laser power and scan speed at the current scan point can cover the effect from these points since it is generally a single track problem.

Parameters P_{im}, v_{im}, P_{in}, v_{in} are the laser power and scan velocity associate to point m and point n, respectively. Δt_{im} and Δd_{im} are the time and distance difference between former point m and current point i. Similarly, Δt_{in} and Δd_{in} are assigned to point n. In this example, $\Delta t_{im} > \Delta t_{in}$ and $\Delta d_{im} > \Delta d_{in}$. Subscript i denotes the i_{th} spot, which uses the global indexing. m and n are the local indexing referring to the i_{th} point. Collecting the variables for all neighboring points facilitates the formulation of the Ω_i for the current focal point i. Collecting the variables for all neighboring points except the points located in the yellow area facilitates the formulation of the Ω_i for the current focal point i. The dashed yellow area is considered as a single-track problem which is already covered by the laser power and scan speed of current point.

With Ω_i formulated, melt pool area can be expressed as a function of processing parameters and processing history. The smallest Ω_i is an empty matrix which is assigned to the first focal point on a toolpath since no previous points exist at that moment. Points in inner build areas usually have larger Ω_i than those located on the edge. The NBEM factors can be calculated by:

$$f(\Omega_i) = \begin{bmatrix} P_{i1}/v_{i1} \\ P_{i2}/v_{i2} \\ \vdots \\ P_{ij}/v_{ij} \end{bmatrix}^T \begin{bmatrix} f_{\Delta t}(\Delta t_{i1}) & f_{\Delta d}(\Delta d_{i1}) \\ f_{\Delta t}(\Delta t_{i2}) & f_{\Delta d}(\Delta d_{i2}) \\ \vdots & \\ f_{\Delta t}(\Delta t_{ij}) & f_{\Delta d}(\Delta d_{ij}) \end{bmatrix} \quad (1)$$

$\theta_i^{\Delta t}$ and $\theta_i^{\Delta d}$ represent the integrated factor of $f(\Omega_i)$ on time and distance perspective. $f_{\Delta t}(\Delta t_{ij}$ and $f_{\Delta d}(\Delta d_{ij}$ represent the scaling functions of time-lapse and distance, respectively. In Equation (2) and Equation (3), the input laser power P_{ij} of the neighboring point j provides a fundamental impact. Function $f_{\Delta t}(\Delta t_{ij})$ and $f_{\Delta d}(\Delta d_{ij})$ are used to scale the neighboring-effect from 0 (no impact) to 1 (strongest impact). Points geometrically and/or temporally remote to the current focal point are scaled to have minimal impact. Δt_{ij} or Δd_{ij} can be too large to provide any impact since an irradiated area is limited by its size.

$$\theta_i^{\Delta t} = \sum_{j=1}^{j=n} f_{\Delta t}(\Delta t_{ij} \frac{P_{ij}}{v_{ij}} \quad (2)$$

$$\theta_i^{\Delta d} = \sum_{j=1}^{j=n} f_{\Delta d}(\Delta d_{ij} \frac{P_{ij}}{v_{ij}} \quad (3)$$

The time-neighboring-effect focuses on modeling the preheating conditions of the current focal point, which depends on powder cooling rate. The cooling rate can affect the preheating temperature of melting. The literature indicates the temperature of the focal point decreases quickly at the beginning but the total time for cooling and irradiated area can be varied [22,23]. In this work, the time-neighboring-effect is formulated exponentially:

$$f_t(\Delta t_{ij}) = a_1 e^{a_2 \Delta t_{ij}} \quad (4)$$

where $f_t(0) = 1$ and $f_t(\Delta t_{max}) = 0$. The parameters a_1, a_2 and Δt_{max} is a fixed value which is derived from experiments.

The distance-neighboring-effect aims to formulate the spatial impact such as spattering and denuded powder. Simulation and experimental results indicate the denuded width of an irradiated area is ranged from 0.04 mm to 0.06 mm for high-resolution scanning [24,25]. The distance-neighboring-effect is formulated as:

$$f_d(\Delta d_{ij}) = b_1 e^{b_2 \Delta d_{ij}} \quad (5)$$

where $f_d(0) = 1$ and $f_d(\Delta d_{max}) = 0$. Optimal coefficient b_1 and b_2 will be determined by experimental data. Δt_{max} and Δd_{max} equal to 20 ms and 0.6 mm in this study. The melt pool area, $\tilde{y}_i$, is a function of laser power at current spot, P_i, current scan speed, v_i, and NBEM time and spatial factors $\theta_i^{\Delta t}$ and $\theta_i^{\Delta d}$.

$$\tilde{y}_i = f(P_i, v_i, \theta_i^{\Delta t}, \theta_i^{\Delta d}) \quad (6)$$

2.2 Hypothesis of L-NBEM

In general, melt pool size depends on the energy absorbed by the powder. Higher energy density imported to the powder can make the metal powder particles melted to liquid and fuse to the nearby area easier [26, 27]. Once the metal liquid contacts the powder outside the laser spot, if there is enough additional energy, it would melt more metal powder thus enlarge the melt pool. According to this phenomenon, melt pool size typically is an outcome of thermal energy input. The following hypothesis is made based on this finding.

This study generated the data using the same testbed at one AM build with virgin metal powder. It assumes the machinery and environmental conditions remain the same during the entire process. The model would ignore the variance of powder particle size, changing of chamber temperature and humidity, and fluctuation of laser power. The L-NBEM method of this study considers them as constant parameters for all layers.

Simulations and experiments indicate that the melt pool size is a product of energy input. Laser power and scan speed are two significant components of energy density [28, 29]. The NBEM method includes these two major variables according to the importance of them relates to the energy input. Given the same energy input, however, the melt pool size can be changed due to different preheating temperatures [30]. Higher initial temperature establishes a preheating condition of the powders thus generate larger melt pool size. As a result, factors that may affect the preheating temperature should be included. The track-wise factors in the same layer are characterized by the NBEM method. L-NBEM mainly introduces additional layer-wise factors. The total energy input and cooling time on the previous layer determine the preheating temperature of the current layer. Generally, it is a heat accumulation and releasing process.

The first layer of the part usually builds on the bare build plate with relatively ideal conditions of surface roughness and uniform chamber temperature. The single-track experiment shows the melt pool under the same process parameters produce fewer uncertainties on the bare plate than coarse powders [29]. However, the powders for later layers are spread on the previous layer unless overhanging occurs. Therefore, the L-NBEM method assumes the melting conditions of the previous layer can affect current melt pool formation. To cover this hypothesis, the L-NBEM method would characterize the features of a specific field on the previous layer. This field locates at the projection area of the current NBEM area. Those features from the layer-wise affect to the melt pool size.

Another hypothesis of L-NBEM method is the current layer can only be impacted by the most recent layer. It assumes the layer-wise melt pool features has already covered the thermal history of all former layers.

2.3 Overview of L-NBEM

The L-NBEM method divides the potential factors of the melt pool size into two groups. The first group includes the track-wise factors on the current layer within the NBEM region, the red dashed area in Figure 3. The second group includes the layer-wise factors on the previous layer within the projection of the NBEM region. Figure 3 shows an example of NBEM and L-NBEM regions on Layer 9 and Layer 8. Both layers using the serpentine scan pattern. Arrow lines show the scan path from the beginning to the end. The red and black arrows represent scanned tracks and future tracks, respectively. The orange square represents the NBEM region. Historical points within the NBEM region would be used to calculate the track-wise factors. The red dot located in the center is the current laser spot. The surface plot of Layer 8 represents the melt pool area map. The colormap ranges from 0 mm^2 to 0.04 mm^2. The orange box is the projection area of NBEM region, which crops the L-NBEM region. Historical points located within the L-NBEM region would be used to calculate the layer-wise variables.

Five NBEM factors are formulated to the track-wise input variables: building time from start point to the laser spot (t_i), laser power (P_i), scan speed (v_i) at the laser spot, NBEM time factor ($\theta_i^{\Delta d}$), and NBEM distance factor ($\theta_i^{\Delta d}$). The layer-wise input variables that represent the effect from the previous layer

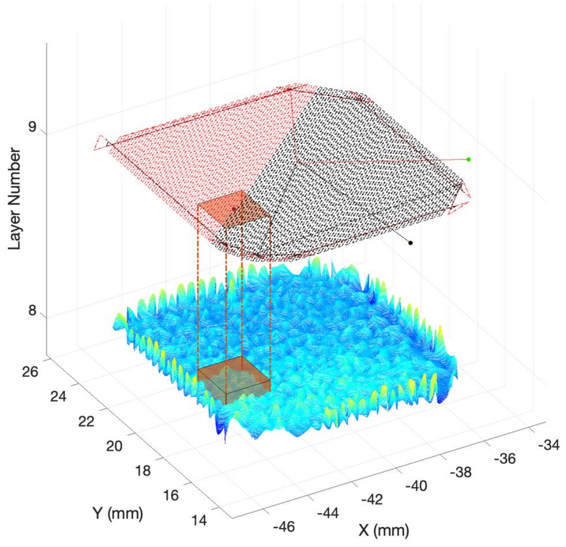

FIGURE 3: An example of two neighboring layers using serpentine scan pattern.

are: total energy input on the previous layer (J), laser idle time from the end of the previous layer to start of current layer (λ), mean (A_{avg}), maximum (A_{max}), and standard deviation (A_{var}) of the melt pool area of the L-NBEM region. The general formulation of the L-NBEM model to predict the melt pool area $\tilde{y}_i$ at current laser spot can be presented as:

$$\tilde{y}_i = f(t_i, P_i, v_i, \theta_i^{\Delta t}, \theta_i^{\Delta d}, J, \lambda, A_{avg}, A_{max}, A_{var}) \tag{7}$$

Figure 4 is the 2D view of Figure 3 when stacking the layers into a 2D plot. If the laser spot located on edge, NBEM and L-NBEM would have fewer points. This study uses a square box to filter NBME and L-NBEM fields. However, there is no limitation on the shape of the region.

2.4 Input and Output of L-NBEM

Table 1 lists the input variables in Equation (7) for their unit and function. Variable with star sign indicates it represents the layer-wise effect. Pound sign marks the dependent variable. Energy input is the total energy input from the previous layer, which is a production of laser power at each time step and the total time step. This study sets a constant time step to 10 μs. Thus, the total energy input of any layer could be presented as:

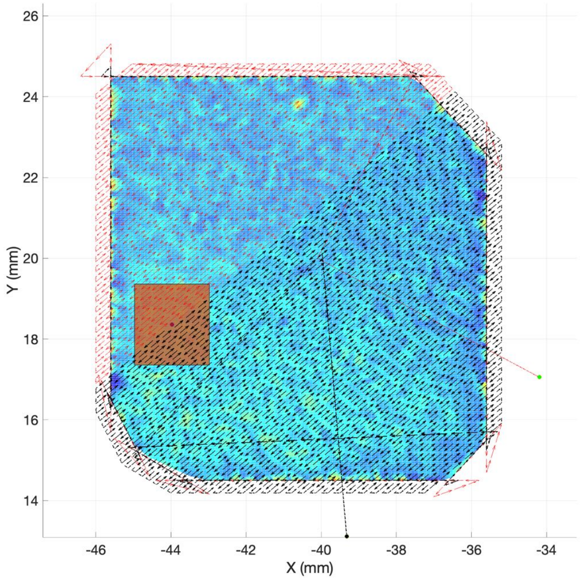

FIGURE 4: 2D view shows the top view of Figure 3 that visualize the layer-wise and track-wise effect when stack two layers together.

$$J = \sum_{i=1}^{n} P_i \tag{8}$$

Where P_i is the laser power for the i_{th} laser spot, n is the total laser spots for one layer. In fact, the laser spots are not discrete points since they are physically continuously connected. This work uses the time interval ($10 \mu s$) from the digital commands to separate the laser spots. Thus, the index i of the laser spot is the same to the time step.

Figure 5 shows three examples of melt pool coaxial images. These images were taken at different locations of one layer with same laser power and scan speed. Figure 5(a) is the melt pool less than regular size. Figure 5(b) is the melt pool with average size. Figure 5(c) is the melt pool with very large area. This study chooses area as the output to represent the melt pool size. The grayscale threshold 100 is used to find the contour of the melt pool. The pixels within the contour are considered as the melt pool. The melt pool coaxial image is 120 × 120 pixels, where each pixel is a 8 $\mu m \times 8$ μm square.

Figure 6 shows the melt pool area measured by different threshold values. Figure 6(a) is the original melt pool coaxial image. Figure 6(b) shows the melt pool size by grayscale thresholding set at, 100, 120, and 180. The smallest melt pool area,

TABLE 1: Name, symbol, unit, and function of the variables. The pound sign (#) marks the dependent variables. The star sign (*) marks the variables representing the layer-wise effect.

Variable name	Symbol	Unit	Function
Building time	t_i	ms	Calculate the cumulative heat
Laser power	P_i	W	Input heat source
Scan speed	v_i	mm/s	Affect the energy density at the laser spot
NBEM time #	$\theta_i^{\Delta t}$	N/A	Characterize the time effect
NBEM distance #	$\theta_i^{\Delta d}$	N/A	Characterize the spatial effect
Energy input *, #	J	W	Calculate the total energy input from previous layer
Idle time *	λ	ms	Calculate the cooling time
Mean area *, #	A_{avg}	mm^2	Calculate average melting conditions of previous layer
Maximum area *, #	A_{max}	mm^2	Calculate extreme melting conditions of previous layer
Standard deviation of area *, #	A_{var}	mm^2	Evaluate the variation of melt pool of previous layer

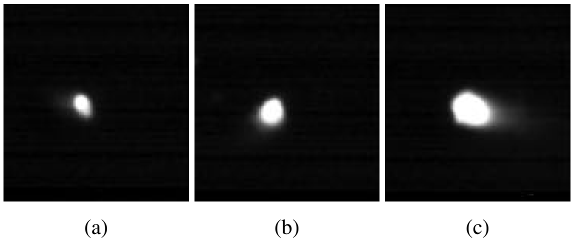

FIGURE 5: Sample melt pool coaxial images taken at different locations.

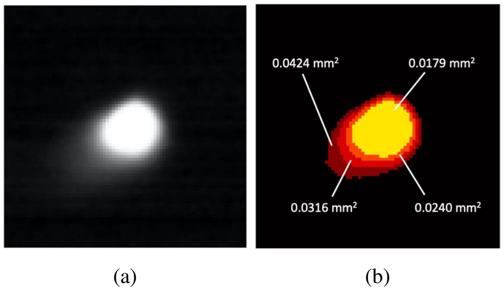

FIGURE 6: Melt pool area measurement based on different threshold grayscale value.

0.0179 mm^2, is derived based on the highest thresholding 180. The largest melt pool area, 0.0424 mm^2, is measured using the lowest thresholding 80. These two values represent the wrong melt pool size since both thresholding is out of the range found physically. This study selects 100 as the threshold value to measure all the melt pool images. The selected threshold may not be the most accurate number to find the actual melt pool. However, it can represent the melt pool size changes caused by scan pattern and process parameters if all the measurements using the same criteria. Specific to the example shown in Figure 6, the area is 0.0316 mm^2 by grayscale threshold 100.

2.5 Modeling

A feedforward neural network (NN) model is trained to represent the L-NBEM model. Figure 7 plots the structure of the neural network that include input layer, hidden layer, and output layer. The 10 variables in Equation 7 construct the input layer. The hidden layers contain two fully connected layers with 20 nodes for each. Melt pool area constructs the output layer. Levenberg-Marquardt is the activation function. For comparison purpose, polynomial regression is used to build the model by traditional power-speed method.

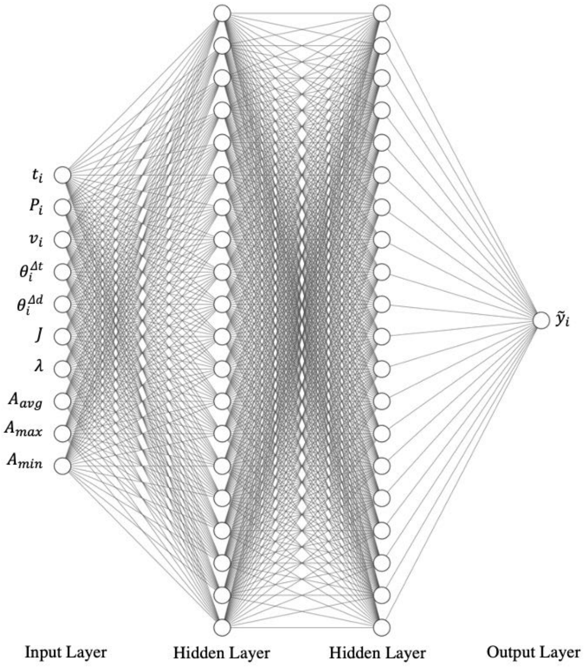

FIGURE 7: Structure of the Neural Network.

2.6 Validation

This study uses the leave-one-out cross-validation (LOOCV) method to validate the proposed method. The data of the layer being validated would not be included in the training dataset for each layer. It would be the validation dataset to validate the model for this layer. An n-layers problem would establish n models for LOOCV.

The criteria for performance evaluation are Average Relative Error Magnitude (AREM) and Average maximum Error Magnitude (Average-MREM) [20]. AREM can represent the average error for all predictions of one particular layer.

$$AREM = \frac{\sum_{i=1}^{m} |y_i - \tilde{y}_i|}{my_i} \qquad (y_i \neq 0) \qquad (9)$$

where m is the total number of validation data points. Parameters y_i and $\tilde{y}_i$ are the actual observation and prediction value of the melt pool area. Since only positive laser power can create melt pool and this experiment always turn on the laser during the build, this study would not have divisor equal to zero.

The average-MREM calculates the average error of the 100 largest error points of each layer. This method aims to evaluate the performance of L-NBEM for extreme conditions. The MREM formula for one layer is:

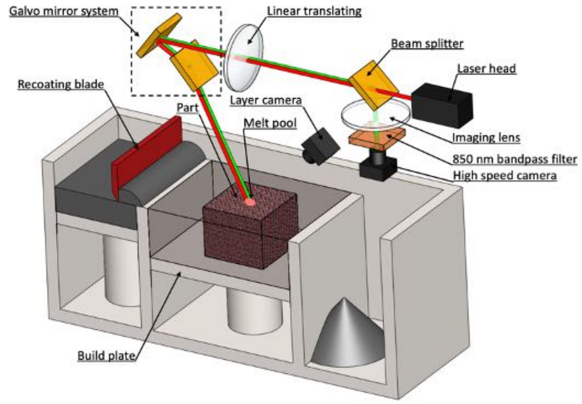

FIGURE 8: The conceptual model of AMMT [14].

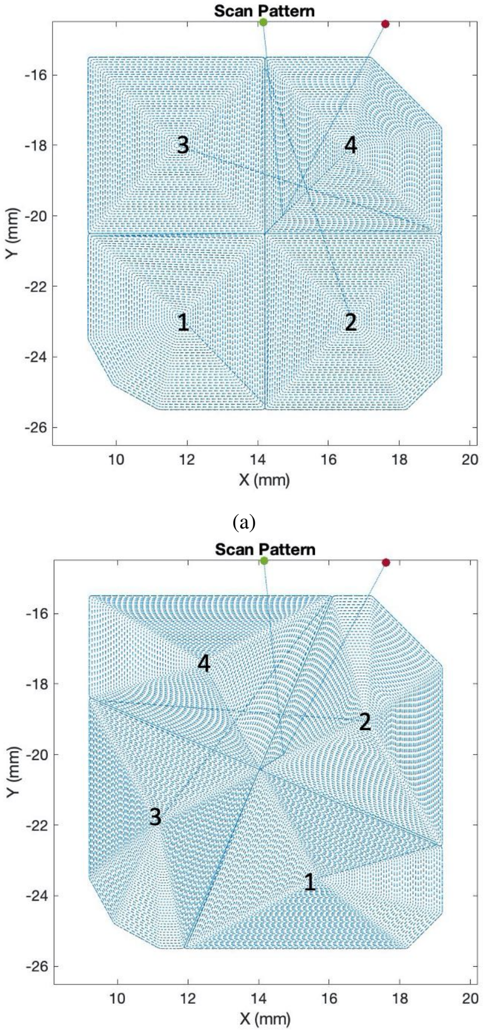
$$MREM = max(\frac{|y_i - \tilde{y}_i|}{y_i}) \qquad (y_i \neq 0) \qquad (10)$$

3 EXPERIMENT DESIGN

The experiment is conducted on the Additive Manufacturing Metrology Testbed (AMMT) at National Institute of Standards and Technology (NIST) as shown in Figure 8. The AMMT [25] is a fully customized metrology instrument that enables flexible control and measurement of the Laser Powder Bed Fusion process. An in-house developed AM software (SAM), which is capable of stereolithography (STL) slicing, scan path planning, G code generation and interpretation [31], was used to program the different scan strategies for the experiment. Inconel 625 powder and substrate were used, where the substrate has a dimension of 101.6 $mm \times$ 101.6 $mm \times$ 12.7 mm. Twelve rectangular parts (with chambered corners) of dimensions 10 $mm \times$ 10 $mm \times$ 5 mm were laid on the substrate, with a minimum spacing of 10 mm between the parts. Each part was built with a different scan strategy. The melt pool was monitored by a high-speed camera which is optically aligned with the heating laser, such that the image of the melt pool is maintained stationary within the camera's field of view. The camera was triggered at every 200 μs (i.e., 2000 frames per second), with an integration time of 20 μs.

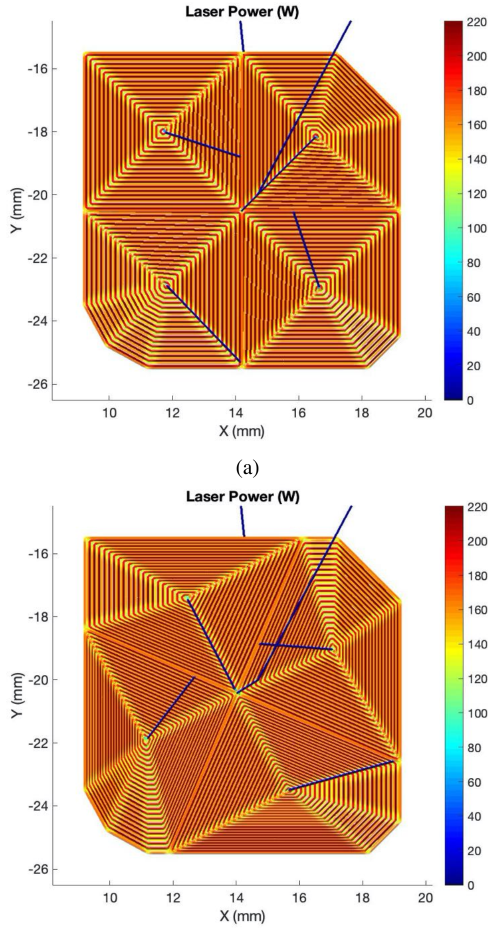
The experiment applies the 'island' spiral concentrating scan strategy to build the part. The part has 250 layers where each layer is 20 μm. To avoid high heat concentration and introduce variance of the island shape, the machine would rotate the centroid angle at each layer. The rotation angle between layers is 83.4 degree and the first layer divide the islands in the vertical intersection as shown in Figure 9(a). After rotating the intersection for 83.4 degrees, the scan pattern for Layer 2 is shown in



(a)

(b)

FIGURE 9: Scan pattern for Layer 1 (a) and Layer 2 (b) of the part. The scan starts at green point and finishes at the red point. Numbers marks the scan order for each island



(a)

(b)

FIGURE 10: Laser power for Layer 1 and Layer 2

Figure 9(b). For each layer, the laser beam starts at the green point and firstly scan the contour of the part and each island. The laser then moves from the edge spirally concentrating to the center of the first island. After finishing the first island at the island center, it moves to the edge of the second island.

Figure 10 shows the laser power of Layer 1 and Layer 2. The dark blue lines represent when laser traveling between islands with no power input. The machine reduces the scan speed when laser turning direction. The machine reduces the layer power for scan speed to avoid high energy input. The range of laser power and scan speed is from 0W to 234.83 W and 0 to 900 mm/s, respectively.

The AMMT uses XY2-100 control system to control the laser scan [31]. It specifies the laser process parameters (laser coordinates, power, and camera trigger) at each time step. Figure 11 shows the digital commands in a spreadsheet from step 25852 to 25874. Column A and Column B have the laser spot position on the x-axis and y-axis. Column C is the laser power. Column D identifies the coaxial camera trigger. The camera would capture an in-situ image when the value change to 2. The time interval between two steps is 10 μs. The scan speed is calculated from the position between two steps.

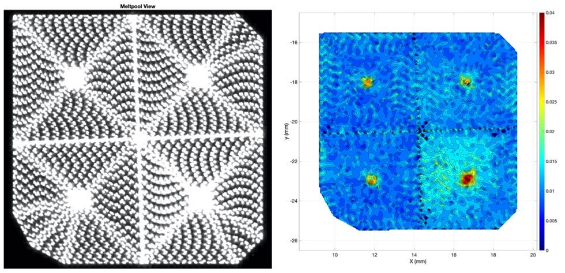
FIGURE 11: The XY2-100 digital commands from step 25852 to step 25874. The column on the left is the time step.

The experiment builds 12 parts at the same time that placed on different positions on the build plate. In other words, the machine needs to scan 12 parts at different locations of each layer. The camera, however, can only focus on one part of each layer. As a result, the experiment collects the melt pool data for the particular part every 12 layers. Finally, a total of 21 layers of data are available for training and validating the L-NBEM model. It include 6,192,495 rows of digital command data for 21 layers and 118,928 melt pool in-situ images. The melt pool area is calculated from these in-situ images using grayscale threshold value 100.

4 RESULT

This section compares the L-NBEM prediction performance with the traditional power-speed model and the NBEM model. For visualization, the melt pool area is mapped into contour plots. All the contour plots, for both measurement and prediction, use the same colormap that ranged from 0 (dark blue) to 0.04 (red) mm^2. Figure 12 shows an example of the transmission from the melt pool images to the melt pool area map. Figure 12(a) distributes all 4,589 melt pool in-situ images of Layer 177 in one map at the position where the image taken. The melt pool area is calculated using a threshold of gray scale 100. Figure 12(b) uses the measured melt pool data to create the contour plot. The melt pool size changes at different locations. For example, the center of each island has larger area than island average. The bottom right island has largest melt pool out of the entire layer.



(a)

(b)

FIGURE 12: (a) is the map of melt pool in-situ images of Layer 177. (b) is the melt pool area contour plot of this layer.

Figure 13 shows the contour plot from Layer 201 to Layer 249. The solid red box on the left lists the scan pattern and process parameters of Layer 249. The dashed red box on the right lists the scan pattern of Layer 213. Layers present different features on melt pool size, which is mainly caused by the changes in scan strategy. The objective of the L-NBEM model is to predict the variance between layers caused by track-wise and layer-wise variables.

To visualize the result, Figure 14 stacks all the measured layers in one 3D view with a 0.5 transparent ratio. As shown in the figure, the melt pool area average, island average, and oversized melt pool field present significant differences between layers. Some layers have an average area of around 0.02 mm^2. However, others can be as low as 0.015 mm^2. The oversized melt pool is highly clustered at the island center. Furthermore, due to the rotation rule of the island division between layers, the red area twisted from the bottom layer to the top layer. Figure 14 shows the contour plot of the measured melt pool area for all available 21 layers. The colormap is ranged from 0 to 0.04 mm^2.

The melt pool measurement is first compared to the prediction by the traditional power-speed model using the polynomial regression method. The polynomial regression is a form of linear regression in which the relationship between the independent variable x and dependent variable y is modeled as an nth degree polynomial. The power-speed model is popular and reliable in solving most single track problems [29]. The formulation of the model is:

$$\tilde{y}_i = f(P_i, v_i) \tag{11}$$

Figure 15 shows the contour plot of the melt pool predicted from the power-speed model. The AREM and Average-MREM of the LOOCV is 19.41% and 77.30%. As shown in the figure,

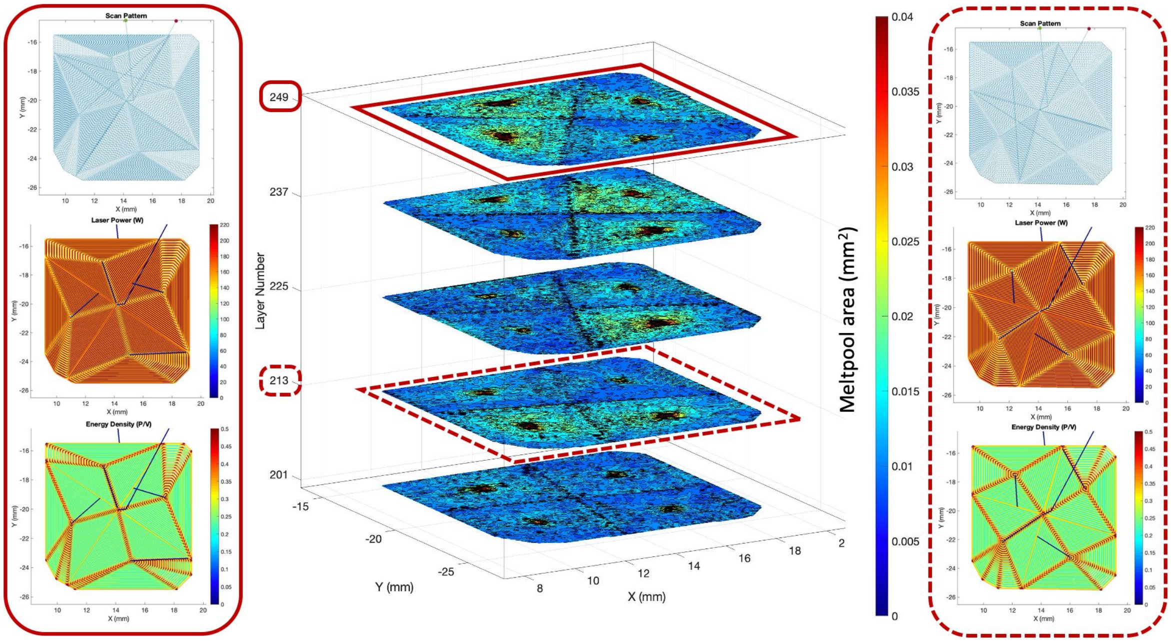


FIGURE 13: The contour plot from Layer 201 to 249. The solid and dashed boxes show the scan pattern for Layer 213 and 249.

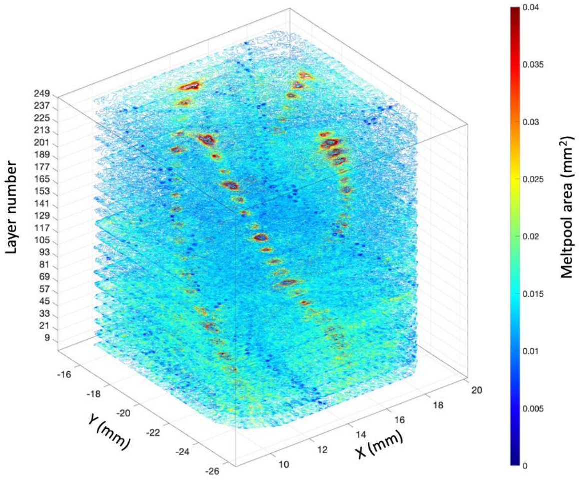

FIGURE 14: The contour plot of the measured melt pool area for all 21 layers.

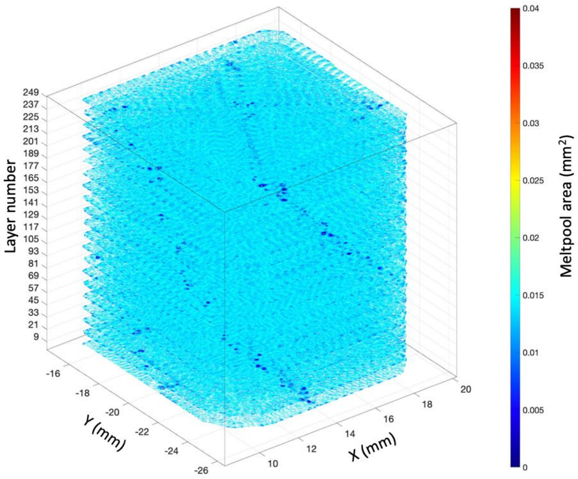

FIGURE 15: The contour plot of the melt pool prediction by power-speed model.

the prediction of each layer is very different to the actual melt pool area. It can predict some fields with relatively small melt pool due to insufficient energy input, the darker blue area. However, the major issue of this model is that it cannot distinguish the difference caused by the scan pattern, such as irregular melt pool field at the island center.

For comparison, the NBEM method is used to single layer model for all 21 layers. It is also the first time to test this approach using multi-layers experimental data. The NBEM model, which was designed for solving single layer problems, can pre-

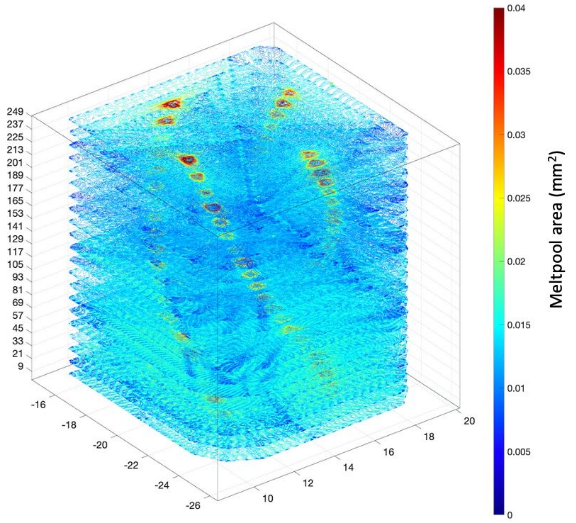

FIGURE 16: The contour plot of the melt pool size prediction by the NBEM model.

dict the irregular melt pool area due to scan pattern changes. The NBEM model is trained using the quadratic polynomial regression method. The AREM and Average-MREM of LOOCV is 15.23% and 70.3%, respectively.

Figure 16 shows the melt pool area predicted by the NBEM method. Compared to Figure 14, the model can predict the regular and irregular melt pool located on the layers. The differences between layers are also reflected on the contour plots. However, due to a lack of consideration for the layer-wise effect, predictions for the the details remain an issue.

Figure 17 shows the prediction resulted from the L-NBEM model. The LOOCV result of this method presents the lowest AREM and average-MREM, 12.12% and 64.13%, respectively. The contour plot based on the L-NBEM prediction is the closest to the actual measurement compared to the power-speed and NBEM models.

Figure 18 shows the LOOCV AREM for the melt pool predictions using the power-speed, NBEM, and L-NBEM models based on the data for all the 21 layers. L-NBEM has the lowest global average AREM. L-NBEM also demonstrates the lowest AREM for 19 layers. However, Layer 69 of L-NBEM presents the largest AREM (22.52 %) while the NBEM model presents the lowest AREM (14.22%) for Layer 213.

5 DISCUSSION AND FUTURE WORK

The objective of this work is to extend the NBEM method from a single layer approach to a multi-layer approach for melt pool size prediction. For this purpose, this study introduces five

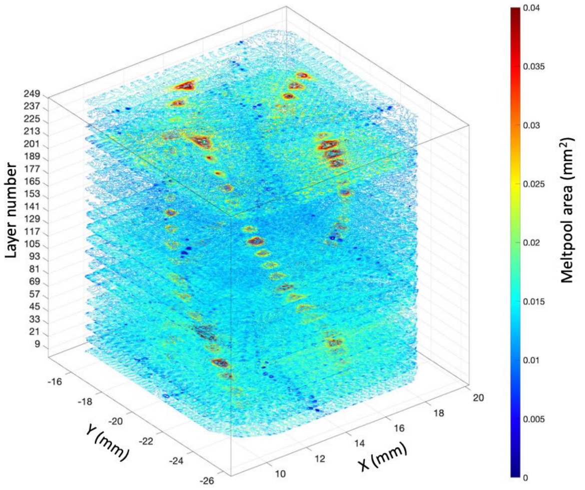

FIGURE 17: The contour plot of the melt pool prediction by the L-NBEM model.

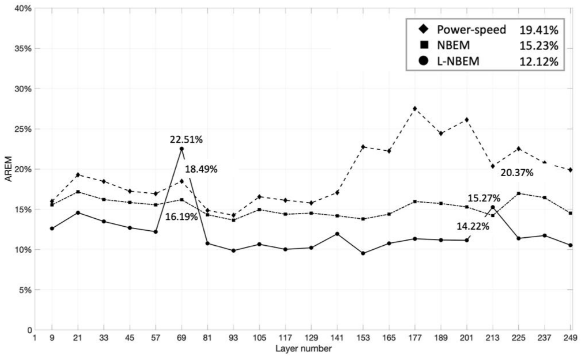

FIGURE 18: LOOCV AREM for all 21 layers of power-speed (P-v), NBEM, and L-NBEM methods.

additional variables to enhance the model performance. Generally speaking, the track-wise variables captured in the NBEM model characterize the effect from the scan pattern of the current layer. The newly added layer-wise variables characterize the effect of the previous layers. By introducing these new variables, L-NBEM can predict the melt pool size better for 3D AM builds.

An experiment provides more than 100,000 coaxial melt pool in-situ images and 6 million high sampling digital commands to validate the effectiveness of the proposed approach. All the data are deployed for training and validating the L-NBEM model using the LOOCV method. The L-NBEM model shows the lowest AREM compared to both the traditional power-speed and the NBEM models. The L-NBEM model can predict both regular melt pools that following general energy density rules and irregular melt pools introduced by the scan pattern. The model may be helpful for layerwise feedback process control of LPBF machines.

However, it is also observed that the L-NBEM model cannot guarantee a predictive accuracy for all layers. For example, Layer 69 is an outstanding layer that shows large predictive errors. The AREM of that layer reaches 22.51% which is higher than that of the NBEM model and that of the power-speed model. The error could be introduced because of the neural network construction. Various neural network configurations were tried, such as changing the number of hidden layers and neurons, different functions, and different parameters. However, none of them improved the results significantly. Layers with outstanding prediction errors exist and show up randomly. In the future, a more comprehensive machine learning approach would be investigated to reduce the modeling inconsistency. Model uncertainty quantification should be considered since such modeling uncertainties may significantly affect the melt pool size prediction [32, 33].

The prediction error may also be generated from the experimental method. The part was built with 250 thin layers. However, due to a data acquisition limitation, the in-situ melt pool monitoring data was captured every 12 layers. Because of that, some layer-wise variables were calculated from estimates instead of direct measurements. This could lead to many data errors prior to model training. A more precise experimental design may help address this issue.

Future work would focus on building the correlation between melt pool size and final material properties such as porosity and residual stress. When preparing this paper, the co-authors were working on collecting the ex-situ data of the parts using X-ray computed tomography (XCT) scan. The preliminary findings based on the XCT scan data indicate that the distribution of the voids is similar to the melt pool area distribution. As shown in Figure 19, larger melt pool size regions (measured) usually locate at the center of each island at every layer. Due to the island division rotation strategy, these regions form a circle after projecting all the layers into a 2D figure. Coincidentally, the preliminary result of the XCT data shows the voids of the part in a similar pattern. A physics based explanation is that large melt pool size regions reflect the overheating at the island center during the process. The overheating may create keyholes and finally produce the voids. Future work would investigate the potential correlation between melt pool size and porosity. If part porosity and melt pool size have a great correlation, it would be possible to predict voids using in-situ melt pool images.

6 DISCLAIMER

Certain commercial systems are identified in this paper. Such identification does not imply recommendation or endorsement by NIST; nor does it imply that the products identified are necessarily the best available for the purpose. Further, any opinions, findings, conclusions, or recommendations expressed in this material are those of the authors and do not necessarily reflect the views of NIST or any other supporting U.S. government or corporate organizations.

Using Text Analytics Solutions with Small to Medium Sized Manufacturers: Lessons Learned

Michael Brundage[1*] and Radu Pavel[2]

Michael.brundage@nist.gov, pavel@TechSolve.org

Abstract

As Smart Manufacturing becomes more prevalent throughout industry, manufacturers are continuing to look for ways to more efficiently apply advanced data analysis methods to improve their decision processes. One promising area for improving decision making is through the use of natural language processing (NLP) methods on text-based data in maintenance. Maintenance personnel often capture important information on the problems and repairs throughout the manufacturing facility in informal text. This information is key to improving maintenance decisions, such as scheduling, dispatching, diagnosis, and inventory management, but is difficult to access due to the informal and domain specific nature of the text. Methods are available to aid manufacturers with parsing through this information, however small-to-medium sized manufacturers (SMMs) still have issues in implementing NLP solutions in practice. To this end, this paper discusses lessons learned in applying a NIST developed methodology to SMMs maintenance data.

1 Introduction

Within a manufacturing facility, maintenance logs that capture repair information, e.g., the problem, the solution, or the cause, are often completed by various operators or maintenance technicians. These technicians and operators often do not follow a set terminology or structure when entering this information. These inconsistencies in entering data even occur when only one person captures such information, such as when a manager enters all maintenance logs into a database. Due to such data logging inconsistencies, it is often difficult to observe or discover patterns or actionable information, particularly when a supervisor that is not directly involved with the maintenance process is reviewing the maintenance logs.

NIST researchers have developed technology using text analytics that has the ability to address this deficiency through its ability to assign tags, identify patterns, and extract actionable information from industrial data logs (Sexton Nestor, 2019). This methodology and subsequent analysis techniques have been developed for some time (Sexton, 2018; Sharp, 2019; Brundage, 2018; Sexton, 2017, Sharp, 2017). The software is open-source and available on GitHub[†] for all to use. Currently, the software helps maintainers annotate their Maintenance Work Order (MWO) data through a process called "tagging". The MWOs are inputted as comma-separated variable (.csv) files with UTF-8 encoding into the Nestor GUI and the user goes through the tagging process to create an annotated, tagged MWO dataset.

Brundage, Michael; Pavel, Radu. "Using Text Analytics Solutions with Small to Medium Sized Manufacturers: Lessons Learned." Paper presented at Model-Based Enterprise Summit, Gaithersburg, MD, US. March 30, 2020 - April 03, 2020.

Considering the potential of the technology, NIST works with industry to further refine and improve their solution through assessment trials with data from manufacturers that can help reveal opportunities for improvement both in technology efficiency and in robustness of its applicability. TechSolve is working with NIST to assess the capabilities of the technology using maintenance data from manufacturing organizations willing to learn more about the potential advantages and suitability of such technology for the annotation, organization and analysis of their maintenance work orders/logs.

2 Data Collection Process

TechSolve leveraged its network of manufacturers to identify and recruit companies considered good candidates for this effort. A list of companies was compiled and readied for engagements starting in January 2019. Twenty seven (27) companies were contacted and assessed. Due to confidentiality constraints, the name of the companies cannot be disclosed. However, a list of their NACIS (North American Industry Classification System) codes and main characteristics is provided in Table 1, below.

Table 1. NAICS code, approximate number of employees, and the annual revenue for the companies contacted during this project (companies listed in random order)

No	**NAICS Code**	**Employees**	**Annual Sales**	**Notes**
Company 1	332119 - Metal Crown, Closure, and Other Metal Stamping (except Automotive)	60	$19M	Provided data
Company 2	336350 - Motor Vehicle Transmission and Power Train Parts Mfg	189	$37M	Provided data
Company 3	326199 - All Other Plastics Product Mfg 333514 - Special Die and Tool, Die Set, Jig, and Fixture Mfg	42	$10M	Declined to provide data

Company 4	332111 - Iron and Steel Forging	16	$4.2M	Declined to provide data
Company 5	332710 - Machine Shops	30	$629K	Declined to provide data
Company 6	333111 - Farm Machinery and Equipment Mfg	72	$42M	Provided data
Company 7	442299 - All Other Home Furnishings Stores	10	$1.5M	No electronic files
Company 8	334413 - Semiconductor and Related Device Mfg	142	$48M	Concerned with trade secrets/confidentiality
Company 9	311612 - Meat Processed from Carcasses	360	$25M	Expressed interest but no follow-up from company
Company 10	332710 - Machine Shops (Primary)	30	$6.1M	No follow-up from company
Company 11	322211 - Corrugated and Solid Fiber Box Manufacturing (Primary)	15	$5.9M	Declined due to limited availability of data
Company 12	333413 - Industrial and Commercial Fan and Blower and Air Purification Equipment Manufacturing (Primary)	31	N/A	Did not express interest in the opportunity

Company 13	335999 - All Other Miscellaneous Electrical Equipment and Component Manufacturing (Primary)	127	$25M	Management did not consider they have significant equipment and associated maintenance to qualify for this project
Company 14	423830 - Industrial Machinery and Equipment Merchant Wholesalers (Primary)	200	$1.7M	Management did not want to pursue opportunity
Company 15	333618 - Other Engine Equipment Manufacturing (Primary)	13	N/A	Did not express interest in the opportunity
Company 16	333249 - Other Industrial Machinery Manufacturing (Primary)	6	N/A	Management admitted they do not yet collect data in electronic format
Company 17	336390 - Other Motor Vehicle Parts Manufacturing (Primary)	2	N/A	Too small; limited maintenance necessary
Company 18	332710 - Machine Shops (Primary)	235	$39M	Very slow to reply. Too busy to commit for opportunity
Company 19	333922 - Conveyor and Conveying Equipment Manufacturing (Primary)	800	$800 M	Did not express interest in the opportunity

Company 20	331524 - Aluminum Foundries (except Die-Casting) (Primary)	18	$2M	Committed to send data but stopped short of sending a file
Company 21	332812 - Metal Coating, Engraving (except Jewelry and Silverware), and Allied Services to Manufacturers (Primary)	21	$2.8M	Did not express interest in the opportunity
Company 22	811310 - Commercial and Industrial Machinery and Equipment (except Automotive and Electronic) Repair and Maintenance (Primary) 336390 - Other Motor Vehicle Parts Manufacturing (Secondary)	366	$76M	Did not express interest in the opportunity
Company 23	336412 - Aircraft Engine and Engine Parts Manufacturing (Primary)	100	$16M	Did not express interest in the opportunity
Company 24	333511 - Industrial Mold Manufacturing (Primary)	183	N/A	Expressed interest but declined sending files
Company 25	334418 - Printed Circuit Assembly (Electronic Assembly) Manufacturing (Primary)	170	$44M	Did not express interest in the opportunity

Company 26	332911 - Industrial Valve Manufacturing (Primary)	150	$50M	Expressed interest but declined sending files
Company 27	333912 - Air and Gas Compressor Manufacturing (Primary)	50	$1.3M	Expressed interest but declined sending files

Although some of the companies expressed interest in the program, they withheld from sharing data over confidentiality and trade secret concerns. Other companies specified that they did not collect data, although they are interested to implement "best practices" and appropriate software solutions, such as computerized maintenance management systems (CMMS) or enterprise resource planning (ERP) systems. Such companies expressed the need for help in identifying those "best practices" and appropriate software, and mentioned that they had difficulties identifying a solution suited for them due to lack of knowledge in the field. In other cases, the companies were collecting maintenance information but could only output it in a printed form and were unable to export files in excel or .csv file format.

3 Lessons Learned

The companies collecting data in electronic format typically used three types of software: 1) a non-maintenance specific database (e.g., access or excel), 2) a computerized maintenance management system (CMMS) (e.g., Fiix), or 3) more generic planning system, such as the Enterprise Resource Planning (ERP) system (e.g., Plex). The companies looking to upgrade their maintenance work order capturing routine to an electronic platform, expressed interest in best practices and available/recommended solutions on the market – e.g. what would be the criteria to choose a good system for us? What system would be best for us? The companies that were already in possession of a software platform were interested to know if their practices and the way they are collecting the information are aligned with best practices. In addition, the manufacturers were interested in what would be more efficient and relevant analytics and charting for the maintenance work order they collect.

Concerning the engagement with industry, it was found that manufacturers recognize that the health and maintenance of the manufacturing assets represent an important area of their operations. The importance of maintenance appeared to be directly proportional with the size of the company and the cost of the product being manufactured. Nevertheless, from the contacted manufacturers that were engaged in communications with TechSolve, approximately 30% did not seem to have computerized means of capturing the maintenance work order data. This has been justified either from the perspective of the size of the company (too small), or the limited complexity of the equipment (e.g. conveyors or welding equipment). A limited number of companies, approximately three, confirmed they are collecting maintenance work order data and expressed interest in providing data; however, they were unable to export the data in csv or excel format. The main findings of the interactions with the companies that were contacted are summarized below:

- Approximately 75% of the companies that were contacted for this initiative expressed interest to learn more. However, only 50% of the interested companies moved forward with phone conversations or in-person visits. Eventually, from all contacted companies, only seven expressed intent to provide files, of which only three provided files eventually. From the three organizations that provided files, one was very concerned with the confidentiality of the data to the point that all operator names, asset names, and their locations had to be coded/changed.

- The majority of the companies expressed concern with and asked for maintaining the confidentiality of the information. If data sharing would be desired and further publication of the results, then the data should be stripped of identifiers and the provider should approve its release before the publication of the data and/or of the results.
- The companies compliant with ISO 9001 and AS9100 were more likely to have maintenance work order data.
- The companies that have maintenance records typically use a CMMS or ERP system to capture the information, and the work orders are logged in a database.
- Concerning the use of maintenance work order data, some companies appeared to have software with various capabilities to generate graphs or run statistics. However, the full functionality of the software, or the actual use of the software capabilities was not presented to the TechSolve team. Nevertheless, all companies expressed the desire to get better analytics and ways of visualizing data that would allow them to better understand the maintenance activities and extract actionable information.
- Long term, the companies expressed interest in implementing monitoring systems that would enable condition-based maintenance approach, versus reactive or preventative approaches.
- With regard to the maintenance work order data, all companies expressed interest in a solution that would help them better organize that data, and were interested to learn more about NIST's efforts on guidelines, standardization, and technology development addressing the manufacturing assets maintenance
- Due to the variety of systems used to collect data, the files shown had various column headers. Although only a limited number of files have been provided, the sample covers the typical scenarios discussed with industrials that span from custom made spreadsheets with small number of columns in an Excel file or Access database or using CMMS files with very large number of columns
- The variety of data collection format or the confidentiality restrictions imposed initial organization and filtering of the data files to enable proper processing with the NESTOR software and sharing the information with the NIST team.

After the examination of the maintenance work order files provided by the manufacturers, the following observations became apparent:

- Each company seem to collect data in its own, custom way, based on internal needs and guidance from the software provider; however, no particular "best practices" were pointed out or noticed.
- The names of the columns describing the maintenance task and/or resolution was different across the processed files.
- There often are no accurate records of the actual time it took to repair one item.
- There is limited information of who noticed the fault and who repaired the fault.
- Some descriptions are too simplistic, others may only be understood by someone that is very familiar with the manufacturing asset.
- It is needs to be clear to what extent the information is used for analysis and potential improvement opportunities. In general, the users would like to be able to derive (with simplicity) additional analytics/charting facilitating actionable information.

4 Conclusions and Future Work

This paper discusses lessons learned with SMMs for implementing a text analytics solution for analyzing maintenance work orders. The biggest concern of the manufacturers was providing proprietary information for analysis, thus, anonymization methods are important to improve the overall text analytics process. Most manufacturers that collected data had analytics and visualizations, but wanted more intuitive tools. Lastly, these manufacturers expressed interest at more predictive capabilities for discovering maintenance needs in the future and overall, the manufacturers involved in this initiative expressed interest in efforts associated with PHM for manufacturing assets.

The manufacturers involved in this study agreed that it would be very helpful to have guidance on best practices and product selection criteria with regard to capturing and processing maintenance work order data. Standards in the space of text analytics for manufacturers are needed to aid manufacturers in performing this analysis themselves (Weiss, 2019; Sexton Standards, 2019). The natural language processing concept and the availability of a technology to be used for organizing and annotating their data was regarded positively.

Abstract

Maintenance and error logs for machines in manufacturing organizations are typically written as informal notes by operators or technicians working on the machines. These logs are written using a combination of common language and internally-used abbreviations and jargon. Due to inconsistencies in the terminology used during error logging and in identifying root causes of issues, the data needs to be cleaned before automated analyses can be effectively used. This can require a human to go through and clean/tag the data, disambiguate multiple terms, and sometimes assign additional tags to the data objects to aid automated classification. With some organizations storing over a million records of legacy maintenance report data, this is not entirely feasible. We introduce a visual analytic approach to help analysts sift through such heterogeneous datasets so that the inconsistent data can be tagged and categorized with minimum manual effort. Though such data typically includes metadata such as date, time, severity, machine IDs, etc., in this paper we focus on the manually-entered text descriptions. We use metrics such as word occurrence frequency and information-theoretic metrics to visually highlight common and uncommon issues and fixes that occur in the maintenance logs. We illustrate our approach with data from industry and discuss future research directions to address scalability, metadata, and other approaches for grouping similar logs.

1 Introduction

Machine error diagnosis and prediction is an issue in which the manufacturing industry heavily invests due to its direct effect on machine availability and throughput. Some organizations often maintain cross-functional teams of engineers with expertise covering design, analysis, and manufacturing to help identify and correct such problems quickly. With the growth of Smart Manufacturing and inexpensive and easy to use sensors, the demand for data-driven solutions for machine diagnostics and prognostics has increased. Organizations thus maintain machine maintenance and error logs to help analysts identify patterns and subsequently formalize root-cause analysis of errors. This, in turn, helps organizations plan preventive and predictive maintenance practices.

However, maintenance and error logs for machines can be both human- and sensor-generated. Human-generated logs are typically written as informal notes by technicians, who often use their own jargon when referring to machines, parts, and processes. These terms are frequently not consistent across groups in the organization, making it difficult for analysts to identify similar logs. Sensor-generated logs tend to be highly general and lack relevant and contextual machine-specific information. This data poses the opposite problem: sensors often have similar logs even though the logs are generated from a variety of machines for a variety of problems. Finally, both

Brundage, Michael; Chandrasegaran, Senthil; Zhang, Xiaoyu; Ma, Kwan-Liu. "Using Text Visualization to aid Analysis of Machine Maintenance Logs." Paper presented at Model-Based Enterprise Summit, Gaithersburg, MD, US. March 30, 2020 - April 03, 2020.

human- and machine-generated logs are sometimes inconsistent: humans are prone to errors in identification and labeling of symptoms and diagnoses, while sensors can have errors that may result in erroneous/missing logs or corrupted data.

There are ongoing efforts to clean, consolidate, tag, and categorize maintenance and error logs to aid automated diagnostics and prognostics. This cleaning effort requires manual tagging and repairing of data, disambiguation of terms, and assigning of specific terms to aid automated classification of the data. With some organizations storing over a million records of legacy maintenance report data, this is not entirely feasible without aid of tools. Recent semi-automated approaches have used the human in the loop along with natural language processing techniques to aid the above disambiguation and tagging. However, these methods still require making assumptions in the process of cleaning and categorizing data to extract useful and/or actionable information.

To aid human analysts in viewing large datasets, grouping them, and observing patterns and anomalies that aid labeling and categorization of data, we propose the use of visual analytics. The science of visual analytics supports data analysis using computational techniques and interactive visualizations [7]. Specifically, it allows analysts to forage for information, collect evidence, and form schema that leads to hypotheses, a process called the visual sensemaking loop [20]. In this paper, we introduce a visual analytics approach meant for aiding qualitative text analysis and categorization, and apply it to the analysis and categorization of machine log data. We focus on the manually-entered text descriptions and outline requirements that need to be fulfilled to manually analyze and tag such log data for better sensemaking. We describe how the visual analytic approach addresses these requirements, and illustrate the approach with a use-case scenario of maintenance log data from the industry. We close with recommendations for incorporating metadata and approaches for better scalability.

2 Background

With increasing emphasis on smart manufacturing and a push toward eliminating machine downtime, process monitoring, diagnostics, and prognostics have gained prevalence. The complexity and volume of data that needs to be sifted through to achieve this improved maintenance of equipment have prompted the application of visual analytics into product lifecycle management (PLM) [21]. This potential application area was anticipated almost at the inception of visual analytics when Keim et al. [17] suggested that visual analytics may be used in engineering for analyzing complex data that arise from design, production, and feedback from product use. In this section, we will provide a background on the complexity of making sense of machine error and maintenance logs, and the application of visual analytics to address this complexity.

2.1 Processing Human- and Sensor-Generated Logs

System log analysis—analysis of logs automatically generated by the system—is commonly used to track system resilience. It is also used in the case of failure for root cause analysis and in the case of preventive maintenance to identify recurring patterns, such as temporal, systemic, or even seasonal. Typical tools used for such analyses use automated analyses and seldom resort to visualization approaches.

Automatic log analysis tools [8, 13, 14, 16, 19, 30] typically use a range of analyses such as correlation analysis, signal analysis, pattern mining, correlations, resilience analyses at the application level, and spatial/temporal event analysis. For instance, HELO (Hierarchical Event Log Organizer) [14], an event log mining tool, extracts event formats by pattern-mining log files from large-scale supercomputers, using predefined message templates. A model-based approach is used by ELSA (Event Log Signal Analyzer) [13], a toolkit for event prediction. It models the normal flow at a stable event state, and in the event of system failure, tracks the abnormal flow of events using a combination of data mining and signal processing.

There exist visualization-oriented tools for tracking and analyzing machine logs, but these are few, and most of them use relatively basic visualizations. For instance, LogMaster [12] and LogAider [8] use generic visualizations for mining event correlations. LogAider reveals potential correlations that include across-field (through probabilistic analysis of fields), spatial, and temporal correlations. LogMine [16] is a framework for the unsupervised, scalable end-to-end one-pass analysis of large-scale, heterogeneous logs. LogDiver [19] supports lossless data compression, models application failure paths, and cross-validates models and/or results of analyses. More recently, machine learning approaches such as DeepLog [10] have been introduced. Specifically, Deeplog uses a deep neural network model which uses stacked Long Short-Term Memory (LSTM) to detect anomalies, and dynamically updates the models to accommodate for changing log patterns.

The idea of using visualization and visual analytics for monitoring and diagnostics in factories is a relatively new research area. Recent work includes ViDX [29], a visual analytic system for historical analysis and real-time monitoring of factory assembly lines. ViDX uses visualization principles to create outlier-aware aggregate representations of process data and employs user-steerable algorithms for outlier detection. La VALSE [15] is a scalable log visualization tool that uses multiple visualizations for interactive event analysis based on multiple logs. ViBR [5] is a system that visualizes bipartite relationships using a minimum description length principle to aggregate the relationships. The system has been successful in log analyses that include vehicle fault diagnostics by identifying co-occurring faults, comparing faults that co-occur in different vehicle clusters, and comparing faults across vehicles with shared properties.

2.2 Visual Analytics for Text Data

Root cause analysis and preventative action is a crucial area of interest to the manufacturing industry, necessitating logging maintenance and error log data, as discussed earlier. Approaches to parse this data for an automated or even semi-automated solution for diagnosis or prognosis has typically involved knowledge bases [4], manual "tagging" systems assisted by natural-language text parsing support [23][1], and information extraction methods applied to maintenance logs [24, 25]. While our approach also proposes the use of natural language processing (NLP) techniques, we use visual analytics to keep the human in the loop for correcting and tagging the parsed data through the visual representation of and interaction with the data processing results.

Defined as "the science of analytical reasoning facilitated by interactive visual interfaces" [7, p. 4], visual analytics uses visualization support throughout the *process* of analyzing (typically unstructured) datasets. In other words, visual analytics makes "*our way of processing* data and information transparent for an analytic discourse." [17, p. 155]. At the center of all visual analytic systems is the analyst—the human in the loop—who is aided by the system in combining complex datasets, collect evidence, identify correlations, and develop insights. At every stage of this process, the analyst is aided by a combination of visualizations and algorithms.

Visual analytics support for text analysis often focuses on analyzing connections between multiple sources of text, from intelligence reports to news articles to even unstructured social

[1] An open source tool for this process, called Nestor is available here: https://www.nist.gov/services-resources/software/nestor

media texts such as tweets and posts on forums. Some of the earliest text analytic tools were designed for intelligence analysis. Of these, Jigsaw [26] is one of the more prominent and still-used tools. It identifies connections between documents using entities in text data and metadata, highlights these connections to the user, and allows the user to reorganize this information to aid their insight-gathering process. It uses coordinated views such as graphs, calendars, and document overviews, all of which can be filtered and edited by the analyst to identify potential security threats. Other approaches make more use of metadata, such as time-stamps. For instance, Tiara [28], a system for temporal analysis of text documents, is used to analyze data relevant to emails, instant messages, and even patient records. It uses statistical text analysis techniques such as topic modeling to categorize the document collections thematically based on their content, and shows the variation of themes over time. It also allows users to select and examine any theme-based collection in detail, across and at defined time intervals. Other topic-modeling-based text analysis tools include HierarchicalTopics [9], which as the name suggests, uses a hierarchical topic modeling algorithm to identify themes within themes. It combines this with a temporal view showing the evolution of topics over time and allows users to explore and edit topics hierarchically. Other approaches are more suitable for single or very few, but large documents such as historical texts. An example is VariFocal Reader [18], which uses automated annotations and topic modeling to reveal thematic and structural patterns that are useful when analyzing large documents.

In this paper, we adapt our prior work that uses visual analytics with a dominant text visualization component that we developed to aid qualitative analysis of text data [6]. We do this by helping the user identify concepts of interest, categorize associated text, and use their custom categorizations to further analyze the text. We illustrate the suitability of this approach in helping users identify patterns and inconsistencies in any terminology used in machine logs. This will help analysts create useful categorizations of machine logs that will help problem diagnosis, and to subsequently create machine learning models.

3 Design

While individual fields of machine maintenance logs may vary between organizations, they usually have some common features, such as the machine identifier, problem description, the description of the remedial action taken, and the dates on which the problem was reported and closed. While it is possible to “group” these logs by some of the features such as machine ID, it becomes less obvious to group the logs based on the type of problem, the type of solution, or patterns in the dates on which they tend to occur. Such categorization often requires the expertise and insight borne by experience. The goal of our approach is to help such experienced personnel sift through and examine large volumes of data without needing to examine each record closely.

3.1 Design Rationale

We draw from research in visual analytics—“the science of analytical reasoning facilitated by interactive visual interfaces” [7, p. 421]—to design an appropriate interface for our approach. We identify the following requirements for prognostics of machine maintenance.

R1 Identify Common Occurrences: One of the main requirements in machine maintenance log analysis is to identify recurring problems that—while individually may not cause significant downtime—through their frequency of occurrence cost significant resources in repairing and downtime. These may not always be linked to the same kinds of machines, or even have the same descriptions.

R2 Identify Patterns in Occurrences: Some maintenance issues may manifest as several problems that occur together or in succession to cause a much more significant issue than the individual reports suggest. Other issues may occur only in some kinds of machines, or when some operators are working certain machines, or even certain days of the week, month, or year. Combined with the earlier-identified issue of inconsistency in the descriptions, the need to identify patterns in maintenance logs is only matched by the challenges posed in identifying such patterns.

R3 Identify Anomalies: When taking stock of problems that occur over a long period, there may be a need to identify rare, yet significant problems. These could refer to the problems themselves, or their rare occurrence in a specific machine or part. Such anomalies could be lost to cursory scrutiny when looking for commonly-occurring problems, but if ignored could escalate over time.

R4 Allow Manual Categorization: Identifying patterns, anomalies, and common issues is often not a single-stage process. The relevant analyst or domain expert may need to tag certain groups of problems with a descriptor, add a memo for continued monitoring, or even need verification from a colleague.

R5 Aid Iterative Analyses: Once manual categories are identified, the system should allow the user to filter the existing data using these categories, which will further reveal commonly-occurring keywords.

3.2 Interface Design

Based on the above rationale, we decided on a primarily text-based visualization approach, shown in Fig.1. The visualization is largely extended from our prior work on developing a visual analytic approach to aid qualitative text analysis [6]. Since our focus in this work is on the content (and less so on the metadata), the text component of the data is shown in the central panel. These descriptions are logged by the machine technicians and/or operators and include reports that can describe the problem, the solution, or both. This being a preliminary approach that examines how the existing qualitative analysis system can be used for analyzing patterns in the data, we do not incorporate temporal or other metadata such as machine IDs, operator IDS, severity or cost-related information.

The text shown in the central column follows a "skim formatting" [3] where the font weight for each word corresponds to a predefined criterion. In our case, we use the word information content [22], which is based on the assumption that the less frequently-used a word is in a corpus, the more information it contains. For a more focused application, we can use analyst-defined metrics that give greater weight to keywords associated with rare and severe issues (requirement **R3**) in conjunction with—or instead of—such generic metrics. The information content metric can also be computed on a specific domain, such as existing corpora of operation or repair manuals.

On the right is a word cloud that is automatically computed from the uploaded text. It is scaled proportional to frequency and the words are arranged sequentially in descending order of frequency. The skim formatting described earlier is applied to the word cloud as well. Selecting a set of text in the central column will filter the word cloud to reflect only the selection. The word

Figure 1: The interface adapted from our earlier work in Chandrasegaran et al. [6], shown here with approximately 600 records of maintenance logs for HVAC (heating, ventilation, and air-conditioning) systems at a specific site.

cloud can be used to identify commonly-occurring terms in the maintenance logs (requirement **R1**).

A set of checkboxes on the bottom are used to highlight parts of speech or named entities (person, place, names). These can be useful to highlight when the analyst is looking for logs that mention geographic locations, or when the names of operators/repair persons are mentioned.

An overview pane on the left shows several overview visualizations. The first is a "text overview" that simply gives a mini-map view of all the records in the collection. It also shows the position of the current record of interest (as an orange bar) corresponding to the text in the central panel on which the mouse currently hovers. As shown in Fig. 2, selecting a word in the word cloud shows all its occurrences in the main text as well as in the overview panel (requirement **R2**).

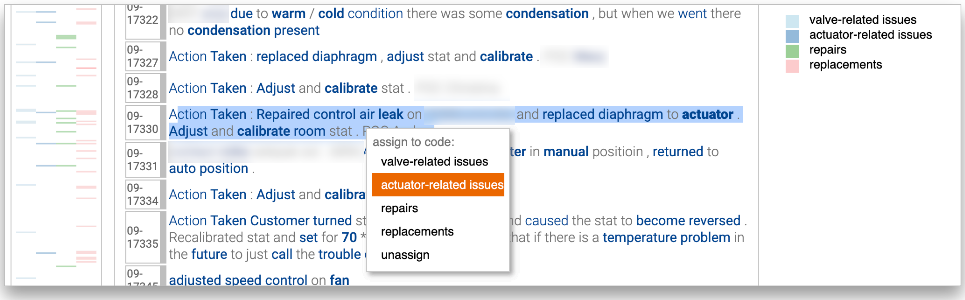
Figure 2: A detail of the interface showing how selecting a word from the word cloud (right) highlights all records where that word occurs, in both the detailed text view and the text overview panes.

Additional overviews include an information content heatmap that provides an overview of the skim formatting described earlier, parts-of-speech/named entity tag overviews, and an overview of user-applied categories. These categories are specified in an input field on the top right part of the interface (Fig. 1). Once the categories are specified, they can be assigned to individual fields or groups of sequential fields as shown in Fig. 3 (requirement **R4**). Assigning a category to one or more fields of text updates the overview visualization immediately to the left of the text display. Once the categories of interest have all been assigned, co-occurring problems and—once temporal data can be integrated—temporal and recurring patterns can be visually identified, and these co-occurrences can be further tagged and newer categories assigned to them iteratively (requirement **R5**).



09-17322 [redacted] due to warm / cold condition there was some condensation , but when we went there no condensation present

Figure 3: Detailed view of the text and code (category) definition and overview fields showing the categories assigned. A category is assigned by selecting a block of text and assigning a category from a drop-down menu shown above. When a category is assigned to a text, it updates the overview visualization on the left.

4 Implementation

As explained in Section 3, the system presented here is adapted from our earlier work directed at qualitative text analysis [6]. The system is implemented as a web-based application in HTML5 and JavaScript, with a Node.js backend where the data is uploaded and processed to be visualized on the browser. Most of the language processing operations, including tokenization, parts-of-speech tagging, named-entity recognition, and information content measurement are performed at the server end using Python's Natural Language Toolkit [1], and the Stanford POS [27] and NER [11] taggers. At the front end, the interactive visualizations are created using the D3.js [2] JavaScript library. The code is available as open-source[2].

5 Use Case Scenario

To illustrate the system in action, we present a use-case scenario with a dataset of 600 records concerning the maintenance of an HVAC (heating, ventilation, and air-conditioning) system of a set of office buildings. Since our focus is primarily on the text descriptions, we remove all temporal and machine/operator-related metadata before uploading it into our system. Refer back to Fig. 1 for an overview of this dataset when processed and viewed in the system.

We consider an analyst—a maintenance specialist interested in identifying commonly-occurring patterns where repair and/or replacement is required. Once the analyst loads the data, they take a closer look at the word cloud view (Fig. 1) and see that the more commonly-occurring terms seem to be generic terms—mostly verbs—that appear to be concerned with

[2] https://github.com/senthilchandrasegaran/textplorer/

remedial action, such as “taken”, “found”, “checked” etc. The letter “f” also appears frequently, and upon closer inspection, is revealed to be aggregated from all the mentions of temperatures in Fahrenheit. The first *item*—a component that finds frequent mention—is “valve”. Selecting this word in the cloud immediately highlights all its occurrences in the text and the overview (see Fig. 2). The highlights in the overview visualization show that “valve” does indeed appear fairly uniformly across the maintenance records. The analyst is curious if most of the valve-related issues also relate to actuators. They select “actuator” in the word cloud, but realize that they need to see co-occurrence patterns, i.e. cases where valve-related issues co-occur with actuator-related issues.

The analyst decides to create a category called “valve-related issues”, and another called “actuator-related issues”. They manually select every field that shows the occurrence of the word “valve” and assign the category “valve-related issues” to it. They follow a similar process for the actuators (as shown in Fig. 3). They are also curious to see the distribution of valves/actuators repaired and those that are replaced. They create two more categories called “repairs” and “replacements” and through a similar process, continue assigning categories.

Figure 4: Detail view of the categorization overview showing co-occurrences of the manually-created categories.

Once the categories are assigned, they inspect the co-occurrences of these categories closely (see overview in Fig. 1 and detailed view in Fig. 4). A close inspection of the co-occurrences shows the analyst that most valve- and actuator-related issues are repaired (with a few replacements), and that there are few cases where valve-related problems co-occur with actuator-related problems. The analyst continues with more inclusive terms for repair such as “fixed”, “removed”, “cleaned” and so on, assigning the same category of “repair” to them, to hunt for more patterns.

6 Conclusion

Visual analytics has been shown to be the best solution for sense-making when it comes to semi-structured data such as maintenance logs. In this paper, we illustrate how a visual analytics approach that was designed for qualitative text analysis can be used for analyzing the raw text from machine maintenance logs. Specifically, we identified requirements such as identifying common occurrences, patterns and anomalies, and the need for manual categorization and iterative analyses that an analysis tool should address for use in machine maintenance logs. We made the argument for how a visual analytic approach—which combines automated analysis techniques with human-in-the-loop interfaces—is suitable to address such requirements. We described our interface and with a use-case scenario, illustrated how the system can be used to identify similar maintenance logs, manually assign categories to these entries, and use category co-occurrence to form further insights.

Our current approach was illustrated with a machine log dataset with around 600 records. For our future work, we plan to extend our approach to be more scalable, as machine logs can extend to thousands or even millions of records. While visual representations such as word clouds and information-content maps are scalable, text overview and detail displays need to be redesigned to scale to such large records. One approach we plan to use is to incorporate machine log metadata to separate logs that may be unrelated (and can thus be examined separately). We also plan to use dimensionality-reduction techniques that can make use of metadata to automatically suggest clusters based on similarity metrics, or weights that can be derived through discussions with analysts. We will iteratively refine our approach through longitudinal studies with technicians experienced in machine maintenance for better environmental validity.

Abstract

The polarization switching speed of ferroelectric (FE) hafnium zirconium oxide (HZO) is studied with the device size down to sub-μm in lateral dimension. Ultrafast measurement of transient switching current on metal-ferroelectric-metal (MFM) device with a crossbar array or a single crossbar structure is performed to analyze the switching dynamics. A record fast polarization switching of 360 ps is achieved for 15 nm thick HZO with 0.1 μm^2 crossbar array device structure. The observed record switching speed is found to be limited by domain wall propagation speed in the nucleation limited switching process. It is further verified after significant reduction of RC delay of the devices and the implementation of crossbar array structure.

Introduction

Ferroelectric hafnium oxide [1] has been widely studied as a promising CMOS-compatible material in commercial ferroelectric device applications. The remarkable endurance and retention performance [2] make FE HfO$_2$ suitable for non-volatile ferroelectric random-access memory (FeRAM) and ferroelectric FET (FeFET) devices. However, fast operational speed [3-11] is crucial for FE HfO$_2$-based memory to replace the current commercial memory products. Previous works [3-5] demonstrated that switching speed of FE HfO$_2$ can reach sub-ns regime in a single MFM device with an area of ~6 μm^2. Direct fast speed measurement on a much smaller size MFM capacitor is challenging due to small capacitance and high access resistance of metal contacts.

In this work, we fabricated crossbar array devices with 100-200 nm in size along with single crossbar devices with similar total areas for comparison. We performed transient current measurements and analysis with an ultrafast pulse measurement setup. Polarization switching dynamics in single and array crossbar devices is studied and quantitatively characterized. By applying nucleation limited switching (NLS) model [12] to the net switching current, a record fast switching time of 360 ps is obtained from an array of 0.1 μm^2 crossbar device. It confirms experimentally that the domain wall propagation is the limiting factor for the measured hundreds of ps polarization switch speed instead of the RC delay.

Experiments

The devices were fabricated on an insulating sapphire substrate to exclude the impact of parasitic capacitance from the substrate in fast pulse measurements. The fabrication process is described in Fig. 1. Sputtered Au/W metal stack was used as bottom electrode to achieve small series resistance. Anisotropic wet etch of gold was performed after the dry etch of tungsten to prevent possible short circuit between the top and bottom electrodes. The bottom Ti/Au contact pads were formed by e-beam evaporation for a better contact resistance. The growth of 15 nm thick HZO was completed by atomic layer deposition (ALD) at 200 °C [3]. A 20 nm thick tungsten layer was sputtered after HZO deposition, followed by a rapid thermal annealing (RTA) in nitrogen at 500 °C for 1 min. The top Ti/Au electrodes were fabricated by a lift-off process. Dry etching of top W layer was performed using Ti/Au as the hard mask to realize device isolation.

In order to precisely measure the polarization current flowing through a very small size capacitor, crossbar array structure is used to collectively measure a large number of individual small capacitors at the same time. Crossbar array devices consist of ten 1 μm-wide metal electrode stripes at the bottom and twenty 100 or 200 nm-wide metal stripes on the top, as seen in Fig. 2(a). Single crossbar devices with large sizes but same total areas, as shown in Fig. 2(b) and Fig. (3), are designed as control devices for comparison. Fig. 4 shows the cross-section schematic and layer details of the MFM structure. All devices show strong ferroelectricity in polarization versus electric field (P-E) as illustrated in Fig. 5. Positive-up-negative-down pulse sequences, as shown in Fig. 6, are generated by an arbitrary pulse generator to perform direct measurement of transient current. The circuit diagram of the ultrafast pulse measurement setup and established methodology can be found in [3]. Signal reflection is efficiently suppressed by applying impedance matched probes, 50 Ohm terminations and the pick-off tee.

Results and Discussion

Fig. 7 shows a representative PUND transient current measurement. Both pulses share the same input voltage waveform with a 200 ps rise time and the corresponding transient current responses of the switching (first) pulse and non-switching (second) pulse are measured. The transient current I_{pulse1}, I_{pulse2} and the net switching current I_{FE} are plotted in Fig. 8 for a crossbar array device with 15 nm thick HZO as a representative case. The switching current is extracted by the subtraction of I_{pulse1} and I_{pulse2}. The time response of ferroelectric polarization switching charge can be determined by integrating the corresponding net switching current as seen in Fig.9. The FE polarization switching follows the NLS model, which can be described by $P = P_S(1 - \exp(-\left(\frac{t}{t_0}\right)^2))$ in thin film. The t_0 in NLS model is a characteristic switching time constant [10-11] with a record fast 360 ps on 0.1 μm^2 and 640 ps on 0.2μm^2 array devices with 15 nm HZO.

These newly fabricated crossbar devices have lower series resistance compared to unoptimized devices in [3]. Fig. 10 shows the comparison of (a) switching speed and (b) RC delay between this work and ref [3]. The optimized RC delay is 2 magnitudes smaller and falls in a few ps regime, while there are only minor differences in terms of switching speed for devices with comparable area. Therefore, the measured switching speed by NLS model is clarified as FE material property instead of being overwhelmed by device RC delay.

Fig. 11 presents the switching speed of crossbar array and single crossbar devices with comparable total area. It is clear that smaller size MFM with array structure boosts switching speed, while keeping the total area large enough for accurate current measurements. The switching speed in smaller array devices is faster while the parasitic effect is similar for both structures. This is because the switch speed is determined by domain wall propagation speed in FE HZO.

Conclusion

Sub-μm crossbar array FE HZO MFM devices were fabricated and the polarization switching of these devices is studied. Record fast polarization switch speed of 360 ps is obtained. The work unveils that domain wall propagation speed in HZO is the limiting factor for switch speed and more aggressively scaled devices will offer much faster switch speed. The work is supported by SRC JUMP ASCENT Center.

Computational Process Control Compatible Dimensional Metrology Tool: Through-focus Scanning Optical Microscopy

Ravi Kiran Attota

Ravikiran.attota@nist.gov

Abstract—**Using only two derived numbers based on a reference library, this paper shows how through-focus scanning optical microscopy (TSOM) is compatible with computational process control (CPC) for the complete 3D shape process monitoring of nanoscale to microscale targets. This is demonstrated using three types of targets with widths (CDs) and depths ranging from 50 nm to 1.0 μm, and 70 nm to 20 μm, respectively. TSOM is a high-throughput, low-cost and in-line capable optical dimensional metrology method ideally suited for high-volume manufacturing (HVM), complementing other widely used metrology tools.**

Keywords—TSOM, process control, three-dimensional shape, optical microscope, through-focus, Computational Process Control

I. Introduction

As the applications of nanotechnology and micro-technology become widespread, usage of three-dimensional (3D) structures is increasing [1-10]. In addition, increased complexity and the resulting big data during manufacturing processes have resulted in a new paradigm: Computational Process Control (CPC) [11]. In the CPC environment, in-line metrology tools are highly desirable. Here, we present the through-focus scanning optical microscope (TSOM) as a dimensional metrology tool that is ideally compatible with CPC, and has many favorable attributes as a metrology and process control tool [12-21].

II. TSOM

TSOM is a method that collects and exploits the entire through-focus optical intensity information in 3-D space using a conventional optical microscope. Developments in image acquisition techniques have significantly reduced the acquisition time for a set of through-focus images so that it can be as fast as a single conventional microscope image, making TSOM suitable for HVM [22]. A vertical cross-section extracted from this 3D data results in a TSOM image. D-TSOM images are generated by taking a pixel-by-pixel difference between images of two separate targets. D-TSOM images can reveal sub-nanometer differences between nominally identical targets. The color (intensity) patterns of D-TSOM images are usually distinct for different types of parameter changes and serve as a “fingerprint” for different types of parameter variations, while remaining qualitatively similar for different magnitude changes in the same parameter. The magnitude of the optical content of D-TSOM images is proportional to the magnitude of the dimensional differences. The Optical Intensity Range (OIR, the difference between the maximum and the minimum optical intensity, multiplied by 100), provides a quantitative estimate of the difference between the two TSOM images. The utility of D-TSOM is that the color pattern of the D-TSOM image is an indicator of the difference in 3D shape, while the magnitude of the OIR scales the dimensional difference between the two targets.

III. Experiments

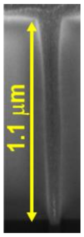

Fig.1

As a demonstration of the application of TSOM to high-aspect ratio (HAR) structures, in an SiO_2 layer on a 300 mm Si substrate with nominally 100 nm CD, 1100 nm depth, and 1000 nm pitch were studied, using a horizontal field-of-view (FOV) of 50 μm. A typical focused ion beam (FIB) cross-sectional view of the HAR target is shown Fig. 1. A mosaic of D-TSOM images obtained for the entire wafer (with central die as a reference target) is presented in Fig. 2(a). From this, four major types of D-TSOM image patterns (Fig. 2(b)) can be identified with their corresponding FIB cross-sectional profile differences as shown in Fig. 2(c).

IV. Process control results

If one considers the information available in Figs. 2(b) and 2(c) as a library, a simple process monitoring procedure can be proposed as shown in Figs. 3 and 4, based on the following rules selected for this demonstration. If the OIR of the D-TSOM image is more than 12, reject the target, as the dimensional differences are more than the tolerable limits. On the lower side, if the OIR of the D-TSOM image is less than 7, accept the target, as the dimensional differences are within the acceptable

Attota, Ravikiran. ”Computational Process Control Compatible Dimensional Metrology Tool: Through-focus Scanning Optical Microscopy.”
Paper presented at 2020 31st Annual SEMI Advanced Semiconductor Manufacturing Conference (ASMC), Saratoga Springs, NY, US. August 24, 2020 - August 26, 2020.

level. If the OIR value is in between 7 and 12, accept the production target if the profiles are symmetric (T1 and T3) and reject if the profiles are asymmetric (T2 and T4). Selection of the rules depends on the desired outcome from the fabrication.

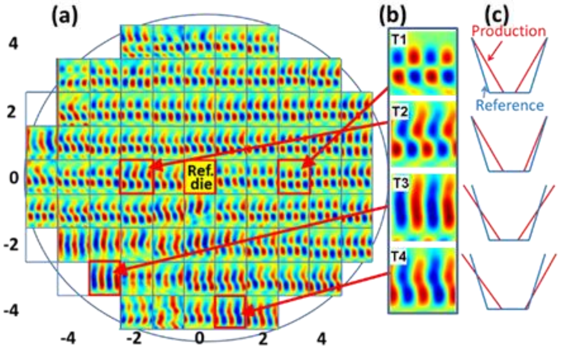

Fig. 2. (a) A mosaic of the D-TSOM images obtained by subtracting the TSOM image of the central reference target from the TSOM images of the targets in the other dies (with color scale bar set to automatic). (b) Four major types (T1, T2, T3 and T4) of D-TSOM image color patterns are identified. (c) *Schematic cross-sectional profile differences corresponding to (b) obtained from FIB cross-sectional analysis.* Nominal values: pitch = 1,000 nm, CD = 100 nm, and depth = 1100 nm. Illumination wavelength = 520 nm, numerical apertures (NA) = 0.75, illumination NA (INA) = 0.25.

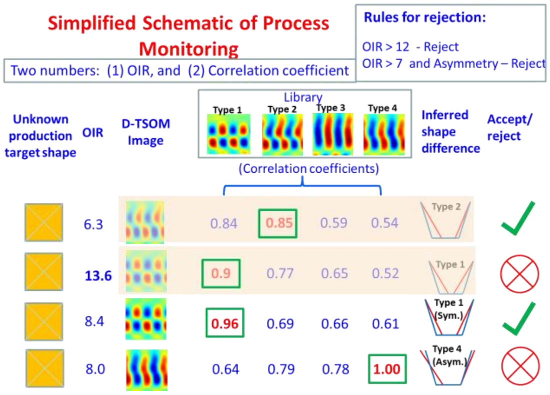


Simplified Schematic of Process Monitoring

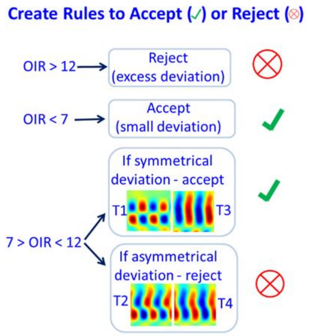
Two numbers: (1) OIR, and (2) Correlation coefficient

Rules for rejection:
OIR > 12 - Reject
OIR > 7 and Asymmetry – Reject

Unknown production target shape	OIR	D-TSOM Image	Type 1	Type 2	Type 3	Type 4	Inferred shape difference	Accept/ reject
	6.3		0.84	0.85	0.59	0.54	Type 2	✓
	13.6		0.9	0.77	0.65	0.52	Type 1	⊗
	8.4		0.96	0.69	0.66	0.61	Type 1 (Sym.)	✓
	8.0		0.64	0.79	0.78	1.00	Type 4 (Asym.)	⊗

Fig. 3. Proposed TSOM-based automated 3-D-shape process control method. The selected test production targets are considered to have unknown 3-D-shape profile (column 1). Comparing the correlation coefficients between the D-TSOM images of the test targets and the library provides the best match (green boxes) from which the possible 3-D shape difference type can be inferred (column 8).

Fig. 3 demonstrates that based on the type of 3-D shape difference, and the magnitude of the dimensional difference, the process control decision of accept/reject can be made based solely on the two numbers: OIR and correlation coefficient with minimal or no human intervention to make it suitable for CPC. A library and a customized rule set must be created beforehand. Note that the process control decision is automatically made on the very optical tool during measurement using the previously mentioned numbers. This method nearly eliminates the need for post-processing.



Create Rules to Accept (✓) or Reject (⊗)

OIR > 12 → Reject (excess deviation) ⊗

OIR < 7 → Accept (small deviation) ✓

7 > OIR < 12 → If symmetrical deviation - accept (T1, T3) ✓

7 > OIR < 12 → If asymmetrical deviation - reject (T2, T4) ⊗

Fig. 4. This schematic shows that only two numbers are needed to accomplish the 3D-shape process control with TSOM. OIR to determine the magnitude of the dimensional deviation, and correlation coefficient to determine the 3D shape similarity.

A second example is shown in Fig. 5 for substantially smaller, isolated line targets with nominal sizes of 70 nm height and 50 nm width [17]. In this case also, since TSOM can identify different types of 3D-shape differences (down to 0.8 nm), the similar procedure presented above can be applied for process control.

	(a)		(b)		(c)		(d)	
LH	72.2	73.0	73.0	71.0	75.7	72.2	71.3	70.2
TW	24.2	24.0	24.0	21.8	27.2	24.2	16.3	11.4
MW	55.3	50.5	50.5	49.3	53.2	55.3	46.7	39.3
BW	63.0	58.2	58.2	58.3	60.7	63.0	55.2	46.4

Fig. 5. Experimental 3D-shape analysis of isolated lines for process control. (a,b,c,d) CD-AFM-measured plots showing different types of 3D-shape differences. (a`,b`,c`,d`) are the corresponding D-TSOM images producing noticeably different color patterns. CD-AFM measured values of line height (LH), top width (TW), middle width (MW) and bottom width (BW, in nanometers) are shown in order for the pair of lines. Nominal height = 70 nm, and width = 50 nm.

A third example for a larger through-silicon via (TSV) target with a nominal diameter and depth of 1 µm and 20 µm respectively, is shown in Fig. 6. The similarity of the two D-TSOM images on the right indicates a similar pattern of dimensional differences. In this case also, the similar procedure presented above can be applied for process control using a library.

V. POTENTIAL APPLICATIONS

TSOM is a high-throughput, low-cost, nondestructive, robust, and easy-to-use 3D shape metrology method. It has 1 nm or better measurement resolution[14] for target sizes (depths/heights) ranging from sub-nanometer to over 100 um (over five orders of magnitude in size range). One of the unique characteristics of the TSOM method is its ability to reduce or eliminate optical cross correlations between different parameters, resulting in reduced measurement uncertainty. All the targets within the field-of-view can be analyzed simultaneously, including isolated structures with random shapes, repeated and non-repeated structures, and a variety of target materials. TSOM complements other tools by filling in some gaps in capabilities.

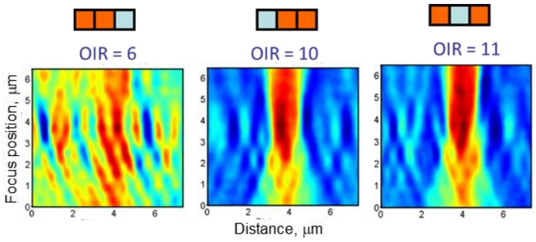


Fig. 6. Measured D-TSOM images representing the pairwise differences between TSOM images of three TSVs in three different dies. Nominal diameter = 1 µm, and depth = 20 µm.

TSOM has been successfully employed for many applications. Demonstrated applications of TSOM include critical dimension (linewidth), overlay (including over 10 um separation), patterned defect detection and analysis, FinFETs, nanoparticles (including soft-nanoparticles), photo-mask, thin-films (less than 0.5 nm to 10 nm) thickness, 2D materials, through-silicon vias (TSVs), high-aspect-ratio (HAR) targets, MEMS/NEMS devices, micro/nanofluidic channels, flexible electronics and micro-resonators/frequency combs. Other potential applications include three-dimensional shape process monitoring of self-assembled nanostructures, waveguides, and nanoimprint targets. Numerous industries benefit from the TSOM method —such as the semiconductor industry, flexible electronics, quantum science, photovoltaics, display, nanotechnology, MEMS, NEMS, biotechnology, data storage, and photonics.

VI. SUMMARY

Here we have briefly presented potential applications of TSOM using a reference library. TSOM could fill some gaps by satisfying the HVM metrology needs of 3-D structures for which 3-D shape process control/monitoring is needed, complementing other widely used metrology tools. We also show that TSOM as presented here has a high compatibility with computational process control.

Abstract

While classification of arbitrary structures in high dimensions may require complete quantitative information, for simple geometrical structures, low-dimensional qualitative information about the boundaries defining the structures can suffice. Rather than using dense, multi-dimensional data, we propose a deep neural network (DNN) classification framework that utilizes a minimal collection of one-dimensional representations, called *rays*, to construct the "fingerprint" of the structure(s) based on substantially reduced information. We empirically study this framework using a synthetic dataset of double and triple quantum dot devices and apply it to the classification problem of identifying the device state. We show that the performance of the ray-based classifier is already on par with traditional 2D images for low dimensional systems, while significantly cutting down the data acquisition cost.

1 Introduction

Deep learning, with its remarkable progress in recent years [1, 2], is ripe for applications in physics [3]. A particular instance having general applicability to physical problems is the classification of arbitrary convex geometrical shapes embedded in an N-dimensional space [4]. Having a mathematical framework to understand this class of problems and a solution that scales efficiently with the dimension N is essential. With increasing effective dimensionality of the system, including parameters and data, determining the geometry with measurements across the full parameter space may become prohibitively expensive. However, as we show, qualitative information about the boundaries defining the structures of interest may suffice for classification.

We propose a new framework for classifying simple high-dimensional geometrical structures: *ray-based classification*. Rather than working with the full N-dimensional data tensor, we train a fully connected DNN using one-dimensional representations in $\mathbb{R}^N$, called "rays", to recognize the relative position of features defining a given structure. We position the boundaries of this structure relative to a point of interest, effectively "fingerprinting" its neighborhood in the $\mathbb{R}^N$ space. The ray-based classifier is motivated primarily by experiments, particularly those in which sparse data collection is impractical. Our approach not only reduces the amount of data that needs to be collected, but also can be implemented *in situ* and in an online learning setting, where data is acquired sequentially.

Third Workshop on Machine Learning and the Physical Sciences (NeurIPS 2020), Vancouver, Canada.

Zwolak, Justyna; Taylor, Jacob; Kalantre, Sandesh; McJunkin, Thomas; Weber, Brian. "Ray-based classification framework for high-dimensional data." Paper presented at Thirty-fourth Conference on Neural Information Processing Systems, Vancouver, CA. December 05, 2020 - December 12, 2020.

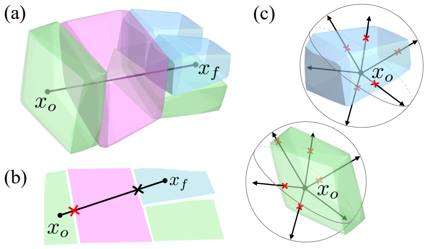

Figure 1: (a) Visualization of a ray $\mathfrak{R}(x_o, x_f)$ from x_o to x_f in $\mathbb{R}^3$. Different colors of polytopes represent different classes. (b) A side-view of the polytopes with two features marked along the ray. The red mark denotes a critical feature. (c) Visualization of the M-projection from point x_o with 6 rays (denoted by black arrows) for two different polytopes in $\mathbb{R}^3$. Note that both M-projections include a ray that does not have a critical feature.

We test the proposed framework using a modified version of the "Quantum dot data for machine learning" dataset [5] developed to study the application of convolutional neural networks (CNNs) to enhance calibration of semiconductor quantum dot devices for use as qubits [6]. Tuning these devices requires a series of measurements of a single response variable as a function of voltages on electrostatic gates. As the number of gates increases [7, 8], heuristic classification and tuning becomes increasingly difficult, as does the time it takes to fully explore the voltage space of all relevant gates. The specific geometry of the response in gate-voltage space corresponds to the number and position of populated quantum dots, which is valuable information in the process of tuning of these systems.

Previous work has shown both theoretically [9] and experimentally [10] that an image-based CNN classifier for 2D volumes, *i.e.*, solid images, combined with conventional optimization routines, can assist experimental efforts in tuning quantum dot devices between zero-, single- and double-dot states. Here, we consider a double- and triple-dot system. We show that using ray-based classification, the quantity of data required (and thus the time required) for identifying the state of the quantum dot system can be drastically reduced compared to an imaged-based classifier.

2 A Framework for Ray-Based Classification

Consider Euclidean space $\mathbb{R}^N$ with its conventional 2-norm distance function d, and a polytope function $p : \mathbb{R}^N \to \{0, 1\}$. The set of points where $p(x) = 1$ constitutes the boundary of a collection of polytopes. For example, a polytope function producing a square in $\mathbb{R}^2$ centered at the origin is $p(x_1, x_2) = \{1 \text{ if } |x_1| + |x_2| = 1; 0 \text{ elsewhere}\}$, where $(x_1, x_2) \in \mathbb{R}^2$. In our quantum dot applications a value of $p = 1$ indicates the location where an electron is transferred in or out of a dot.

Definition 1 (Rays). *Given $x_o, x_f \in \mathbb{R}^N$, the **ray** $\mathfrak{R}_{x_o,x_f}$ emanating from x_o and terminating at x_f is the set* $\{x \,|\, x = (1-t)x_o + tx_f, t \in [0, 1]\}$ (see Fig. 1(a) for a depiction of a ray in $\mathbb{R}^3$).

In practical applications, rays have a natural granularity that depends on the system as well as the data collection density. For quantum dots, the device parameters define an intrinsic separation between critical features that gives the scale of the problem. We refer to granularity of rays in terms of pixels.

To assess the geometry of a polytope enclosing any given point x_o, we consider a collection of rays of a fixed length r centered at x_o. The rays are uniquely determined by a set of M points on the sphere $\mathcal{S}_r^{N-1}$ of radius r centered at x_o, $\mathcal{P} := \{x_m \in \mathcal{S}_{x_o}^{N-1}(r) \,|\, 1 \leq m \leq M\}$. We call a set of M rays, $\mathcal{R}_M := \{\mathfrak{R}_{x_o,x_m} \,|\, x_m \in \mathcal{P}\}$, an ***M*-projection** (see Fig. 1(c) for visualization in $\mathbb{R}^3$).

Definition 2 (Feature). *Given a ray $\mathfrak{R}_{x_o,x_f}$ and a polytope function p, a point $x \in \mathfrak{R}_{x_o,x_f}$ is a **feature** if* $p(x) = 1$.

Figure 1(b) shows two features along a sample ray in $\mathbb{R}^3$. Features along a given ray define its ***feature set***, $F_{x_o,x_f} := \{x \in \mathfrak{R}_{x_o,x_f} \,|\, p(x) = 1\}$, with a natural order given by the 2-norm distance function $d : x_o \times F_{x_o,x_f} \to \mathbb{R}^+$. In general, F_{x_o,x_f} could be empty. Using a decreasing ***weight function*** $\gamma : \mathbb{R}^+ \to [0, 1]$ we can assign a weight to each feature, effectively defining the ***weight set*** Γ_{x_o,x_f} corresponding to its feature set F_{x_o,x_f} as $\Gamma_{x_o,x_f} = \{\gamma(d(x, x_o)) \,|\, x \in F_{x_o,x_f}\}$. The actual choice of function γ needs be altered to fit the problem itself and can be considered another hyperparameter that can help optimize the machine learning process. For the quantum dot case, we chose $\gamma(n) = {}^1\!/_n$.

The assumption that the weight function γ is monotonic in distance lets us define a ray's ***critical feature*** as the point $x \in F_{x_o,x_f}$ with highest (i.e., ***critical***) weight $W_{x_o,x_f} = \gamma(d(x, x_o))$. If $F_{x_o,x_f} = \varnothing$, we put $W_{x_o,x_f} = 0$. This allows us to "fingerprint" the space surrounding point x_o.

Definition 3 (Point fingerprint)**.** *Let $x_o \in \mathbb{R}^N$ be a point from which a collection of rays $\mathcal{R}_M = \{\mathfrak{R}_{x_o,x_f^1}, \ldots, \mathfrak{R}_{x_o,x_f^M}\}$ emanate. The* ***point fingerprint*** *of x_o is the M-dimensional vector consisting of the rays' critical weights: $\mathcal{F}_{x_o} = \left(W_{x_o,x_f^1}, \ldots, W_{x_o,x_f^M}\right)$.*

This point fingerprint $\mathcal{F}_{x_o}$ of x_o is the primary object of the ray-based classification framework. If sufficiently many rays in appropriate directions are chosen from x_o, the fingerprint is sufficient, at least in principle, to qualitatively determine the geometry of the convex polytope enclosing x_o. Due to the cost of experimental data acquisition, determining *how few* rays are sufficient for a machine learning algorithm to make this determination is of crucial importance. Looking to establish a correspondence between the fingerprint $\mathcal{F}_{x_o}$ of point x_o and the class of the polytope enclosing this point, we define the following problem:

Problem 1. *Given a set of bounded and unbounded convex polytopes filling an N-dimensional space and belonging to C distinct classes, $C \in \mathbb{N}$, and a point $x_o \in \mathbb{R}^N$, determine to which of the classes the polytope enclosing x_o belongs.*

Algorithm 1 Ray-based fingerprinting algorithm

```
Step 1. Find $M$-projection centered at $x_o$ given $r$.
Input: $x_o$, $r$, a set $\mathcal{P}$ of $M$ points on the $(N-1)$-sphere
$m \leftarrow 1$; $\mathcal{R}_M \leftarrow$ empty list
for $m = 1$ to $M$ do
    Find $m$-th ray $\mathfrak{R}_{x_o,x_f^m}$ and append it to the list $\mathcal{R}_M$.
end for
Return: List of $M$ rays $\mathcal{R}_M$.
Step 2. Fingerprint $x_o \in \mathbb{R}^N$ using rays in $\mathcal{R}_M$ from Step 1.
Input: $\mathcal{R}_M$, $\gamma : \mathbb{R}^+ \to [0,1]$
$m \leftarrow 1$; $\mathcal{F}_{x_o} \leftarrow$ empty list
for $m = 1$ to $M$ do
    Find the feature set $F_{x_o,x_f^m}$.
    if $F_{x_o,x_f^m} \neq \varnothing$ then
        Identify the critical feature $x_i^m$, find $W_{x_o,x_f^m}$ and
        append it to the list $\mathcal{F}_{x_o}$.
    else
        Append 0 to the list $\mathcal{F}_{x_o}$.
    end if
end for
Return: The point fingerprint vector $\mathcal{F}_{x_o}$.
```

A solution to this problem in the supervised learning setting can be obtained by training a DNN with the input being the point fingerprint and the output identifying an appropriate class. The procedural steps for the proposed classification algorithm for N-dimensional data in the form of pseudocode are presented in Algorithm 1.

3 Experiments: Classifying Shapes in 2D and 3D

The ray-based data is generated using a physics-based simulator of quantum dot devices [11]. An example of a simulated measurement, like the ones typically seen in the laboratory, is shown in

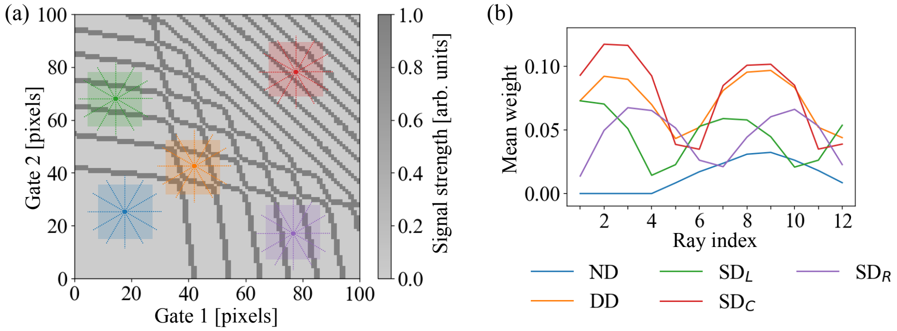

Figure 2: (a) A sample $2D$ map generated with the quantum dot simulator [11] showing the different bounded and unbounded polytopes in $\mathbb{R}^2$ with 12 evenly distributed rays overlaid on 2D scans like the ones used in Ref. [11]. (b) The average trends of the fingerprints with $M = 12$ rays. Fingerprints for SD$_L$ and SD$_R$ are out of phase, as expected from the the curvature of lines defining these states and SD$_C$ is shifted by $1/4$ of the period). The colors (labels) are consistent between both panels.

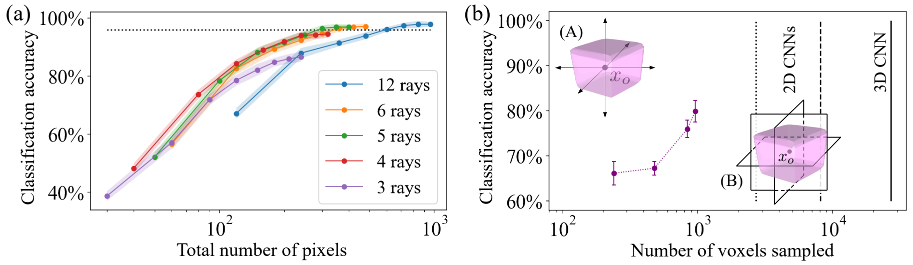

Figure 3: Classifier performance for varying numbers of rays as a function of the total number of (a) pixels measured and averaged over $N = 50$ training runs for the double-dot system and (b) voxel number averaged over $N = 10$ training runs for the triple-dot system. The black dashed line in (a) represents the benchmark from Ref. [11]. The black vertical lines in (b) represent the minimum data requirements for CNN classifier with 3 orthogonal 2D slices (as depicted in insert (B), dotted line), large 2D scan (dashed line), and a full 3D CNN (solid line). Insert (A) shows the M-projection with 6 rays. In both panels, the connecting lines are a guide to the eye only and the $3\,\sigma$ confidence bands.

Fig. 2(a). The x and y axes represent a subset of parameters that can be changed in the experiments (here, gate voltages) and the curves where the signal strength is equal to 1 represent the device response to a change in electron occupation. The slopes of those lines correspond to the location of the quantum dots with respect to the gates. The device states manifest themselves by different bounded and unbounded shapes defined by these curves, as shown in Fig. 2(a). Previous work has confirmed the reliability of a dataset generated with this simulator for the case of a CNN used with $2D$ images, finding an accuracy of $95.9\,\%$ (standard deviation $\sigma = 0.6\,\%$) over 200 training and validation runs performed on distinct datasets [11]. Here, we use a modified version of this dataset, splitting the single-dot (SD) class into 3 distinct classes based on the dot location (Left, Center, Right) as suggested by experimentalists. No-dot (ND) and double-dot (DD) classes are unchanged.

To test the ray-based classification framework in 2D, we use 20 realizations of $2D$ maps qualitatively comparable to the one shown in Fig. 2(a). Using a synthetic dataset allows us to systematically vary the length of the rays and their number. A regular grid of 1,369 points is used for sampling, resulting in a dataset of 27,380 fingerprints. We consider five datasets of M-projections, with $M = 3, 4, 5, 6, \mathrm{and} 12$ evenly spaced rays. The ray length is varied between 10 and 80 pixels (where 30 pixels is the average separation between transition lines in the simulated devices). We ran 50 training and validation tests per combination of rays' number and length (with data divided 80:20). For testing, we generated a separate dataset based on three distinct devices. This allows us to both better determine the classification error for the most efficient number and length combinations of rays and to study the failure cases over the device layout (see Fig. A.1).

Figure 3(a) shows the performance of the ray-based classifier. The accuracy of the classifier increases with the total number of points measured for a fixed number or rays, as expected. However, for a fixed number of points, increasing the number of rays does not necessarily lead to increased accuracy. This is because with a fixed number of points and point density, increasing the number of rays naturally results in shorter rays. Rays shorter than the radius of the interior diameter of the shapes leads to empty feature sets, resulting in uninformative fingerprints. Increasing the number or size of hidden layers in the DNN does not further improve the accuracy (see Table A.1).

To test the proposed framework with triple-dot systems [12], we generated a dataset by sampling 17,576 fingerprints from a single simulated device with three dot gates. We varied the number of rays between 6 and 18, while keeping the length of the rays fixed at 60 voxels. For each configuration, we performed $N = 10$ training and validation runs (with data divided 80:20). As shown in Fig. 3, the classifier accuracy improved from 66.2 % (σ = 0.3 %) for 6 rays to 79.9 % (σ = 0.3 %) for 18 rays.

4 Summary

While our analysis is performed using simulated data, its true advantage becomes clear when put in the context of experiments. Depending on the resolution, measuring 12 rays of length 80 (total of

960 data points) is equivalent to measuring the full $2D$ image (900 data points) as in Ref. [10]. With 6 rays of length 60 pixels, only 360 data points are needed, resulting in $60\,\%$ reduction of the data needed to obtain accuracy of $96.4\,\%$ ($\sigma = 0.4\,\%$). The reduction for 3D data is even more significant.

In conclusion, we have defined a framework to generate a low-dimensional representation of geometrical shapes in a high-dimensional space. We have empirically shown that the ray-based framework is an effective solution for cutting down the measurement cost while preserving high-accuracy of classification on the quantum dot dataset. If the ray-based classifier were implemented in a scheme to tune the double dot, as in Ref. [10], this reduction in data collection significantly improves its viability as a replacement to a hand-tuning scheme by a human operator. We expect this approach will find many related applications outside of the quantum dot domain.

Broader Impact

The authors believe that research presented in this paper does not have ethical aspects. This work furthers the efforts to automate and scale up quantum dot-based quantum computing to larger and more impactful devices. Our approach can also be extended to setups involving the estimation of quantum states in solid-state and atomic experiments, as well as tuning and scalability of other quantum computing architectures. A ray-based approach may find use classifying point clouds if sufficiently ordered. Extending our technique to include intersection points beyond the first critical feature may allow for identification of non-convex shapes in higher dimensions.

Appendix

Overview of failure modes

To better understand the failure cases of the ray-based classifier for the best rays' number and length combinations, we use three test datasets comprised of a regular grid of 1,369 points sampled over three devices distinct from those used for training and validation. Figure A.1 visualizes the classification success on a stability diagrams like the one in Fig. 2(a). The test devices are shown as rows and the different rays' numbers and lengths combinations are shown as columns. As can be seen in columns two and four, with $r = 50$ pixels the classifiers fails when a sampled point falls on the boundary lines for the polygons.

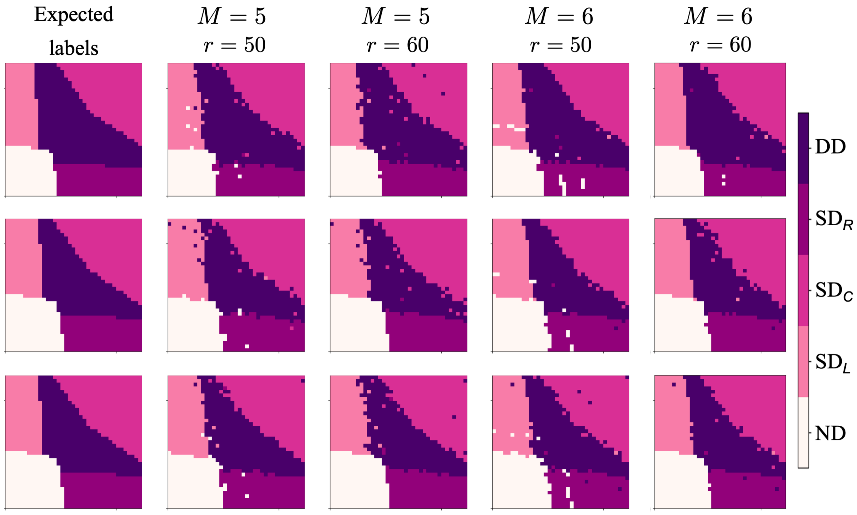

Figure A.1: Visualization of the failing cases overlaid on the test devices, with each row corresponding to a different device. The expected labels are shown in the leftmost column. The remaining columns are the ray-based classifier results for varying number of rays, M, and length of rays in pixels, r.

Analysis of DNN architectures

In experiments presented in Sec. 3 we use a DNN with 256, 128, and 32 neurons and the ReLU activation function for the fully connected hidden layers. The output layer consists of 5 neurons and the softmax activation function. We use the Adam optimizer ($\eta = 10^{-3}$), and the sparse categorical cross-entropy loss function. We found that increasing the size or complexity of the DNN (in terms of more or bigger layers) does not improve the performance of the ray-based classifier. In fact, for certain rays' number and length combination (e.g., 6 rays of length 60 pixels), a smaller network would suffice to achieve the same accuracy (see Table A.1).

Table A.1: Comparison of the varying DNN architectures for a fixed number and length of rays. For each network we report average accuracy, μ_r (%), and standard deviation, σ_r (%), where r denotes the length of the ray (in pixels), for $N = 50$ iterations of training and testing.

DNN	5 rays		6 rays	
	μ_{50} (σ_{50})	μ_{60} (σ_{60})	μ_{50} (σ_{50})	μ_{60} (σ_{60})
64-32	93.6 (0.4)	95.8 (0.4)	94.5 (0.3)	96.3 (0.3)
128-64-32	94.2 (0.4)	96.4 (0.4)	94.6 (0.4)	96.4 (0.4)
256-64-32	94.2 (0.5)	96.5 (0.4)	94.7 (0.4)	96.6 (0.3)

Operando Scanning Electron and Microwave Microscopies in Plasmas: A Comparative Analysis

Andrei Kolmakov[1*] *and Alexander Tselev*[2]

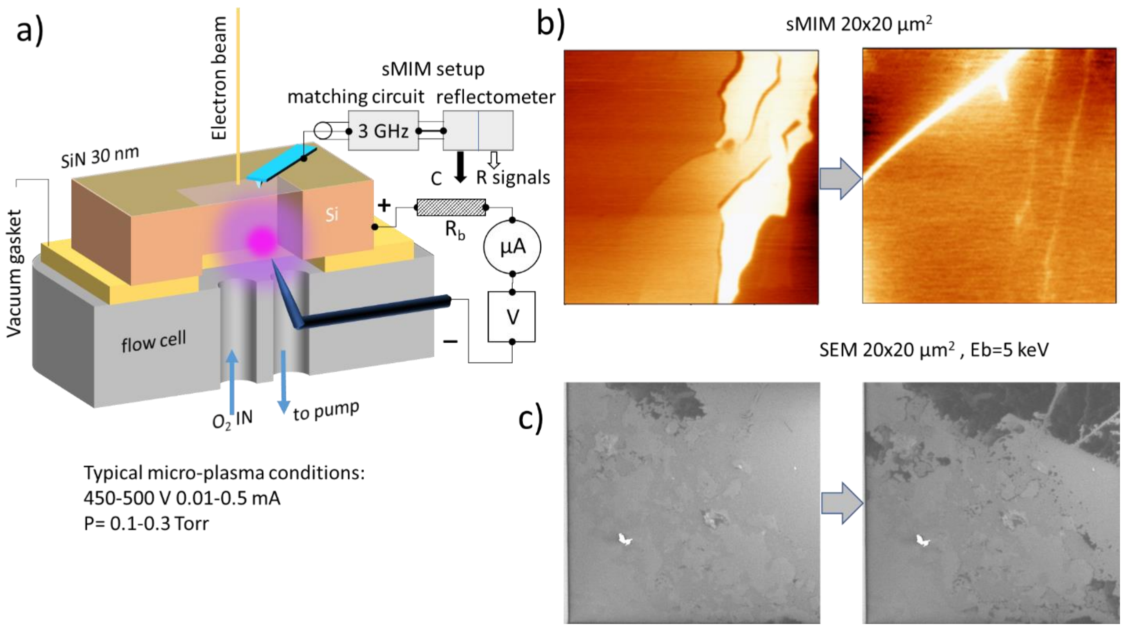
[1] Physical Measurements Laboratory, National Institute of Standards and Technology, Gaithersburg, MD 20899, USA

[2] Department of Physics & CICECO–Aveiro Institute of Materials, University of Aveiro, 3810-193 Aveiro, Portugal

There exists a great need for an operando nanoscale characterization of evolution of surface composition and morphology during plasma-assisted processing. This includes sputter deposition, plasma-assisted etching, plasma-enhanced atomic layer deposition and other processes relevant for semiconductor and aerospace industries, environmental remediation, and biomedical technology. Recently, we proposed near-field scanning-probe-based microwave imaging as a tool to image surfaces immediately (a few seconds) after plasma processing with a sub-100 nm spatial resolution [1].

In this communication, we report on true operando near-field microwave imaging in plasma and its extension to imaging in SEM. The core of our approach is a microflow DC micro-discharge chamber equipped with a few-10s nm-thick SiN membrane transparent to a few keV electrons and microwave radiation (Figure 1a). This membrane isolates the probe of a scanning Microwave Impedance Microscope (sMIM) or an SEM column from plasma environment and thus enables real-time imaging of a surface of interest under plasma conditions. Using model systems, such as graphene, PMMA films, and polystyrene microparticles, we have comparatively explored performance of the SEM and sMIM in the same plasma-assisted processes. In particular, sensitivity, frame rate, spatial resolution, probing depth, and probe-induced effects were evaluated and compared. Figure 1b shows the process of etching of folded graphene by air DC plasma. The same process is depicted in the SEM snapshots in Figure 1c. The sMIM contrast in Figure 1b is due to graphene conductivity which degrades significantly after a few seconds of ca. 200 mW plasma treatment. Under optimal conditions, a resolution of ca. 50 nm can be achieved for metallic objects with commercially available probes. In turn, the contrast formation in SEM is due to local variations in the electron emission yield of the sample. This can be affected by presence of static charges in the SiN membrane. The spatial resolution can be as high as 10 nm with a frame rate on the order of 1 Hz. Interestingly, both the microscopies revealed formation of highly conductive filamentary structures of graphene during plasma etching—a phenomenon that is a subject of ongoing research.

Kolmakov, Andrei; Tselev, Alexander. "Operando Scanning Electron and Microwave Microscopies in Plasmas: A Comparative Analysis." Paper presented at Microscopy and Microanalysis 2020, Milwaukee, WI, US. August 02, 2020 - August 06, 2020.



Typical micro-plasma conditions:
450-500 V 0.01-0.5 mA
P= 0.1-0.3 Torr

Figure 1 (a) Experimental setup for operando sMIM and SEM studies under DC plasma; (b) sMIM (conductance channel) 20x20 μm^2 image of a graphene sample before (left panel) and after a few seconds (right panel) of application of DC air plasma (0.25 Torr, 500 V, 0.4 mA). The overall signal intensity drops (color scales are different in the images) due to local graphene etching, and filamentary structures are formed; (c) A similar sequence of 20x20 μm^2 images in SEM (5 keV) taken during DC (0.25 Torr, 450 V 0.2 mA) plasma treatment

GRADIENT ELUTION MOVING BOUNDARY ELECTROPHORESIS OF HOMEMADE FUEL-OXIDIZER EXPLOSIVES

Shannon T. Krauss[1], Dillon Jobes[2], and Thomas P. Forbes[1*]
[1]National Institute of Standards and Technology, USA
[2]Tulane University, USA

ABSTRACT

The analysis of complex samples without extensive preparation steps (*e.g.,* filtration or centrifugation) is a persistent challenge for applications ranging from forensic identification to high-throughput security screening. Here, a capillary-based microfluidic electrophoresis platform incorporating a hydrodynamic counterflow and capacitively coupled contactless conductivity detection is employed for the detection of inorganic components from propellants, pyrotechnics, and homemade fuel-oxidizer explosives. The bulk counterflow prohibits capillary clogging by particulate or fiber debris, as well as system fouling from fuels, *e.g.,* petroleum jelly or kerosene.

KEYWORDS: Capillary Electrophoresis, Gradient Elution Moving Boundary Electrophoresis, Capacitively Coupled Contactless Conductivity Detection, Propellants, Pyrotechnics, Fuel-Oxidizer Mixtures, Explosives

INTRODUCTION

Capillary electrophoresis (CE) is a selective analytical technique that has found extensive use for separations in biological applications [1]. As CE-based techniques have evolved, these systems have also found utility in applications ranging from separation of narcotic samples to analysis of post-blast debris. An array of configurations, modalities, and platforms have sought to take advantage of the benefits afforded by microfluidics, *e.g.,* automation, reduced sample sizes, multiplexing capabilities, and high-throughput analysis. One such method, gradient elution moving boundary electrophoresis (GEMBE), is a simple technique consisting of a relatively short capillary (5 cm) connecting two reservoirs and the application of an electric field (Figure 1(a)) [2]. Microfluidic electrophoresis platforms employing GEMBE separation modality have demonstrated the analysis of analytes ranging from amino acids to inorganics to opioids [2-4].

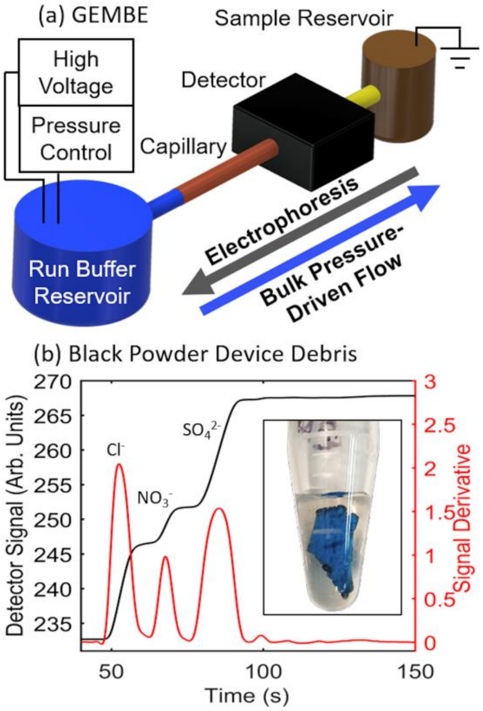

Figure 1: (a) Schematic representation of GEMBE separation. (b) GEMBE analysis of post-blast debris collected from a black powder charge thermoplastic polymer device. Raw signal showing step-wise increases in conductivity (black trace) and raw signal derivative demonstrating traditional peaks (red trace) from signal piece of debris (inset).

EXPERIMENTAL

GEMBE separation is achieved by gradually reducing a pressure-driven hydrodynamic counterflow (Figure 1(a)). As the hydrodynamic counterflow decreases, each analyte sequentially enters the capillary under electrophoretic transport. Each analyte is detected by coupled contactless conductivity detection (C^4D) as a moving boundary or step in conductivity (Figure 1(b)).

A 100 mmol/L acetic acid, 10 mmol/L L-histidine, pH 3.69 buffer and 200 µmol/L calcium chloride internal standard were used for separation under a -600 V/cm (-3000 V voltage) electric field. Following an elevated applied pressure (+30 kPa), the pressure was reduced at -100 Pa/s until all analytes were detected.

RESULTS AND DISCUSSION

The capabilities enabled by GEMBE provide unique utility for the direct analysis of inorganic components from homemade and improvised explosives and post-blast debris. GEMBE has the potential to separate and detect common inorganic oxidizers,

Forbes, Thomas P.; Krauss, Shannon; Jobes, Dillion. "Gradient Elution Moving Boundary Electrophoresis of Homemade Fuel-Oxidizer Explosives." Paper presented at MicroTAS 2020. October 04, 2020 - October 09, 2020.

including nitrate, chlorate, and perchlorate from low explosives without the need for extensive sample preparation or filtration. Figure 1(b) demonstrates the direct analysis of post-blast debris from the controlled heated wire detonation of a black powder (KNO_3/S/C) charge thermoplastic pipe-based improvised explosives device. Individual millimeter sized fragments of the device were analyzed without sample preparation, filtering, or centrifugation to eliminate particulate or other contaminants.

GEMBE separation of pre-blast black powders and black powder substitutes revealed detection of the main nitrate and perchlorate oxidizers without interference from an array of additional organic and inorganic fuels common to these propellants (*e.g.*, sulfur, dicyandiamide, nitro-benzoic acid, or sodium benzoate). Screening of tertiary explosives based on ammonium nitrate or potassium chlorate oxidizers with fuels including aluminum, icing sugar, petroleum jelly, fuel oil, and kerosene was also investigated. The GEMBE configuration excluded these fuels from fouling the capillary, enabled semi-quantitative analysis, and detection down to under 10 µmol/L.

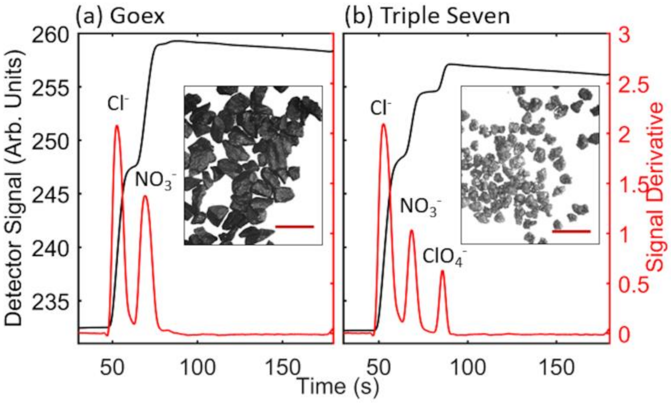

Figure 2: GEMBE separation of (a) Goex black powder and (b) Triple Seven black powder substitute samples containing nitrate and perchlorate. Raw data in black showing stepwise increases in conductivity and derivative representation of the raw data with identified peaks shown in red (internal standard: chloride). Bright field microscopy inset images of each with scale bar:2 mm.

CONCLUSION

GEMBE has the potential for quantitative forensic analysis and high throughput screening applications targeting the inorganic components of homemade explosives and post-blast debris. The nature of the GEMBE counterflow excludes particles, fibers, and detrimental components of samples from entering the capillary. This significantly reduces sample preparation (e.g., filtration or centrifugation) and capillary fouling. In addition, unlike traditional electrophoretic separations, GEMBE does not require a defined injection. This simplification allows for multiplexed devices, scaling up throughput. Furthermore, separation resolution is simply controlled through the rate of pressure reduction and applied voltage.

ABSTRACT

Since the Named Data Networking (NDN) data plane requires name-based lookup of potentially large tables using variable-length hierarchical names as well as per-packet state updates, achieving high-speed NDN forwarding remains a challenge. In order to address this gap, we developed a high-performance NDN router capable of reaching forwarding rates higher than 100 Gbps while running on commodity hardware. In this paper we present our design and discuss its tradeoffs. We achieved this performance through several optimization techniques that include adopting better algorithms and efficient data structures, as well as making use of the parallelism offered by modern multi-core CPUs and multiple hardware queues with user-space drivers for kernel bypass. Our open-source forwarder is the first software implementation of NDN to exceed 100 Gbps throughput while supporting the full protocol semantics. We also present the results of extensive benchmarking carried out to assess a number of performance dimensions and to diagnose the current bottlenecks in the packet processing pipeline for future scalability enhancements. Finally, we identify future work which includes hardware-assisted ingress traffic dispatching, dynamic load balancing across forwarding threads, and novel caching solutions to accommodate on-disk content stores.

1 INTRODUCTION

Named Data Networking (NDN) is a new networking protocol with a data-centric communication architecture based on retrieval of named content rather than packet delivery between hosts [9, 39]. It is one of the most prominent instances of Information Centric Networking (ICN). Communication in NDN is receiver-driven: a consumer sends an Interest packet carrying the desired content name, the network uses this name to forward the request toward a producer or an in-network cache, and eventually a Data packet is returned to the consumer on the reverse path. A fundamental component in a NDN network is the *forwarder* (or router) that implements NDN's communication model following the behavior described by Shi [29, Chapter 3]. Accordingly, an NDN router must perform name-based lookups of potentially large tables using variable-length hierarchical names and simultaneously update its internal state on a per-packet basis. This makes wire-speed NDN forwarding challenging to achieve. At the same time, a number of scientific and other data-intensive applications [1, 4, 23, 27, 28] are hampered by the lack of such high-speed capability.

In this paper we present the design of **NDN-DPDK**, a high-performance NDN forwarder capable of achieving a throughput of over 100 Gbps while running on commodity x86 hardware. NDN-DPDK adopts several architectural optimizations ranging from better algorithms and data structures to reduced kernel and system call overhead, which was made possible by leveraging the fast user-space packet processing framework Data Plane Development Kit (DPDK) [17]. DPDK is available for many common 10/100 Gbps Ethernet adapters and provides a set of libraries to accelerate packet processing tasks, such as ring buffers, memory pools, and thread management. This enables our forwarder to receive and transmit packets directly from user space without going through the Linux kernel. Additionally, NDN-DPDK takes full advantage of the parallelism offered by modern multi-core CPUs.

Our open-source codebase, available on GitHub[1], possesses several unique features that advance the state of the art in NDN software routers:

- First, to the best of our knowledge, NDN-DPDK is the first complete implementation of a high-speed NDN forwarding engine on real hardware. Previous attempts [10, 11, 16, 22, 30, 33, 36] either focused on a subset of the data plane functions, did not support the full NDN protocol and name matching semantics, prioritized modularity and flexibility over performance, or relied on simulations rather than actual implementation.

[1] https://github.com/usnistgov/ndn-dpdk

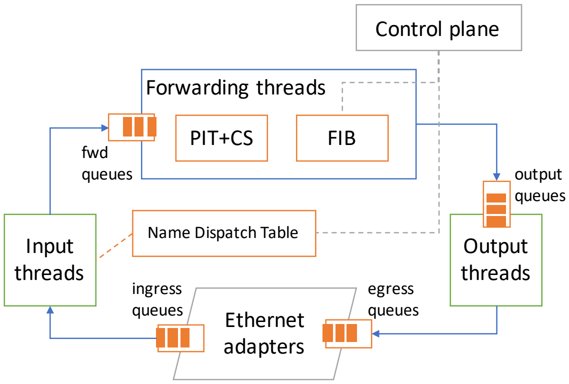

Figure 1: High-level view of NDN-DPDK's architecture.

- Second, since NDN allows for the Interest name to be a prefix of the Data name, we propose a novel approach for fast prefix matching between Interests and Data. An important ingredient of this approach is the PIT token, a small hop-by-hop header field added to each packet to accelerate PIT lookups.
- Third, in order to efficiently support prefix matching in NDN's Content Store, we developed a new solution based on indirect entries. Without such solution, an Interest carrying a non-exact name would have to be answered by the producer, reducing the effectiveness of in-network caching.

The rest of this paper is organized as follows. Section 2 provides an overview of NDN-DPDK's design. The forwarder's input and output stages are described in section 3, where packet dispatching for Interest and Data is also covered. Sections 4 and 5 introduce the main data structures and the details of their implementation. Support for NDN's forwarding strategies is discussed in section 6. The results of extensive performance benchmarks are presented in section 7. Finally, we review previous publications related to ICN forwarding in section 8, and conclude the paper in section 9, where we also list our future work.

2 DESIGN OVERVIEW

The forwarding plane of NDN-DPDK adopts a multi-threaded architecture (fig. 1). Each packet is processed in three stages:

1. The *input stage* receives a packet from a network interface, decodes it, and dispatches it to a forwarding thread according to a Name Dispatch Table (NDT).
2. The *forwarding stage* applies the NDN forwarding rules to the packet; this stage includes the traditional FIB (Forwarding Information Base), PIT (Pending Interest Table), and CS (Content Store) components, as well as the forwarding strategies.
3. The *output stage* prepares outgoing packets and passes them to a network interface for transmission.

This architecture allows the forwarder to make use of all available CPU cores and process several packets in parallel.

2.1 Memory Pools and NUMA Sockets

NDN-DPDK uses DPDK's *mempool* library to preallocate most of its data structures in 1 GiB hugepages. This eliminates the unpredictable latency of calling `malloc()` on the packet processing hot path, and reduces the complexity of handling runtime memory allocation failures. These memory pools are also pinned to physical memory pages and cannot be swapped out by the kernel, which ensures consistent access latency.

Most server-grade machines adopt a Non-Uniform Memory Access (NUMA) design. Under NUMA, each CPU, memory DIMM, and PCIe peripheral belongs to one *NUMA socket*. A CPU can access its local memory (memory located on the same NUMA socket) faster than non-local memory (memory located on a different NUMA socket). Using DPDK's *Environment Abstraction Layer* (EAL) library, NDN-DPDK pins its threads to specific CPU cores, and allocates most data structures used by a thread in NUMA-local memory. This minimizes memory access latency for these data structures.

Similarly, a PCIe Ethernet adapter also belongs to a NUMA socket. All packets received on a given adapter are stored in a memory pool local to that adapter's NUMA socket. Thus, NDN-DPDK assigns the input and output threads serving each interface to CPU cores located on the same NUMA socket. Even so, during normal operations it is inevitable to access packets across NUMA socket boundaries: for instance, when an incoming packet is dispatched to a forwarding thread on another NUMA socket, or when the egress interface happens to be on a different NUMA socket.

2.2 Sharded Data Structures

A classical NDN forwarder has three main data structures (or *tables*): the FIB guides Interest forwarding toward the producer, the PIT gets Data back to the consumer, and the CS provides in-network caching. NDN-DPDK has multiple forwarding threads and they all need to access these three tables. Concurrent access, however, requires thread safety, which would increase the design complexity and reduce performance.

Instead, NDN-DPDK tries to avoid sharing the tables as much as possible: each forwarding thread has a private instance of the PIT and the CS, and a (partial) copy of the FIB. The first two do not require any cross-thread access, thus they are implemented using non-thread-safe data structures, while the FIB still needs to be updated from the control plane and therefore employs a low-overhead *Read-Copy-Update* (RCU) synchronization mechanism (section 4). This approach also enables allocating all three tables for each thread in NUMA-local memory in order to minimize the access latency, as explained in section 2.1.

2.3 Internal Packet Queues

Each forwarding thread receives the packets dispatched to it by the input stage via a set of three FIFO queues, one for each packet type: Interest, Data, Nack. The queues are provided by DPDK's *ring* library, which implements a ring buffer with a fixed capacity and lockless enqueue/dequeue operations. Packets are taken from any one of these queues in *bursts* instead of one at a time. Burst dequeuing amortizes the overhead of the ring buffer bookkeeping operations and reduces the number of CPU instruction cache misses, because multiple packets of the same type are processed together, typically following the same code path.

Initial testing suggested that the forwarding stage can easily become a bottleneck in configurations with few forwarding threads. To alleviate this bottleneck, NDN-DPDK adopts a CoDel-based [15] queue management algorithm between the input stage and the forwarding stage. If the minimum queuing delay stays above *target* (5 ms by default) for *interval* milliseconds (initially 100 ms), the forwarding thread inserts a *congestion mark* [25] in the next packet, prompting the consumer to slow down.

The forwarder also prioritizes Data over Interests, by dequeuing fewer packets from the Interest queue than from the Data queue at each iteration. This is because dropping a Data packet would not only waste the resources already spent on processing the corresponding Interest, but also cause the PIT entry to linger until its expiration, while losing an Interest is less harmful.

2.4 Life of a Packet

An incoming frame is received by an input thread, which parses it according to the NDN Packet format [19] and recognizes it as an Interest (section 3.1). The packet is then assigned to a forwarding thread based on its name (section 3.2) and is placed on a queue that goes to that thread. The forwarding thread dequeues the Interest. It first queries the PIT and the CS (section 5), but, assuming that this node did not recently receive any Interest or Data with the same name, no match is found in either table. Therefore, the thread creates a new PIT entry and records the ingress interface as a downstream node. Next, it performs a FIB lookup (section 4) to determine which forwarding strategy should be making forwarding decisions and the potential next hops. The strategy is invoked and decides to forward the Interest to a particular next hop (section 6.1). The forwarding thread finally passes the Interest to an output thread for transmission (section 3.4).

When a Data packet arrives, the input thread determines which forwarding thread previously handled the corresponding Interest based on a hop-by-hop header field in the Data packet (section 3.3), and passes the packet to that thread. The forwarding thread first locates the PIT entry that can be satisfied (section 5.2). It then checks which downstream nodes have expressed matching Interests and passes copies of the Data packet to output threads for transmission (section 3.4). It also notifies the forwarding strategy that the Interest has been satisfied, so that the strategy can make better decisions in the future (section 6). Finally, the Data packet is cached in the CS and the PIT entry is deleted.

3 FACE I/O AND PACKET DISPATCHING

NDN-DPDK is optimized for 10/100 Gbps Ethernet adapters attached to a PCIe bus. Using DPDK's *poll mode* drivers, NDN-DPDK can send and receive packets directly from user space without going through the operating system kernel. This significantly improves performance by eliminating the overhead of system calls and interrupt handling.

An NDN *face* is a generalization of the concept of network interface, on which NDN packets can be transmitted and received. NDN-DPDK supports only point-to-point faces, unlike other NDN forwarders, and deliberately does not support multicast communication on a single face. This directly follows from NDN-DPDK's primary use case in high-performance computing and data-intensive science [35], where the network is closely managed and peers are administratively configured, thus multicast-based discovery is not needed. Furthermore, to keep the face system simple, NDN-DPDK currently supports only Ethernet faces and cannot tunnel over IP or any other protocols[2]. The user can create one or more faces on a given Ethernet adapter; each face is distinguished by a different remote MAC address and optionally a VLAN ID.

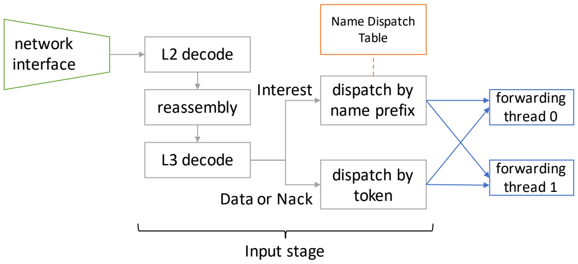

Figure 2: Input thread procedure.

3.1 Input Stage

The forwarder's input pipeline, depicted in fig. 2, starts with receiving frames from an Ethernet adapter. As mentioned before, there can be multiple faces on the same adapter, but each face must have a distinct remote MAC address or VLAN ID. The adapter is configured to steer frames belonging to each face into a different receive queue. An *input thread* is connected to one or more of these receive queues and is responsible for decoding each incoming frame with a three-step procedure: (1) strip the Ethernet header and any VLAN tags; (2) decode as an NDNLP packet [21], performing reassembly if needed; (3) continue decoding the reassembled NDN network-layer packet and classify it as Interest, Data, or Nack.

The decoding routines store information about a parsed packet along with the packet buffer itself, in a private area reserved in the buffer header. This avoids the need for a separate memory allocation, which improves throughput but consumes more memory on a per-packet basis. Moreover, NDN-DPDK's decoding routines are optimized to serve the forwarder and do not have to accommodate the needs of consumer or producer applications. This leads to several design differences compared to the parsers that can be found in any general-purpose NDN library. For example:

- For Data, decoding stops just before the `Content` element, because the forwarding algorithms do not need to know the packet's payload or its signature.
- For similar reasons, the decoder ignores an Interest's `ApplicationParameters` element and everything that comes after it.
- For the `MetaInfo` element in a Data packet, the decoder reads only the `FreshnessPeriod` field, because other fields do not affect forwarding.

[2] Better tunneling support is planned for a future version.

Figure 3: Name Dispatch Table and FIB partitions.

3.2 Dispatching Interests by Name

After packet decoding, the input thread dispatches each network-layer packet to a forwarding thread. For an Interest, a prefix of the name determines which forwarding thread will process the packet. This dispatching algorithm is name-based so that two Interests with the same name end up in the same forwarding thread, which ensures the effectiveness of Interest aggregation. By using a name prefix instead of the entire name, Interests with a common prefix go to the same forwarding thread, which enables the forwarding strategy to collect measurements on a per-prefix basis.

As we will see in section 6, forwarding strategies operate at the FIB entry granularity. In theory, Interest dispatching could follow the FIB entries, which would fulfill the two goals above. However, the FIB is a fairly complex data structure and performing a full lookup in the input stage would be too slow. Therefore, the dispatching algorithm employs a much simpler method to determine the granularity: it takes the first k components of the Interest name as prefix. If the Interest has fewer than k name components, the entire name is used. The value of k should be chosen such that the resulting prefixes are shorter than most FIB entries, to keep forwarding strategy measurements effective, but also long enough that there is a sufficient number of distinct prefixes for load balancing among forwarding threads. NDN-DPDK sets $k = 2$ in its default configuration, but this parameter can be tuned according to the characteristics of the incoming traffic.

After determining the name prefix, the dispatching algorithm queries the *Name Dispatch Table* (NDT), a table unique to the NDN-DPDK forwarder (fig. 3). The input thread dispatches the Interest to the queue leading to the forwarding thread identified by the NDT entry. In order to be as simple as possible and maintain a predictable lookup speed, the NDT is not a name-indexed data structure but a linear vector of 2^b entries ($b = 16$ by default), where each entry contains a forwarding thread identifier. The lookup algorithm computes the SipHash [2] over the name prefix, takes the lower b bits of the hash value as an index into the vector, and returns the forwarding thread identifier in that entry. This allows an NDT lookup to complete in $O(1)$ time complexity.

3.3 Dispatching Data by Token

Data must be dispatched to the same forwarding thread that processed the Interest. As described in section 2.2, each forwarding thread has a private instance of the PIT. Therefore, information about a pending Interest is available only in the forwarding thread that forwarded the Interest and only that thread is able to correctly process a Data in reply to the forwarded Interest.

Although we could perform another prefix-based dispatch on the Data name, the name dispatching algorithm breaks down in one specific case. The NDN protocol allows name discovery: an Interest may be satisfied if its name is a prefix of the Data name and the Interest contains the `CanBePrefix` flag. For example, Data `/A/B/1` can satisfy an Interest with name `/A` and `CanBePrefix=1`. Applying the name dispatching algorithm in section 3.2 and observing that the Interest name in this case has fewer than two components, we can see that the Data would be dispatched under the `/A/B` prefix, while the Interest would be dispatched under the `/A` prefix. If the NDT entries corresponding to these prefixes map to two different thread identifiers, the Data would go to a forwarding thread that has no knowledge about the Interest.

To solve this problem we introduce the *PIT token*, an 8-byte hop-by-hop field carried in the NDNLP header of each packet [21]. Downstream nodes attach a PIT token when transmitting an Interest. Upstream nodes are expected to attach the same token when replying to the Interest with a Data or Nack packet. NDN-DPDK uses a few bits of this token to encode the forwarding thread identifier. When a forwarding thread transmits an Interest, it puts its own identifier in the PIT token. When Data comes back, the input thread can simply read that part of the PIT token and dispatch the Data to the correct forwarding thread.

For a Nack packet, either dispatching method would work correctly. We chose the token dispatching method as it is more efficient.

3.4 Output Stage

The output stage controls the transmission of outgoing packets. For each outgoing network-layer packet, it performs NDNLP fragmentation (if needed), prepends an Ethernet header, and enqueues the resulting link-layer frames for transmission on the Ethernet adapter. In the current version of NDN-DPDK the workload of the output threads is light. However, it will likely increase in the future as we plan to implement more advanced congestion control and queue management schemes in the output stage.

4 FIB STRUCTURE AND LOOKUP

The FIB is a read-mostly table. The forwarding threads perform a *Longest Prefix Match* (LPM) on the FIB to determine where to send each incoming Interest. On the other hand, FIB updates are seldom needed and only occur in response to a management command from the control plane.

NDN-DPDK's FIB design is inspired by So et al. [30]. In their design, the FIB entries are stored in a hash table keyed by the name prefixes. They also propose a 2-stage LPM lookup algorithm:

(1) The FIB has a fixed parameter M, such that the majority of FIB entry names have fewer than M components.
(2) When inserting a FIB entry whose name has more than M components, a virtual entry is inserted at depth M that indicates the maximum FIB depth under its prefix.
(3) Given an Interest, an LPM on the FIB starts with the M-component prefix of the Interest name.

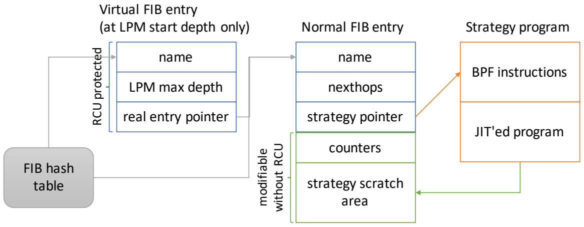

Figure 4: Structure of normal and virtual FIB entries.

(4) If this lookup finds a virtual entry, the LPM is restarted at the maximum FIB depth indicated in the virtual entry.
(5) Otherwise, the LPM continues toward shorter prefixes until a normal FIB entry is found.

In NDN-DPDK, we adopted the same FIB structure (fig. 4) and the same 2-stage lookup algorithm. However, our multi-threaded architecture requires thread safety, which we achieved with two techniques.

First, we use the Userspace Read-Copy-Update (URCU) library [3, 13] to allow both FIB queries from the forwarding thread and FIB updates from the management thread to take place simultaneously. A benefit of RCU is that its read-side overhead is minimal, which matches well with the read-mostly nature of the FIB. We use the quiescent-state-based flavor of RCU because it has the smallest overhead. This flavor requires every thread to periodically indicate a quiescent state; for a forwarding thread, this occurs before processing each burst of packets. The hash table implementation comes from URCU's lock-free resizable RCU hash table, with the resize functionality disabled to provide more predictable performance. FIB entries are allocated from a DPDK memory pool instead of the default `malloc()` memory allocator.

Second, each forwarding thread is given its private FIB instance. Each FIB instance contains only the name prefixes served by the forwarding thread. Compared to having a single FIB shared among all forwarding threads, this approach ensures the FIB entries are allocated on the same NUMA socket as the forwarding thread, avoiding memory access across NUMA boundary. Moreover, it allows the forwarding strategy (section 6) to store collected measurements on the FIB entry itself, without needing a separate measurements table.

5 COMBINED PIT AND CONTENT STORE DESIGN

The PIT and the Content Store are both read and modified frequently in the data plane, specifically:

(1) The CS is queried for every incoming Interest to check if it can be satisfied by cached Data.
(2) If not, the Interest is forwarded and a PIT entry must be inserted, unless one already exists.
(3) Upon receiving a Data packet, the PIT is queried to find which pending Interest(s) can be satisfied.
(4) When a PIT entry is satisfied, it must be erased and a CS entry inserted to cache the Data.
(5) If the CS is full, it may need to evict some entries to make room for the new Data.

Observing that item 4 often deletes a PIT entry and inserts a CS entry at the same name prefix, So et al. [30] propose combining the PIT and the CS into a single hash table, so that a satisfied PIT entry can be replaced with a CS entry without incurring the cost of a second table lookup. NDN-DPDK adopts this design and merges PIT and CS into the *PIT-CS Composite Table* (PCCT).

However, [30] is intended for the CCNx protocol [14], which differs from NDN in the Interest-to-Data matching rules. Both NDN and CCNx allow a Data[3] packet to satisfy an Interest if they have the same name. NDN additionally allows a Data to satisfy an Interest if the Interest name is a prefix of the Data name and the Interest carries the `CanBePrefix` flag. Moreover, NDN Interests can carry a forwarding hint that, when present, should be used in place of the Interest name to determine the forwarding path. These major protocol differences make our PCCT design inevitably different from the one described in [30].

Given the frequent updates in both PIT and CS, a thread-safe PCCT shared across all forwarding threads could easily become a bottleneck. We decided early on that each forwarding thread should have its own private instance of the PCCT. Contrary to the FIB case, the control plane does not need to interact with either the PIT or the CS. Therefore, we can implement the PCCT using non-thread-safe data structures, which are typically faster than their thread-safe counterparts.

5.1 Logical Structure

The overall structure of the PCCT is a combination of three data structures:

- A DPDK *mempool* to allocate PCCT entries from.
- A *name hash table* for name-based lookups. This reuses the SipHash values already computed during packet dispatching (section 3.2).
- A *token hash table* to find what PIT entries can be satisfied by incoming Data, using the PIT token carried on the Data packet (section 5.2).

Logically, each PCCT entry contains a name, a chosen forwarding hint, two PIT entries, and one CS entry (fig. 5). The name is required, but all other fields are optional.

An entry is identified by the combination of its name and the chosen forwarding hint. When a forwarding thread processes an Interest that carries forwarding hints, it performs FIB lookups using those hints, and chooses the first hint that matches a FIB entry. The PIT entry created from that Interest and the CS entry for its reply Data are then placed on a PCCT entry with the chosen forwarding hint. Having the latter as part of the PCCT entry identifier logically isolates the PIT and the CS for each forwarding hint into different partitions. This mitigates a well-known cache poisoning attack caused by forwarding hints and makes NDN-DPDK the first NDN forwarder to *securely* support forwarding hints.

Each PCCT entry can contain up to two PIT entries with the same name and chosen forwarding hint. Per the NDN protocol [19], an Interest may carry the `CanBePrefix` and/or `MustBeFresh` flags

[3] "Data" is NDN terminology; the CCNx equivalent is "Content Object".

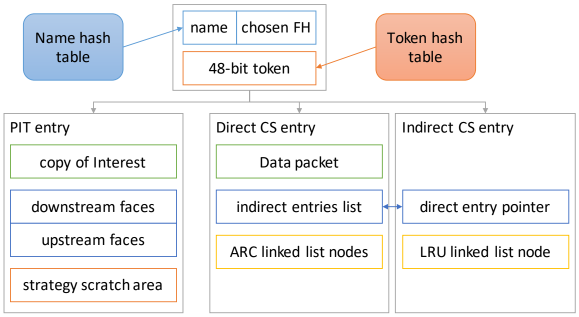

Figure 5: PIT-CS Composite Table.

that affect Interest-to-Data matching in forwarding and caches. However, the protocol is vague on how the PIT should aggregate Interests with the same name but different flags. We argue that two Interests that differ only in the `CanBePrefix` flag can be aggregated because the presence of this flag widens the set of Data that can be matched. On the other hand, two Interests that differ in the `MustBeFresh` flag cannot be aggregated, because forwarding them with the flag set would reject non-fresh Data that would otherwise satisfy the Interest that did not have the flag, while forwarding them without the flag could incorrectly satisfy the `MustBeFresh` Interest with non-fresh Data. Hence, we decided to store up to two PIT entries in each PCCT entry, one with `MustBeFresh` and one without.

5.2 PIT Lookup by Data

As mentioned before, the NDN protocol allows prefix match between Interest and Data. When a Data packet arrives, the forwarder would have to perform an LPM lookup on the PIT to determine which pending Interests can be satisfied. This could become a performance bottleneck or even an attack surface because the Data name can have many components. It is infeasible to apply the 2-stage lookup algorithm (section 4) to the PIT because the overhead of maintaining M would be too high. Instead, we propose a different approach based on the *PIT token*, a short hop-by-hop header field already introduced in section 3.3 for Data packet dispatching. Here, we extend its usage to accelerate PIT lookups.

Whenever a forwarding thread inserts a PIT entry, it allocates a *PCCT entry token* to the enclosing PCCT entry and adds it to the token hash table. Then, every outgoing Interest created from this PIT entry will carry the PCCT entry token inside its PIT token field. When a Data packet comes back, the forwarding thread can quickly locate the PCCT entry in $O(1)$ time via the token hash table. It is still necessary to verify that the Data indeed satisfies the Interest through name comparison, to prevent attacks from forged tokens.

5.3 Prefix Matching in the Content Store

Being a hash table, the PCCT only supports exact match queries using a key that consists of an Interest/Data name and a chosen forwarding hint. Thus, if an Interest name is a prefix of the Data name and the Interest carries the `CanBePrefix` flag, the exact match algorithm cannot retrieve the Data from the hash table. This severely limits the effectiveness of in-network caching, because any Interest carrying a non-exact name would have to be answered by the producer instead of being satisfied from the CS.

To address this issue, NDN-DPDK introduces the concept of *indirect CS entry* to provide partial support for prefix matching. An indirect CS entry is a special CS entry named after an Interest and containing a pointer to a *direct CS entry*. By contrast, a direct CS entry is a regular CS entry named after the Data, and contains the bits of the Data packet itself.

When the forwarder receives a Data in reply to an Interest with non-exact name, it inserts two entries into the CS: a direct entry with the Data name and the Data packet, and an indirect entry with the Interest name and a pointer to the direct entry. This allows CS matching with a prefix name, under the assumption that the consumer application consistently uses the same prefix (or a small subset of prefixes) to perform name discovery. If a future Interest with the same name as the previous Interest arrives, an exact match lookup in the CS using that Interest name will find the indirect entry, from where we can follow the pointer and retrieve the direct entry and the cached Data packet. Conversely, if an Interest with a different name arrives, even if it matches the Data, the forwarder will not be able to find the cached Data because an indirect CS entry for that Interest name does not exist.

6 FORWARDING STRATEGIES

The forwarding strategy is a component that controls various aspects of the Interest forwarding behavior. The strategy decides where to forward an incoming Interest when it cannot be satisfied by the local CS. It also decides whether to perform any corrective actions when a Nack is received. These decisions are based on inputs such as the next hops in the matching FIB entry, the downstream and upstream records in the PIT entry, as well as any collected measurements on recent data retrievals by Interests sharing a common prefix.

Experience with early NDN deployments has shown that different applications need different Interest forwarding behaviors. This provides a strong motivation to support multiple forwarding strategies with different decision making algorithms, and to dynamically choose a forwarding strategy based on application needs and network environments. As outlined by Jacobson et al. [9], the basic idea is for each FIB entry to contain a program, written for an abstract machine specialized to forwarding choices, that determines how to forward Interests. NDN-DPDK realizes this vision using *extended BPF* (eBPF) [5, 18], an evolution of the original Berkeley Packet Filter (BPF) [12].

6.1 Strategy Program

Each strategy is an eBPF program, i.e., a list of low-level instructions, such as load/store, arithmetic, and comparison operators, that can be executed by the eBPF virtual machine. In addition, the program can call a few higher-level routines that are provided to the strategies by the core forwarding engine. These include setting a timer, sending the current Interest on the specified face, and responding to an Interest with a Nack.

The strategy program exports a main function that is invoked, or *triggered*, when:

- An Interest packet arrives and cannot be satisfied with cached Data. The strategy will have to decide how to forward it.
- A Data packet arrives and satisfies an Interest. This trigger allows the strategy to collect path measurements, such as round-trip time and satisfaction ratio.
- A Nack packet arrives and does not fall under one of the simple cases that are automatically handled by the forwarding plane itself. The strategy can then decide if any corrective actions must be taken.
- A timer previously scheduled by the strategy expires.

Both FIB and PIT entries contain a writable *scratch area* for the strategy to store its state and record measurements. The FIB entry scratch area (fig. 4) is suitable for information related to a whole namespace, while the PIT entry scratch area (fig. 5) is suitable for information related to a specific pending Interest. Other than these areas, the strategy is able to inspect the current packet and has read-only access to a subset of fields in the FIB and PIT entries.

6.2 Strategy Selection and FIB Updates

NDN-DPDK associates a forwarding strategy to every FIB entry. When an Interest arrives and cannot be satisfied by the CS, the forwarding plane performs a FIB lookup, and the matched FIB entry determines not only the potential next hops but also which strategy should handle the Interest. This design is in line with [9], except that the strategy eBPF program is not stored in the FIB entry itself, but referenced by the FIB entry, so that the same strategy may be used by multiple FIB entries without storing duplicate copies. Data and Nacks are always handled by the same strategy that processed the Interest. In case the strategy or the FIB entry was changed while the Interest was pending, the forwarder handles the returning Data/Nack packet using a built-in fallback procedure and no strategy is triggered.

After a FIB update, the strategy has to restart with an empty scratch area, because it would be infeasible to migrate the data in the scratch areas during FIB updates. Indeed, although FIB entries are RCU-protected (section 4), the FIB entry scratch area is not. While this allows the strategy to modify the scratch area without going through the relatively expensive write-side RCU procedure, it also means that the control plane thread cannot safely copy the scratch area contents from the old FIB entry to the new one.

7 PERFORMANCE EVALUATION

We conducted extensive testing of NDN-DPDK in order to determine its performance characteristics under a variety of workloads. In particular, we measured the *aggregate forwarding rate*, in terms of bps (bits per second) and pps (Data packets per second), and the *per-packet forwarding latency*, in microseconds. Note that our pps metric accounts only for the Data packets because they are carrying the application content. The total number of packets (Interests and Data) actually forwarded by NDN-DPDK is at least twice[4] the reported amounts.

In all the experiments described below, the forwarder is running on a Supermicro 6039P-TXRT server equipped with dual Intel Xeon Gold 6240 CPUs (18 cores at 2.60 GHz, with Hyper-Threading disabled), 256 GB of 2933 MHz memory in four channels (64 × 1 GB hugepages have been allocated to NDN-DPDK on each NUMA socket), and Mellanox ConnectX-5 100 Gbps Ethernet adapters. The operating system is Ubuntu Linux 18.04, with DPDK v19.11 and NDN-DPDK commit 34f561f4ef0e5790d4999107dcbb4c2eab82af66. The forwarder node is connected to two traffic generators, one on each Ethernet port, via direct attach copper cables. The traffic generators emulate a producer application and a number of consumers requesting content from the producer. Each consumer instance expresses Interests under a given name prefix and employs a congestion control algorithm similar to TCP CUBIC [24]. The Interest names consist of five distinct parts:

1. The producer prefix.
2. The consumer thread ID.
3. The consumer node name followed by a random number that changes with each execution.
4. The placeholder component `/127=Y` repeated as many times as necessary (possibly zero) to make the total Interest name length equal that required by the experiment scenario.
5. The segment number.

An example Interest name is `/C/0/B_77378826/127=Y/127=Y/35=%07%C3`. The producer responds to each Interest with a Data packet, either of the same name or with an additional suffix name component `/127=Z`. The Data packet signature is neither generated by the producer nor verified by the consumer, although a signature field of proper length but with a fictitious value is present in every Data packet.

All experiments share a common "base configuration" consisting in: 8 forwarding threads, 4 components in Interest and Data names, 1000 bytes of application payload in every Data packet, 2^{16} NDT entries (see section 3.2), FIB start depth (the M parameter in section 4) set to 8, and a maximum CS capacity equal to 2^{15} entries per forwarding thread (see section 5). In each experiment we vary some of these parameters in order to assess their impact on the overall performance of the forwarder.

The forwarding rate reported for each benchmark is the arithmetic mean of 10, 50, or 150 consecutive runs (depending on the experiment), executed after a warm-up run whose results are discarded. Each run lasts 60 seconds. The forwarding latency is measured for each packet, from the moment it enters the forwarder's input stage to when it is dequeued by the output thread and handed over to the network adapter for transmission.

7.1 Forwarding Threads and Name Length

This benchmark demonstrates how NDN-DPDK's performance scales with the number of CPU cores assigned to the packet forwarding tasks. As described in section 2, each CPU core used by NDN-DPDK is entirely dedicated to running one and only one thread, hence we will use the terms "core" and "thread" interchangeably. Given that the number of input and output threads is constrained by how many network cards are installed on the system, we can only vary the number of forwarding threads, in order to distribute the incoming traffic among a larger or smaller amount of CPU cores.

[4] We say "at least twice" and not "exactly twice" because in the rare case of packet loss, the consumer must retransmit the Interest. These retransmissions are not included in our statistics since they do not affect the final application-layer goodput.

Shi, Junxiao; Pesavento, Davide; Benmohamed, Lotfi. "NDN-DPDK: NDN Forwarding at 100 Gbps on Commodity Hardware." Paper presented at 7th ACM Conference on Information-Centric Networking (ICN 2020), Montreal, CA. September 29, 2020 - October 01, 2020.

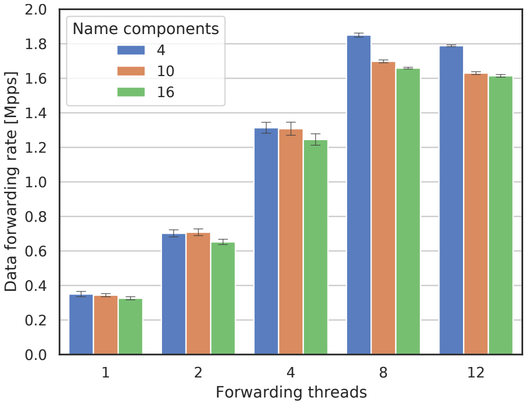

Figure 6: Mean and standard deviation of the throughput with different numbers of forwarding threads and name components.

Figure 6 shows that the throughput grows almost linearly up to 4 forwarding threads, then slows down but still improves up to 8 threads, where we reach a peak rate of about 1.84 Mpps (million Data packets per second). Further increasing the number of threads beyond that does not help performance, in fact the throughput slightly declines with 12 threads, as more cores on the same CPU are competing for hardware resources. A deeper analysis, not reported here for lack of space, revealed that with 8 or more forwarding threads, the input stage of the forwarder's pipeline becomes the bottleneck. We plan to eliminate this bottleneck in a future version of NDN-DPDK.

In fig. 6 we also illustrate the effect of the Interest name length, expressed in number of name components, on the overall forwarding rate. Longer names make the forwarder marginally slower, up to 10 % in the worst case, and the slowdown is more pronounced with 8 and 12 forwarding threads, i.e., when the input stage becomes the bottleneck. This can be explained by the fact that it is the input thread that parses the Interest name (section 3.1) and the time complexity of the decoding algorithm is linear in the number of name components.

7.2 Data Payload Length

The application-layer payload is carried inside NDN Data packets in a field called `Content`. As detailed in section 3.1, NDN-DPDK never decodes or otherwise accesses this field, because it is completely opaque to NDN routers and does not affect any forwarding decision. Therefore, we expect that varying the Data payload length will have very limited impact on the forwarder's performance. The benchmark results in fig. 7 indeed confirm our intuition: the difference between best-case and worst-case pps forwarding rate never exceeds 10 %.

This experiment also allows us to determine the maximum aggregate throughput in bits per second (bps) that can be delivered by NDN-DPDK between two network adapters: 108 Gbps, with 8000 bytes of content per packet. This number represents the application-layer *goodput*, thus excluding all Ethernet headers, Interests/Data names, Data signatures, and so on.

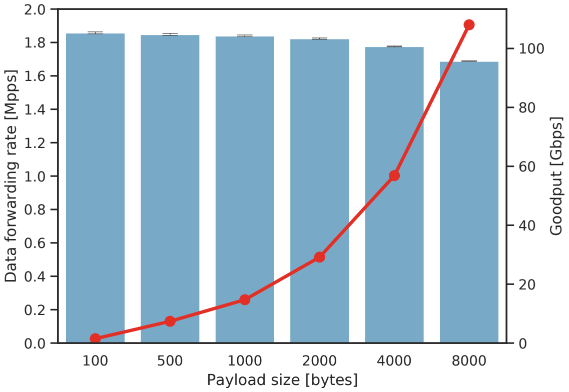

Figure 7: Mean and standard deviation of the throughput in Mpps (bars) and Gbps (line) with varying Data payload sizes.

7.3 Scalability of FIB Lookup

We tested the scalability of NDN-DPDK's FIB lookup algorithm (section 4) with up to 1 million entries (name prefixes). We can notice from the table below that the number of FIB entries has no impact on the forwarding rate, while the Interest latency is only minimally affected.

	Fwd. rate (kpps)		Interest latency (µs)	
FIB entries	Mean	σ	Median	95th percentile
10^4	1840	5.59	90	227
10^5	1835	4.92	92	234
10^6	1839	4.42	97	249

7.4 Content Store Capacity and Hit Ratio

One major feature of NDN-DPDK is the built-in support for a limited form of prefix matching in the Content Store, i.e., the ability to return, in some cases, a cached Data packet that has a longer name than the incoming Interest. However, this type of lookup is more expensive than a simple exact match algorithm due to the additional indirection and the greater number of PCCT entries that need to be consulted, as explained in section 5.3. With this benchmark we tried to quantify the performance difference between exact and prefix match. In order to trigger a meaningful number of CS hits, we added a second consumer node to the experiment topology, connected to the forwarder through a third Ethernet port. The second consumer starts fetching content 100 ms after the first one.

Figure 8 shows the aggregate throughput results of 150 runs, together with the linear regression line obtained via Theil-Sen estimation [26, 32]. Overall, prefix matching is 15 % to 17 % slower than exact matching when the CS capacity is set to 2^{17} entries per thread, and between 10 % and 18 % slower with a capacity of 2^{20} entries. We can also see from the figure that the forwarding rate is positively correlated with the hit ratio. This is because satisfying

Shi, Junxiao; Pesavento, Davide; Benmohamed, Lotfi. "NDN-DPDK: NDN Forwarding at 100 Gbps on Commodity Hardware." Paper presented at 7th ACM Conference on Information-Centric Networking (ICN 2020), Montreal, CA. September 29, 2020 - October 01, 2020.

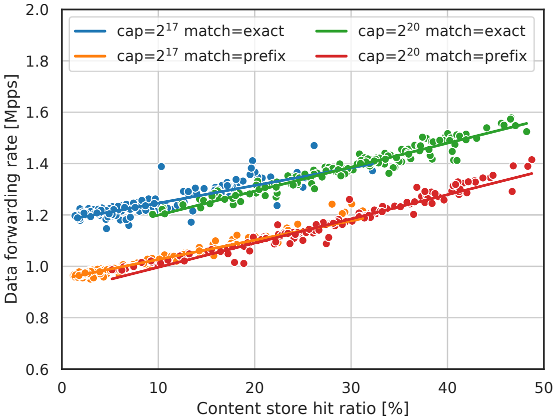

Figure 8: Forwarding rate vs. hit ratio with exact and prefix match and different Content Store capacities.

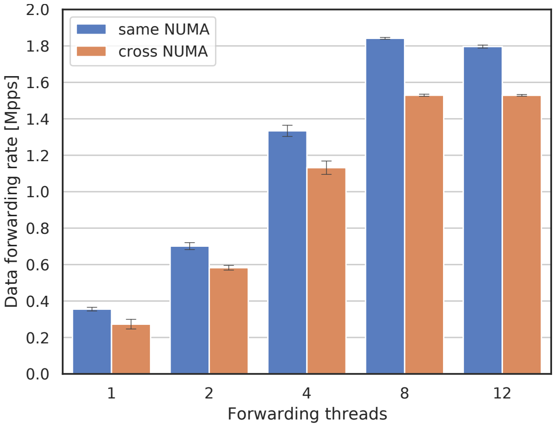

Figure 9: Mean and standard deviation of the throughput under same-NUMA and cross-NUMA memory accesses.

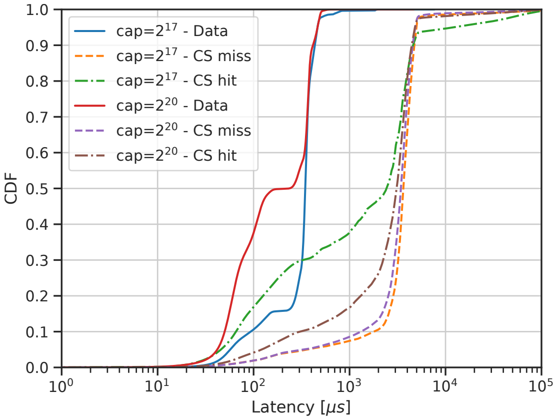

Figure 10: Cumulative distribution function of the forwarding latency with exact name matching.

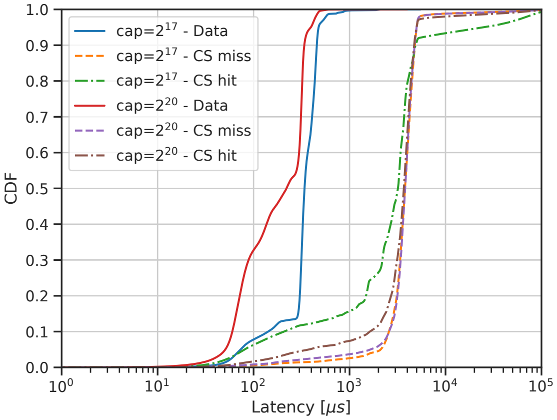

Figure 11: Cumulative distribution function of the forwarding latency with prefix name matching.

more Interests from the cache means that fewer packets will have to be further processed through the pipeline stages.

We also looked at the processing latency of each of the three main code paths that an incoming packet can take: *CS miss* (an Interest that is forwarded upstream), *CS hit* (an Interest that is answered with a Data packet from the local cache), and *Data* (a Data packet that is inserted into the CS and then forwarded downstream). The latency distributions are plotted in figs. 10 and 11 for the two scenarios of exact and prefix matching.

7.5 Impact of Nonlocal Memory Access

As mentioned in section 2.1, accessing memory on another NUMA socket incurs a higher latency compared to accessing local memory. In this benchmark, we measured the impact of cross-NUMA memory accesses on NDN-DPDK's performance. We ran the same test twice: first between two network cards installed on the same NUMA node as the forwarding threads, then we moved one of the cards to the other NUMA node, thereby forcing all traffic to require non-local memory accesses in either the Interest or the Data direction. The experiment was repeated 50 times for each scenario. The results in fig. 9 confirm that repeatedly crossing the NUMA boundary can significantly degrade the packet processing throughput, up to 20 % slower with 8 forwarding threads.

8 RELATED WORK

The research community has studied numerous performance aspects of the NDN and CCN forwarding models in great detail [11, 31, 33, 34, 36–38]. However, most of these works focus on just one or few facets of the problem, such as scalable FIB lookup, efficient name encoding, distributed PIT architectures, and hierarchical Content Stores, but only a handful of papers propose a complete design for a high-speed name-based forwarding engine.

Shi, Junxiao; Pesavento, Davide; Benmohamed, Lotfi. "NDN-DPDK: NDN Forwarding at 100 Gbps on Commodity Hardware." Paper presented at 7th ACM Conference on Information-Centric Networking (ICN 2020), Montreal, CA. September 29, 2020 - October 01, 2020.

Caesar [16] is the first full implementation of a content-centric router with a design based on hash tables. Its data plane runs on a specialized hardware platform consisting of four 10 GbE line cards and takes advantage of several hardware-specific accelerations. The FIB is distributed across the line cards and, in addition to a hash table, it uses a prefix Bloom filter, which requires hardware assistance to be beneficial. *Caesar* does not support prefix matching between Interest and Data names and relies on a custom packet format with a few fixed-length header fields to expedite parsing, therefore it cannot easily be extended to handle NDN semantics.

Another notable router design centering on hash tables is proposed by So et al. [30]. NDN-DPDK took several key ideas from this paper, enhancing them to provide additional features and support the more powerful NDN name matching semantics, as explained in the previous sections. Among them, the 2-stage LPM algorithm, the PIT partitioning scheme, and the unification of the PIT and CS data structures. A similar FIB lookup scheme is also described by Fukushima et al. [6]; however, this approach is effective only on FIB entries that are leaf nodes in the name hierarchy tree.

Kirchner et al. [10] present two open-source implementations of their software CCN router *Augustus*: a standalone monolithic forwarding engine based on DPDK and running on general-purpose hardware, and a modular prototype built with the Click framework. Their solution is able to reach a throughput of 10 Mpps, but it suffers from several shortcomings that preclude its practical deployment in NDN networks. For instance: (1) It implements a custom ICN packet format that contains a fixed-length header that complicates future evolutions of the protocol, in violation of NDN's "universality" design principle [20]. (2) Similarly to *Caesar*, it can perform only an exact match between Interest and Data packets. (3) To take advantage of hardware dispatching, *Augustus* encapsulates ICN packets in IPv4 packets and configures the adapter's Receive Side Scaling (RSS) in such a way that the hash result depends only on the source IPv4 address. To ensure that a returning Data packet is dispatched to the thread that has the corresponding PIT entry, *Augustus* requires the IPv4 source address field to contain the CRC32 hash of the name. This technique, while functionally similar to NDN-DPDK's PIT token, requires neighboring routers to agree on a hash function before they can communicate. (4) The FIB is not designed to be thread-safe, thus rendering FIB updates impossible while the forwarder is handling data plane traffic.

Other approaches that use hop-by-hop state carried between Interest and Data to accelerate or eliminate PIT lookups have been proposed in CCN-GRAM [7] and ADN [8].

9 CONCLUSION AND FUTURE WORK

This paper describes NDN-DPDK, our implementation of a high-performance NDN forwarder on commodity server hardware. NDN-DPDK is built upon a number of novel ideas, such as the introduction of the PIT token for efficient Interest-Data prefix matching, the introduction of indirect CS entries for efficient CS prefix matching, resulting in more effective in-network caching, and the secure support for NDN's forwarding hints. Initial benchmarks demonstrate that NDN-DPDK is capable of sustaining 1.8 Mpps, or a corresponding 108 Gbps when 8 kB Data packets are used.

Lessons learned from the benchmarking effort helped us identify future work needed for performance improvements in NDN-DPDK. As we observed, the input thread becomes the bottleneck when there are 8 or more forwarding threads. We are exploring potential design changes to allow attaching multiple input threads to the same Ethernet adapter. At the same time, we hope that hardware acceleration can speed up packet dispatching by sending the vast majority of incoming packets directly to a forwarding thread, bypassing the input thread bottleneck and ensuring that the packet buffers are allocated from a memory pool on the same NUMA socket as the forwarding thread. This goal can be achieved progressively:

1. If the network card's RSS supports matching at arbitrary offsets in the Ethernet frame, Data and Nack can be dispatched directly, by configuring RSS to read the PIT token field. This will reduce the work of the input thread to just processing Interests and fragmented packets.
2. Dispatching Interests will likely require eBPF/P4 hardware or FPGA-based solutions. One idea is to download a copy of the NDT into the hardware accelerator, which will then (partially) decode the incoming NDN packets and perform NDT lookups with the Interest names, using the algorithm in section 3.2. At this point, only fragmented packets need to be processed by software input threads.

Our roadmap for future releases also includes: (1) Expanding the Content Store capacity by caching some packets in persistent memory (e.g., Intel Optane) or NVMe disk storage. These devices are more cost effective and energy efficient than traditional RAM, and would potentially allow a forwarder to have caching capacity in the order of a few terabytes. However, their slower access speed requires novel multi-tier caching algorithms. (2) Automatic load balancing among forwarding threads by dynamically adjusting the NDT entries to spread the forwarder's workload. (3) VXLAN tunnelling with hardware offloads. (4) Continuous in-depth performance profiling, to guide further optimizations in memory access (e.g., CPU cache prefetching) and data structure design (e.g., hash table collision resolution algorithms). (5) Implementation and benchmarking of in-forwarder cryptographic processing, such as implicit digest for Data packets. (6) New forwarding strategies with enhanced capabilities.

A Document-based View of the Risk Management Framework

Joshua Lubell, National Institute of Standards and Technology <joshua.lubell@nist.gov>

Abstract

Cybersecurity professionals know the Risk Management Framework (RMF) as a rigorous yet flexible process for managing security risk. But the RMF lacks a document focus, even though much of the process requires authoring, reviewing, revising, and accessing plans and reports. It is possible to build such a focus by looking more closely at these documents, starting with the *System Security Plan* and the roles of key participants responsible for it. Such a document- and role-centric view of the RMF process can lead the way toward more efficient and less error-prone security assurance.

1. Introduction

The National Institute of Technology's (NIST's) Risk Management Framework (RMF) [JTFTI2018] defines a rigorous yet flexible process for managing security risk. Application of the RMF process provides the evidence needed to justify assurance that an information system is operating within acceptable risk tolerance. The United States Government's Federal Information Security Modernization Act (FISMA) mandates RMF use for federal agencies and their contractors, yet the RMF process is sufficiently flexible to be used by all sorts of organizations. For example, Graves et al. show how an additive manufacturing service provider can use the RMF to assess system security risk [Graves] .

The RMF lists the roles and responsibilities (summarized in Section 2.3) of those primarily responsible for managing an organization's risk. Yet it is up to the organization whether multiple people fill a single role, whether a single person fills multiple roles, or whether a role is outsourced. Such a decision is based on multiple factors, including size of the organization, its appetite for risk, budget constraints, regulatory requirements, and the consequences of a loss of confidentiality, integrity, or availability (CIA) of the information its systems store, process, or transmit. One extreme might be a large government agency

Lubell, Joshua. "A Document-based View of the Risk Management Framework." Paper presented at Balisage: The Markup Conference, Washington, DC, US. July 27, 2020 - July 31, 2020.

or corporation with an entire department dedicated to information security risk management, with teams responsible for each role. The opposite extreme might be a family-run small business where all operational roles are filled by a single technology-savvy employee or outside service provider, and executive roles are filled by an owner, who consults with outside experts as needed. Regardless of whether the organization is large or small, public or private sector, or deals with information where a loss of CIA would be catastrophic to many people or few people, the RMF process establishes who is responsible and accountable for information security assurance.

Executing the RMF process requires preparation, modification, and review of a variety of documents. Although the RMF is structured and precise in describing its process, it describes these documents in an unstructured and disjointed manner. The documents are referenced in the context of the risk management tasks that involve them and of the people who are responsible for preparing, modifying, and reviewing them. But the RMF provides no schema or declarative markup vocabulary for these documents. It is therefore up to organizations using the RMF to provide document authoring guidance. Some organizations use spreadsheet or word processor document templates. Others use software tools such as the United States government's Cyber Security Evaluation Tool [CSET], which uses a questionnaire-driven approach to produce a Security Assessment Report document.

However, these templates and tools are one-off efforts that do not interoperate. A document created using one of them cannot be easily imported into another. Also, a template or tool designed for one organization's document may be unusable for another organization. And while a template provides guidance on formatting and structure, it has only limited ability to validate a document's completeness or consistency. As a result, RMF users lack the good authoring and content management tools they need to efficiently edit, navigate, share, and evaluate the very documents that are central to system security assurance.

As an initial step toward remedying the lack of tool support, this paper demonstrates a way to derive from the RMF a more document-centric view of risk management. This envisioned document-based view supplements the existing RMF guidance by providing an alternative way of looking at security assurance that is less process-focused and more oriented toward publishing, i.e., document authoring and management. Such a document focus can facilitate the development of schemas, tools for authors, reviewers, and approvers, and content management systems to better support distribution and archiving of risk management information. Beneficiaries would be the people filling the risk management roles listed in Section 2.3. This paper does not attempt to define machine-readable document models for the RMF. That goal, which is too ambitious for a single paper (or single person for that matter) is a long-term goal of NIST's Open Security Controls Assessment Language (OSCAL) project [OSCAL] [Piez19]. However, the methodology this paper demonstrates could be useful to projects such as OSCAL as a means for ensuring that such document models are faithful to the RMF process-centric guidance.

But why choose NIST's RMF for this investigation when there are other frameworks for system security assurance such as the ISO 27000 [ISO27000] and ISO/IEC 15408 [ISO15408] families of International Standards? This paper chooses the RMF as its basis because the RMF is widely used within the federal government and voluntarily used outside the federal government. And the RMF does not exist in a vacuum. The RMF's system life cycle process and use of systems engineering terminology are derived from ISO/IEC15288 [ISO15288], a systems engineering standard covering processes and life cycle stages [Zemrowski]. Also, some RMF tasks can be executed using NIST's “Framework for Improving Critical Infrastructure Cybersecurity” [NIST], a voluntary risk-based management approach used widely in both private and public sectors internationally. Additionally, the RMF process is compatible with any of the standardized catalogs of security controls. A security control is a safeguard or countermeasure that protects the confidentiality, integrity, and availability of a system and its information. Although the RMF refers users to the NIST Special Publication (SP) 800-53 [JTFTI2013] guidance for selection and tailoring of security controls, users not subject to FISMA are free to substitute security controls from ISO 27001 [ISO27001], ISO/IEC 15408, or other sources.

This paper proceeds as follows. The next section provides a high-level introduction to the RMF process and illustrates a document-focused view of RMF focusing specifically on the *System Security Plan* —

representative of the various documents involved in the RMF process — and its associated workflows. The third section discusses other relevant research and development contributions. The last section concludes the paper.

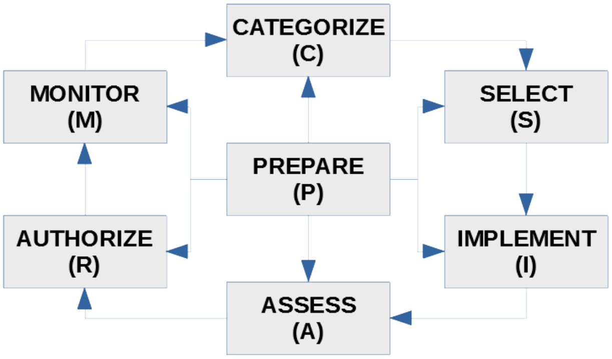
2. RMF-derived System Security Plan Workflows

The RMF defines a process that organizations can use to manage risk at both the enterprise-wide and system levels. The process is iterative and adaptive in response to new threats or changes to an organization's mission or business functions. The RMF process has a series of seven steps: *Prepare*, *Categorize*, *Select*, *Implement*, *Assess*, *Authorize*, and *Monitor*. Each step consists of multiple tasks. Each task has a set of potential inputs, some of which are expected outputs from other tasks. A task output that serves as an input to another task is often a document, although the RMF does not recommend specific document formats or schemas. These documents and the choreography between parties responsible for producing, reviewing, modifying, and consuming them constitute a set of workflows.

2.1. RMF Steps and High-level Workflow

Figure 1 illustrates how the seven RMF steps relate to one another and form a high-level workflow, with the caveat that steps are not always required to be followed in order. Also, although the connectors between steps are unidirectional, it is sometimes necessary to go backwards. For example, as discussed in Section 2.4.5, an assessment may trigger a re-implementation of security controls. The *Prepare* step's tasks lay the groundwork necessary to carry out the other RMF steps accurately and efficiently. Because the RMF process is iterative and adaptive, a task outcome from one of the six other steps may require revisiting one or more *Prepare* tasks.

Figure 1.



Risk Management Framework steps [JTFTI2018].

The six other RMF steps each serve the following purposes:

Categorize Describes the system and classifies the impact of loss of confidentiality, integrity, and availability of the information it stores, processes, and transmits.

Select Chooses an initial set of controls for the system, tailoring them as needed to reduce the risk to an acceptable level.

Implement Implements the controls and describes their deployment.

Assess Determines whether the controls are implemented correctly and are fit for purpose.

Authorize Determines whether the system is safe to operate or use based on acceptability of risk to operations, assets, and people. Authorization in this context is not to be confused with authorizing a user/process/device access to a system's resources. The former is a risk management function. The latter is a system function that should be subject to security controls enforcing identity management and access control policies.

Monitor Continuously monitors the system and associated controls to assess control effectiveness, report changes to the system and its environment, assess risk and impact, and report security posture.

The RMF is process-oriented and task-oriented. It is not document-oriented, although many task inputs and outputs are documents. As such, RMF guidance is organized by steps and their tasks rather than organized by document. Therefore, RMF specifies document workflows implicitly rather than explicitly. Extracting an implicit document workflow involves analyzing task descriptions that mention the document or a subset of the document as a potential input or expected output.

2.2. System Security Plan and Sample Document Model

This paper studies the *System Security Plan (SSP)* and its associated workflow based on the RMF tasks most involved with producing it. The SSP is only one of several documents integral to the RMF process. However, SSPs cover a significant subset of RMF tasks and involve all seven RMF steps. The SSP documents the security requirements for an information system and describes the security controls in place or planned for meeting those requirements [OMB]. The “system” in an SSP may be an individual workstation or laptop, a server, or a networked device. Networked devices can include operational technology such as “Internet of Things” devices, 3D printers, digitally controlled machines, industrial switches, and programmable logic controllers. Alternatively, a system may be a logically grouped collection of computers and/or devices. Thus, a single SSP can apply to more than one computer or device.

The RMF uses prose text to describe the information required for an SSP but provides no machine-readable schema for automated syntactic validation of whether an SSP is complete. This paper uses the current draft form of the OSCAL architecture, which includes an SSP document model, as an alternative approach for supporting the RMF SSP documentation objectives and enabling automated validation.

The OSCAL GitHub repository includes, as an example, an Extensible Markup Language (XML) document valid with respect to this SSP model. This simple example represents the SSP of a partially-implemented system that provides enterprise logging and log auditing capabilities and uses controls from the SP 800-53 catalog. This paper's analysis of step-level workflows (Section 2.4) uses this example as a means of showing how individual tasks within each RMF step affect the SSP contents. Figure 2 shows a high-level view of the example using a spreadsheet-like grid.

                      system-implementation
                      control-implementation
```

High-level OSCAL SSP document model example.

Some of the major SSP document model elements are defined as follows:

`import-profile`
References a pre-defined set of security requirements, for example a baseline from SP 800-53.

`security-sensitivity-level`
Indicates the system's overall information sensitivity categorization. May be “low”, “moderate”, or “high”.

`system-information`
Describes all the information types the system stores, processes, or transmits, for example, historical logging and auditing information. Each description specifies the impact of a loss of confidentiality, integrity, and availability of the information type.

`security-impact-level`
Specifies target levels of confidentiality, integrity, and availability for the system.

`authorization-boundary`
Establishes a system's scope of protection. Authorization boundary determination is the act of specifying what the organization is directly responsible for protecting.

`system-implementation`
Specifies the types of users who interact with the system and their roles, the system's component parts, services (e.g., ports and protocols), interconnections, and inventory items.

`control-implementation`
Describes how the system implements a set of controls. For each control implemented, specifies the control's description and set of implemented requirements satisfied.

`component`
Defines a part of an implemented system. A `component` can be hardware, software, or a service, policy, process, or procedure. Although not shown in Figure 2, components are critical model elements in that they enable the expression of relationships between implemented controls, hardware and software assets, and policies and business processes.

2.3. Key Participants

RMF Appendix D [JTFTI2018] lists the roles and responsibilities of key participants in the risk management process. These include the following key participants primarily responsible for RMF tasks impacting the SSP.

Information Security Officer	Oversees security responsibilities at the organizational level.
Authorizing Official	Assumes accountability for operating a system. May empower a designated representative to carry out many of the activities related to the execution of the RMF. However, only the Authorizing Official can determine whether the risk from the operation or use of the system is acceptable.
System Owner	Buys, develops, integrates, modifies, operates, maintains, and disposes of a system. Responsible for creating and maintaining the SSP.
Information Owner or Steward	Establishing the rules for appropriate use and protection of a specified type of information. A system may contain information from multiple information owners or stewards.
Common Control Provider	Implements, assesses, and monitors common controls. Common controls can be inherited by multiple systems, thus reducing the complexity and protection costs of an organization's IT infrastructure. For example, hardware token-based authentication, implemented enterprise-wide using Personal Identity Verification cards, is an example of a common control.
Security Architect	Ensures that the enterprise architecture addresses stakeholder protection needs and the corresponding system requirements necessary to protect organizational missions and business functions.
Control Assessor	Evaluates implemented controls to determine their effectiveness.

For a small organization, one person might fulfill multiple roles. Conversely, a large organization could have multiple people filling a single role, for example, a team of Control Assessors. Also, some roles can be outsourced to third parties, such as Common Control Provider, Control Assessor, and System Owner (as in the case of a cloud-based service). Other roles, such as Authorizing Official, cannot be outsourced as they require executive-level accountability.

2.4. Step-level Workflows

The following subsections describe the SSP publishing workflow centered around each RMF step. A figure highlighting the RMF step illustrates each workflow. The highlighted RMF step has a bulleted list of the subset of RMF tasks for that step directly pertaining to the SSP. This bulleted list does not exist explicitly in SP 800-37 but is derived from the subset of expected outputs that involve SSP content authoring, SSP content review, or determination of SSP approval. The figure also shows key participants responsible for these tasks with dashed connectors pointing either to the RMF step or to a directional arrow leading to or from the step. A second figure indicates which portions of the SSP document model described in Section 2.2 get populated or modified in each workflow. The *Categorize* and *Select* publishing workflows (Section 2.4.2 and Section 2.4.3) also include XML code illustrating how the `component` element enables traceability between control implementations, assets, business processes, and policies.

2.4.1. Prepare

Two *Prepare* tasks that result in modification to the SSP are “Common Control Identification” and “Authorization Boundary” determination. As shown in Figure 3, the Information Security Officer and Authorizing Official add content to the SSP. The Information Security Officer identifies common controls at the organizational level and documents their planned implementation. The Authorizing Official determines and documents a system's authorization boundary, using the system design documentation as input.

Figure 4 indicates the portions of the SSP document where new information is added, namely the `authorization-boundary` element and the portion of the `control-implementation` element pertaining to common control documentation. System design documentation comprises much of the input to the “Authorization Boundary” task. The RMF provides no guidance on this documentation's contents or structure but suggests that it includes a mix of prose and diagrams defining and identifying system elements, their interactions and the environment in which the system operates. Thus, `authorization-boundary` might reference a diagram showing an authorization boundary including the server and logging software with an environment of operation including client devices or services that write to or read from the log. `control-implementation` specifies any common controls inherited by the logging and auditing system. For example, if the system is located in a facility with physical access controls, `control-implementation` would include the physical access controls. The *Select* step-level workflow (Section 2.4.3) includes an example of `control-implementation` XML markup that does not specify a common control, but rather is specific to the logging and auditing system.

Figure 4.

                                                                            Logging and
                                                                            Auditing System
                                               description
                                               annotation
                                                 (2 rows)
                                               security-sensitivity-level   moderate
                                               system-information
                                               security-impact-level
                                               status
                                               authorization-boundary
                      system-implementation
                      control-implementation
```

Affected portions of SSP document.

2.4.2. Categorize

Two *Categorize* tasks that result in modification to the SSP are “System Description” and “Security Categorization”. As shown in Figure 5, the System Owner, Information Owner or Steward, and Authorizing Official bear primary responsibility for tasks impacting the SSP contents. The System Owner is primarily responsible for the System Description task and, together with the Information Owner or Steward, bears joint responsibility for the Security Categorization task. The Authorizing Official reviews the security categorization results and decides whether to approve the categorization. If approved, the RMF process proceeds with the *Select* step. Otherwise, the categorization process must be repeated.

As shown in Figure 6, the *Categorize* step populates a substantial portion of the SSP. The two tasks together create content for the `system-implementation` element and most of the `system-characteristics` element content except for its `status` and `authorization-boundary` sub-elements. `system-information`, a child element of `system-characteristics` not shown in Figure 6, lists a single information type: “System and Network Monitoring”. The specified impact of a loss of confidentiality, integrity, and availability is obtained by referencing NIST's “Appendices to Guide for Mapping Types of Information and Information Systems to Security Categories” [Stine], which provides a catalog of information types with suggested impacts.

`system-implementation` contains many descendant elements representing the system's components, assets, and roles responsible for these entities. The OSCAL SSP example defines several logging and auditing system components. These include the server software, the enterprise logging, monitoring, and alerting policy, the systems integration and inventory management processes, and the enterprise's configuration management guidance. In the interest of brevity, this paper only shows XML markup and content pertaining to the logging, monitoring, and alerting policy. The following XML defines the policy component, assigning it an identifier and assigning responsibility for maintaining the policy to the legal department.

```
<component id="component-logging-policy" component-type="policy">
    <prop name="version">2.1</prop>
    <prop name="last-modified-date">20181015</prop>
    <status state="operational"/>
    <responsible-role role-id="maintainer">
        <party-id>legal-department</party-id>
    </responsible-role>
</component>
```

The XML below defines the logging server asset as part of the system's asset inventory. The logging server is assigned an administrator and owner. `implemented-component` references a component implemented in a given system inventory item. Thus, the logging server implements both the server software and policy components.

```
<inventory-item id="inventory-logging-server"
                asset-id="asset-id-logging-server">
    <responsible-party role-id="asset-administrator">
        <party-id>enterprise-asset-administrators</party-id>
    </responsible-party>
    <responsible-party role-id="asset-owner">
        <party-id>enterprise-asset-owners</party-id>
    </responsible-party>
    <implemented-component component-id="component-logging-server"
                           use="runs-software"/>
    <implemented-component component-id="component-logging-policy"
                           use="enforces-policy"/>
</inventory-item>
```

Lubell, Joshua. "A Document-based View of the Risk Management Framework." Paper presented at Balisage: The Markup Conference, Washington, DC, US. July 27, 2020 - July 31, 2020.

2.4.3. Select

The *Select* tasks that result in modification to the SSP (shown in Figure 7) are “Control Selection, Tailoring, and Allocation” and “Documentation of Planned Control Implementations”. The System Owner and Common Control Provider jointly bear primary responsibility for selecting and tailoring the system's security controls. The Security Architect and Information Security Officer are jointly responsible for control allocation. Allocation entails determining whether controls shall be system-specific, hybrid, or common, and then assigning the controls to the system elements (i.e., machine or environment in which the system operates) responsible for providing a security capability. The System Owner and Common Control Provider are responsible for documenting the controls and plans for their implementation in the SSP, as represented in the `control-implementation` element in Figure 8. `import-profile` contains a reference to common controls (such as the physical access controls mentioned in Section 2.4.1) identified during the *Prepare* step.

                       system-characteristics
                       system-implementation
                       control-implementation
```

Affected portions of SSP document.

`control-implementation` is updated to include additional controls needed to supplement the inherited common controls. The System Owner selects SP 800-53 control AU-1 (Audit and Accountability Policy and Procedures), whose control statement is shown in Figure 9. The italicized text inside brackets represents parameters. Selecting a SP 800-53 control requires inserting values for these parameters. Appendix A provides the AU-2 control statement as represented in OSCAL's SP 800-53 catalog model. As Appendix A shows, the OSCAL catalog model uses a `part` element to represent each of the nested list items in Figure 9. Each `part` has an `@id` attribute. Each of the three parameters is represented by a `param` element, also with an `@id` attribute.

Figure 9.

> The organization:
>
> a. Develops, documents, and disseminates to [*organization-defined personnel or roles*]:
>
> i. An audit and accountability policy that addresses purpose, scope, roles, responsibilities, management commitment, coordination among organizational entities, and compliance; and
>
> ii. Procedures to facilitate the implementation of the audit and accountability policy and associated audit and accountability controls; and
>
> b. Reviews and updates the current:
>
> i. Audit and accountability policy [*organization-defined frequency*]; and
>
> ii. Audit and accountability procedures [*organization-defined frequency*].

Security control AU-1: Audit and Accountability Policy and Procedures [JTFTI2013].

The SSP documents the selection and planned implementation of AU-1 by associating each part of the control statement with the component that implements the part, assigning parameter values as needed. The following XML represents the planned implementation of list item "b.", sub-list item "i." from Figure 9 ("The organization … Reviews and updates the current … Audit and accountability policy [*organization-defined frequency*]").

```
<control-implementation>
    <implemented-requirement control-id="au-1">
      ...
      <statement statement-id="au-1_smt.b.1">
          <by-component component-id="component-logging-policy">
              <set-parameter param-id="au-1_prm_2">
                   <value>annually, and other times as necessary in
response to regulatory or organizational changes</value>
              </set-parameter>
          </by-component>
      </statement>
      ...
   </implemented-requirement>
</control-implementation>
```

`by-component` references the component implementing this portion of the AU-1 statement. The *organization-defined frequency* parameter is assigned the value "annually, and other times as necessary in response to regulatory or organizational changes".

Once the controls and their planned implementation are documented, the Authorizing Official reviews the SSP to determine if it is complete, consistent, and satisfies the system's security requirements. If approved, the RMF process proceeds with the *Implement* step. Otherwise, the *Select* step must be repeated.

2.4.4. Implement

As the final task culminating the *Implement* step, the System Owner and Common Control Provider update the SSP's control implementation information (shown in Figure 10) to reflect any differences between the actual control implementations and the planned implementation documentation produced in the *Select* step. Figure 11 shows that the update results in a modification to the SSP's `control-implementation` element as needed to reflect the actual implementation.

```

Affected portions of SSP document.

2.4.5. Assess

During the *Assess* step (Figure 12), the System Owner and Common Control Provider update the SSP to reflect the state of the controls after the Control Assessor's initial assessment and any changes made in response to recommended “Remediation Actions”. If the assessment indicates controls were not properly implemented, the *Implement* step needs to be revisited. The assessment findings could also possibly trigger an update to a system-level or organization-wide risk assessment, requiring a return to the *Prepare* step.

As was the case for the *Implement* step (Figure 11), the *Assess* step's effect on the SSP document is limited to modification of the `control-implementation` element.

2.4.6. Authorize

Following an analysis of risk from operating or using the system, the Authorizing Official determines whether the response to the risk is acceptable. The "Risk Response" is based on a review of the System Owner's and Common Control Provider's modification to the SSP (Figure 11), and of related documents such as assessment reports and Plan of Action and Milestones (defined in Section 3.3) for addressing any SSP deficiencies. These documents together comprise the Authorization Package. A determination that the Risk Response is unacceptable results in a return to the *Implement* step, as shown in Figure 13.

2.4.7. Monitor

There are three tasks in the *Monitor* step that can trigger updates to the SSP, as shown in Figure 14. They are "System and Environment Changes", "Authorization Package Updates", and "System Disposal". Examples of system and environmental changes include machine elements such as hardware or software upgrades, human elements such as staff turnover, and environmental or physical elements such as physical access controls or relocation of the facility. These changes result in the System Owner or Common Control Provider updating `system-information` and `system-implementation` (as shown in Figure 15) and a return to the *Categorize* step. The *Prepare* step must be revisited as well if determined necessary by the Information Security Officer.

                      control-implementation
```

Affected portions of SSP document.

To achieve timely risk management, the System Owner and Common Control Provider update the SSP included in the Authorization Package in response to continuous monitoring results. These “Authorization Package Updates”, like “System and Environment Changes”, affect the RMF workflow and SSP contents as shown in Figure 14 and Figure 15, respectively.

System Disposal — removal of a system from operation — requires multiple actions (e.g., media sanitization, configuration management, record retention) for which the System Owner bears primary responsibility. These actions result in updating the `status` element in the SSP as shown in Figure 15.

2.5. A “Publishing” Perspective

The previous subsection analyzed the RMF workflows from an SSP document perspective. This subsection looks at the analysis results from the viewpoint of three activities central to SSP document “publishing”: authoring, reviewing, and updating. *Authoring* is the creation of new SSP document content. *Reviewing* is the evaluation of SSP content to determine whether it meets a set of criteria. *Updating* is the modification of existing SSP content in response to reviewer feedback, new implementation experience, or an environmental change. Table 1 summarizes the results of this publishing-focused analysis.

SSP authoring takes place mainly during *Categorize* and *Select*. As shown in Section 2.4.2 and Section 2.4.3, most of the SSP content is created during these RMF steps, by the System Owner and — to the extent that the system leverages common controls — Common Control Provider. Some authoring also takes place during *Prepare* when the Information Security Officer identifies common controls and documents their planned implementation. The Authorizing Official documents the authorization boundary during *Prepare*, but this consists mostly of references to concepts from other documents such as system design documents and diagrams.

SSP reviewing occurs during most RMF steps, but especially during *Assess* and *Authorize* where reviewing is the central purpose of the step. The Authorizing Official is the chief reviewer of the RMF process and has the greatest authority and accountability. The Control Assessor and Information Security Officer have important reviewer roles as well. These three reviewers have differing and complementary qualifications. The Authorizing Official is a senior executive or business owner with an intimate understanding of organizational mission, budget constraints, and security and privacy risks. The Control Assessor is an information security expert with the detailed knowledge necessary to evaluate effectiveness of control implementations. The Information Security Officer has expertise spanning both security assurance and implementation and offers both an organization and systems perspective.

SSP updating occurs during *Implement*, *Assess*, and *Monitor*, with the System Owner and possibly the Common Control Provider bearing primary responsibility. Given that the System Owner and Common

Control Provider also have outsized roles in SSP authoring, it follows that their requirements should be given top priority when developing SSP document schemas and editing tools.

Table 1.

SSP authoring, reviewing, and updating throughout the RMF process.

Activity	RMF Step	Primary Responsibility
Authoring	*Prepare*	Information Security Officer, Authorizing Official
	Categorize	System Owner, Common Control Provider, Information Owner or Steward
	Select	System Owner, Common Control Provider, Security Architect, Information Security Officer
Reviewing	*Categorize*, *Select*	Authorizing Official
	Assess	Control Assessor
	Authorize	Authorizing Official
	Monitor	Information Security Officer
Updating	*Implement*, *Assess*, *Monitor*	System Owner, Common Control Provider

This paper claimed in Section 1 that a document-centric analysis can lead to improved schemas and tools for the key participants in the RMF process. The analysis in Section 2.4 and subsequent analysis in this subsection support that claim by providing these takeaways:

- Authoring schemas and editing tools should prioritize the needs of the System Owner and Common Control Provider. People fulfilling these roles may have technical knowledge about systems and/or controls for which they are responsible. They are less likely, however, to have risk management or security assurance expertise. Because these roles produce and maintain much of the SSP content, making their authoring and update tasks easier and less error-prone should result in better cybersecurity and cost savings to their organizations.

- Solutions that automate review/update workflows have the challenges of accommodating not only reviewers, but also authors performing updates. Additionally, these solutions should be tailored to the differing needs and areas of expertise of the Authorizing Official, Control Assessor, Information Security Officer reviewer roles.

- Since no single tool can fit the requirements of all key participants in the RMF process, interoperability standards are needed to support an ecosystem of tools. The proposed and evolving OSCAL document formats could meet this need. Another candidate is the Darwin Information Typing Architecture, discussed in Section 3.2.

3. Related Work

Each of the following research and development efforts offer insights or technologies relevant to this paper's document-based analysis of the RMF. The first offers lessons learned from a publishing discipline outside the realm of security assurance. The second is a standards architecture that supports publishing workflows and can also enable specialized data models for controls, catalogs, and profiles. The third is a cyber risk measurement technique whose utility would be enhanced by the document-focused view of the RMF this paper advocates.

3.1. Incentive-focused Document Workflow Analysis

A publishing workflow's success depends upon the actors involved being incentivized to work toward a common goal. In the case of RMF-based security assurance, there are two common scenarios. For United States federal agencies and their contractors, the System Owner, Information Security Officer, Authorizing Official, and other participants are all incentivized by FISMA to adhere to the RMF process. Non-federal companies and organizations have no FISMA requirement. However, the RMF's system life cycle approach ensures that security plans and implementations are mission-based and tied to business requirements. Therefore, even without a common incentive such as FISMA compliance, good systems engineering practices can result in mutually reinforcing incentives for those responsible for SSP development and development of other RMF document outputs.

Piez [Piez20] studies workflow participant incentives in research journal publishing enterprises: an industry quite distinct from security assurance. There are some parallels in terms of roles (Author versus System Owner, Peer Reviewer versus Control Assessor, Journal Editor versus Authorizing Official) and process steps (*Review* versus *Assess*, *Accept/Reject* versus *Authorize*). However, there are significant differences in incentives. For example, security assurance strongly encourages identification and implementation of common controls wherever possible. Research articles submitted to journals, on the other hand, are required to have intellectual content that is mostly original. Even survey articles, where previously published work is highlighted, must contain a thorough and substantive analysis of the prior art.

Unlike security assurance, where deployment of declarative document markup technologies such as OSCAL is in its infancy, journal publishing workflows have been XML-enabled for a long time. However, as Piez points out, XML has achieved its greatest successes in post-production processes where authors and reviewers are not involved. Despite decades of XML implementation experience in the journal publishing world, most authors still submit papers in word processor formats, and many use spreadsheets for managing and responding to reviewer comments. Lessons learned regarding what works and what does not from the journal publishing industry could help markup technologists determine the implementation approaches most likely to be successful in automating and streamlining development of SSPs and other security assurance documents. However, implementers of security assurance publishing tools should be aware that incentives among security assurance workflow participants differ from the ecosystem of incentives that exist in the journal publishing world.

3.2. DITA

The Darwin Information Typing Architecture (DITA) [OASIS], a standardized XML-based architecture for authoring, managing, reusing and transforming technical content, could provide the foundation for an interoperable set of tools to meet the needs of SSP authors, updaters, and reviewers. Unlike other declarative markup language frameworks, DITA supports the definition of element types that are *specializations* of other element types [Kimber]. Specializations inherit not only the syntactic structure of their base element type, but also the processing behavior. To understand the benefits of specialization in the context of the RMF process, suppose a DITA element type was defined for control catalogs, with specializations for SP 800-53, ISO 27001, and ISO/IEC 15408. Then a tool developer could leverage the same code implementing the generic catalog element type to support the RMF *Select* step for all three catalogs.

Although OSCAL has a generic catalog schema that can be extended to support other catalogs besides SP 800-53, OSCAL does not support specialization in the general sense. For example, the OSCAL `control-implementation` element's support for parameters (discussed in Section 2.4.3) accommodates SP 800-53 but may not be needed for other catalogs. Therefore, `control-implementation` is *over-specified* for catalogs without control parameters. Conversely, consider a catalog whose controls have properties not pre-defined in OSCAL. `control-implementation`'s content model can be extended using OSCAL's `prop` element to provide name-value pairs for these additional control properties.

However, the OSCAL `control-implementation` element would then be *under-specified* without supplemental documentation for how OSCAL tools should handle the `prop` extensions. DITA's specialization mechanism provides a formal way to avoid over-specification and under-specification, explicitly separating general syntax and processing behavior from specialized syntax and processing behavior.

The DITA Open Toolkit [DITA-OT], an output-producing processor that transforms input authored using DITA-conforming XML vocabularies into other formats, implements an extensible workflow for integrating DITA processing with other tasks. The DITA Open Toolkit could potentially be used for automating the authoring and review of SSPs and other documents in the RMF process. SCAP Composer [Lubell19] [Lubell20], a DITA Open Toolkit plug-in that contributes toward implementing the RMF "System and Environment Changes" task (see Section 2.4.7), provides an example of applying DITA specialization and the DITA Open Toolkit's extensible workflow mechanism to solve a security assurance problem.

3.3. Cybersecurity System Risk Indicator (CSRI)

Wilbanks [Wilbanks] developed a methodology to measure system cybersecurity risk that suggests potential benefits of deploying declarative markup technologies in the security assurance space. Wilbanks's CSRI, used within the United States Department of Education's Federal Student Aid cybersecurity risk management program, employs a set of weighted risk factors to quantify a system's vulnerability to cyber threats. Many of these risk factors are computed by extracting relevant information from documents associated with the RMF process. For example, one highly weighted risk factor involves analyzing a system's Plan of Action and Milestones (POAM), a document created by the System Owner and Common Control Provider based on the Control Assessor's findings and recommendations. The POAM describes planned actions with due dates to correct deficiencies identified during the assessment. The CSRI's POAM risk factor score is based on the number of unmet milestones, their criticality, and aging (how many are overdue).

Because POAMs and other risk management-related documents are typically in word processor or spreadsheet formats, extracting the information needed to compute document-based CSRI risk factors is a time-consuming, manual process. If these documents were tagged in a declarative markup language, they would be more amenable to structured queries and optimized presentation of results. For example, a CSRI dashboard user interface that computes and displays risk factors could be efficiently implemented using low-cost and ubiquitous XML- or HTML5-based technologies.

4. Conclusion

This paper presented a new approach that supports the creation of the System Security Plan, a critical Risk Management Framework output. The new approach, based on an SSP document model defined using declarative markup and on the RMF roles primarily responsible for documenting the SSP, offers an alternative view into security assurance. By emphasizing roles and how they relate to SSP document elements, this alternative view provides a roadmap for implementers of standards and tools for authoring and accessing the information in SSP documents. The same approach used in this paper can be extended to other documents arising from the RMF process such as assessment reports and POAMs. With the research and development results discussed in Section 3, the document and role-centric view of the RMF process can lead the way toward new standards and tools enabling more efficient and less error-prone security assurance.

But, to quote [Piez20], "the platform is not the capability." The best languages, schemas, and tools in the world are supplements — but not substitutes — for the expertise required to assess cyber-risk, the systems engineering skills needed to identify common controls or establish authorization boundaries, and the hardware, software, and people skills needed to implement security controls.

A. OSCAL Representation of AU-1 Subset

The following listing, extracted from the OSCAL SP 800-53 catalog, represents the AU-1 control statement shown in Figure 9.

```

Abstract. Mobile edge computing (MEC) is an emerging paradigm that integrates computing resources in wireless access networks to process computational tasks in close proximity to mobile users with low latency. In this paper, we propose an online double deep Q networks (DDQN) based learning scheme for task assignment in dynamic MEC networks, which enables multiple distributed edge nodes and a cloud data center to jointly process user tasks to achieve optimal long-term quality of service (QoS). The proposed scheme captures a wide range of dynamic network parameters including non-stationary node computing capabilities, network delay statistics, and task arrivals. It learns the optimal task assignment policy with no assumption on the knowledge of the underlying dynamics. In addition, the proposed algorithm accounts for both performance and complexity, and addresses the state and action space explosion problem in conventional Q learning. The evaluation results show that the proposed DDQN-based task assignment scheme significantly improves the QoS performance, compared to the existing schemes that do not consider the effects of network dynamics on the expected long-term rewards, while scaling reasonably well as the network size increases.

Keywords: Mobile Edge Computing (MEC), Task Assignment, Double Deep Q Networks (DDQN)

1 Introduction

The rapid development of Internet of Things (IoT) has generated a huge volume of data at the edge of the network. This requires a large amount of computing resources for big data analysis and processing, the capability of real-time remote control over both real and virtual objects, as well as physical haptic experiences. Cloud computing has been proposed as a promising solution to meet the fast-growing demand for IoT applications and services. However, centralized cloud data centers are often far from the IoT devices and users. How to provide high quality of service (QoS) to the interactive IoT applications, especially at the edge of the network, is still an open problem. This motivates a new paradigm referred to as mobile edge commuting (MEC), also called multi-access edge computing or fog computing, which extends cloud computing to the network edge

Hsieh, Li-Tse; Liu, Hang; Guo, Yang; Gazda, Robert. "Quality of Service Optimization in Mobile Edge Computing Networks via Deep Reinforcement Learning." Paper presented at The 15th International Conference on Wireless Algorithms, Systems, and Applications (WASA 2020), Qingdao, CN. September 13, 2020 - September 15, 2020.

[1, 2]. Edge nodes or edge devices provide computing services and carry out computationally intensive application and data processing tasks at the edge of the network between end users and cloud data centers. They can be computing servers or micro data centers deployed with routers, gateways, and access points in wireless access networks, and can also correspond to portable devices such as mobile phones, drones, robots, and vehicles with excessive computing resources that can be utilized to offer services to others. MEC can reduce transmission latency and alleviate network congestion. It also allows network operators to provide value-added real-time services and enhance QoS to end users.

A resource demand estimation and provisioning scheme for an edge micro data center is presented in [3] to maximize resource utilization. In [4], the authors proposed a hierarchical game framework to model the interactions where the edge nodes help the cloud data center operators process delay-sensitive tasks from mobile users and to determine the edge node resource allocation, service price, and pairing of edge nodes and data center operators with Stackelberg game and matching theory. These works focus on the interaction between edge nodes and cloud data centers to better serve the users, but they either abstract the MEC layer as a single edge server or assume that the edge nodes are independent of each other without consideration of their cooperation in processing tasks. The authors in [5] proposed an offloading scheme that allows a MEC edge node to forward its tasks to its neighboring edge nodes for execution to balance the workload fluctuations on different nodes and reduce the service delay. However, the paper made many idealized assumptions in assigning the tasks to the edge nodes, such as a fixed task arrival rate at each edge node as well as pre-known queuing delay of each node and transmission delay between the nodes. Their task assignment algorithm utilizes the classical model-based techniques that relies on these idealized assumptions to minimize service delay for one-shot optimization under a given deterministic MEC network state. Such an approach fails to capture the broad range of network parameters and ignores the impacts of dynamic network situations and heterogeneous nodes to the network performance.

On the other hand, reinforcement learning techniques can capture a wide range of control parameters and learn the optimal action, i.e. the policy for task assignments, with no or minimal assumptions on the underlying network dynamics. The conventional Q-learning algorithm is based on a tabular setting with high memory usage and computation requirements and is known to overestimate action values under certain conditions [6]. Recently, double deep Q networks (double DQN or DDQN) were introduced to address the problems of conventional Q-learning, which combines double Q-learning with two deep neural networks [7]. DDQN can provide large-scale function approximation with a low error and reduces the overestimations.

In this paper, we propose an online DDQN-based algorithm for task assignment in dynamic MEC networks, which accounts for both performance and complexity. The proposed algorithm takes into consideration the cooperation among the edge nodes as well as the cooperation between the edge nodes and a cloud data center. It performs sequential task assignment decisions in a series of control epochs to enable the nodes to help each other process user tasks and optimize a long-term expected QoS reward in terms of the service delay and task drop rate. The algorithm is designed to operate under stochastic and time-varying task arrivals, node processing capabilities, and network communication delays without a prior knowledge of these underlying dynamics. A decomposition technique is also introduced to reduce computational complexity in DDQN learning.

The remainder of the paper is organized as follows: Section 2 describes the problem formulation. In Section 3, we derive the online DDQN-learning based cooperative MEC task assignment algorithm in detail. In Section 4, we provide the numerical experimental results. Finally, the conclusions are given in Section 5.

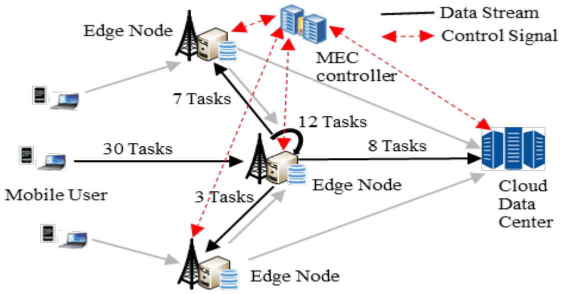

Fig. 1. An example MEC system model.

2 Problem Formulation

Fig. 1 illustrates an example MEC system model for consideration in this paper. A set of N edge nodes, $\mathcal{N} = \{1, \dots, N\}$, with computing, storage, and communication resources are co-located or integrated with cellular base stations (BSs) or WiFi access points (APs) in a wireless access network. IoT devices or mobile users connect to nearby edge nodes through their cellular or WiFi radios and send their computation-intensive tasks to the edge nodes to be processed. When an edge node receives tasks from its associated users, it either processes them locally, or forwards part or all of its unprocessed tasks to other edge nodes or to a remote cloud data center for processing if the node does not have sufficient resources to complete all the tasks. The remote cloud data center, n_c is modeled as a special node that is equipped with powerful computing capability but incurs a high network delay due to the distant location.

We assume that the system operates over discrete scheduling slots of equal time duration. At the beginning of a time slot t, a controller in the MEC network collects the network conditions and determines a task assignment matrix, $\boldsymbol{\Phi}^t = [\phi_{n,j}^t : n, j \in \mathcal{N} \cup n_c\}$. It informs the edge nodes to offload or receive computing tasks to/from the other nodes depending on the task assignment, where $\boldsymbol{\phi}_n^t = [\phi_{n,j}^t, \phi_{j,n}^t : j \in \mathcal{N} \cup n_c\}$ represents the task assignment vector regarding edge node n. $\phi_{n,j}^t$ specifies the number of tasks that edge node n will send to node j for processing in the time slot t, and $\phi_{n,n}^t$ is the number of tasks that are processed locally by edge node n. We assume that the data center n_c will process all the received tasks by itself without offloading them to the edge nodes, i.e. $\phi_{n_c,j}^t = 0, j \in \mathcal{N}$.

We first formulate the problem of stochastic task assignment optimization and then explore the methods to solve the optimization problem. Each edge node maintains a queue buffering the tasks received from its users, and q_n^t represents the queue length of node *n* at the beginning of time slot *t.* The queue size is bounded as $q_n^{(max)}$. It is assumed that the number of computational tasks arrived at edge node *n* in time slot *t*, A_n^t, is random and its distribution is unknown in advance. We denote $\boldsymbol{A^t}$= $\{A_n^t : n \in \mathcal{N}\}$. The task processing capability of node *n* in time slot *t*, denoted as s_n^t, which is the maximal number of tasks that node *n* can serve in the slot *t*, is also time-varying and unknown in advance due to the variable task complexity and adaptation of CPU cycles based on the power status and heat. The queue evolution of node *n* can then be written as $q_n^{t+1} = \max\{0, \min[q_n^t + \mathrm{A}_n^t + \sum_{i \in e_n} \phi_{i,n}^t - \phi_{n,i}^t - s_{n,}^t, q_n^{(max)}]\}$, where $\sum_{i \in e_n} \phi_{n,i}^t$ with $e_n = \{\mathcal{N} \cup n_c\} \backslash \{n\}$ represents the number of tasks that edge node *n* offloads to other nodes, and $\sum_{i \in e_n} \phi_{i,n}^t$ is the number of tasks that edge node *n* receives from other nodes in slot *t*.

When an edge node *n*, $n \in \mathcal{N}$ offloads a task to another node j, $j \in \mathcal{N} \cup n_c$ for execution at time slot *t*, it incurs an network delay cost, denoted as $c_{n,j}^t$. Let $\boldsymbol{c}_n^t = (c_{n,j}^t, c_{j,n}^t : j \in \mathcal{N} \cup n_c)$ represent the network delay vector for offloading the tasks from node *n* to any other node j, or vice versa, and $c_{n,n}^t = 0$. The network delay between two nodes is also time-varying and unknown in advance due to dynamic network conditions, traffic load, and many other uncertain factors. For a node *n*, $n \in \mathcal{N} \cup n_c$, at the beginning of time slot *t*, we characterize its state by its queue size q_n^t, its task processing capability $s_{n,}^t$, and the delay cost to offload a task to other nodes $\boldsymbol{c}_n^t$, thus $\boldsymbol{\chi}_n^t = (q_n^t, s_{n,}^t \boldsymbol{c}_n^t)$. The global state of the MEC network at the beginning of scheduling slot *t* can be expressed as $\boldsymbol{\chi^t}$= $(\boldsymbol{\chi}_n^t: n \in \mathcal{N} \cup n_c) = (\boldsymbol{q^t}, \boldsymbol{s^t}, \boldsymbol{c^t}) \in X$, where $\boldsymbol{q^t}$= $\{q_n^t : n \in \mathcal{N} \cup n_c\}$, $\boldsymbol{s^t} = \{s_n^t : n \in \mathcal{N} \cup n_c\}$, $\boldsymbol{c^t} = \{\boldsymbol{c}_n^t : n \in \mathcal{N} \cup n_c\}$, and X represents the whole MEC system state space.

We consider real-time interactive IoT applications and employ the task service delay and task drop rate to measure the system QoS. The task service delay, d_n^t, is defined as the duration from the time a task arrives at an edge node to the time it is served, and the task drop rate, o_n^t, is defined as the number of dropped tasks per unit of time. Given the MEC network state, $\boldsymbol{\chi^t}$= $(\boldsymbol{q^t}, \boldsymbol{s^t}, \boldsymbol{c^t})$ at the beginning of a time slot *t*, a task assignment $\boldsymbol{\Phi}^t = \boldsymbol{\Phi}(\boldsymbol{\chi^t}) = [\phi_{n,j}(\boldsymbol{\chi^t}): n, j \in \mathcal{N} \cup n_c\}$ is performed, which results in an instantaneous QoS reward. We define the instantaneous QoS reward at time slot *t* as

$$U\big(\boldsymbol{\chi^t}, \boldsymbol{\Phi}(\boldsymbol{\chi^t})\big) = \textstyle\sum_{n \in \mathcal{N}} [w_d U_n^{(d)}(\boldsymbol{\chi^t}, \boldsymbol{\Phi}(\boldsymbol{\chi^t})) + w_o U_n^{(o)}(\boldsymbol{\chi^t}, \boldsymbol{\Phi}(\boldsymbol{\chi^t}))], \tag{1}$$

where $U_n^{(d)}(.)$ and $U_n^{(o)}(.)$ measure the satisfaction of the service delay and task drop rate, respectively. w_d and w_o are the weight factors indicating the importance of delay and task drop in the reward function of the MEC system, respectively.

As mentioned before, the task arrivals and network states are non-deterministic and vary over time. We therefore want to cast the task assignment as a dynamic stochastic optimization problem, which maximizes the expected long-term QoS reward of an MEC network while ensuring the service delay and task drop rate are within their respective acceptable thresholds. More specifically, we define $V(\boldsymbol{\chi}, \boldsymbol{\Phi}) = \mathrm{E}[(1 - \gamma) \sum_{t=1}^{\infty} \gamma^{t-1} U(\boldsymbol{\chi}^{\boldsymbol{t}}, \boldsymbol{\Phi}(\boldsymbol{\chi}^{\boldsymbol{t}})) |\, \boldsymbol{\chi}^{\mathbf{1}}]$ as the discounted expected value of the long-term QoS reward of an MEC network, where $\gamma \in [0, 1)$ is a discount factor that discounts the QoS rewards received in the future, and $(\gamma)^{t-1}$ denotes the discount to the (t −1)-th power. $\boldsymbol{\chi}^{\mathbf{1}}$ is the initial network state. $V(\boldsymbol{\chi}, \boldsymbol{\Phi})$ is also termed as the state value function of the MEC network in state $\boldsymbol{\chi}$ under task assignment policy $\boldsymbol{\Phi}$. Therefore, the objective is to design an optimal task assignment control policy $\boldsymbol{\Phi}^*$ that maximizes the expected discounted long-term QoS reward, that is,

$$\boldsymbol{\Phi}^* = \arg \max_{\boldsymbol{\Phi}} \big(V(\boldsymbol{\chi}, \boldsymbol{\Phi})\big) \tag{2}$$

$$\text{subject to } d_n^t \le d^{(\max)}, o_n^t \le o^{(\max)}, \forall: n \in \mathcal{N} \cup n_c$$

where $d^{(\max)}$ and $o^{(\max)}$ are the maximal tolerance thresholds for the service delay and the task drop rate, respectively. $V^*(\boldsymbol{\chi}) = V(\boldsymbol{\chi}, \boldsymbol{\Phi}^*)$ is the optimal state value function. We assume that the probability of a network state in the subsequent slot depends only on the state attained in the present slot and the control policy, i.e. the MEC network state $\boldsymbol{\chi}^{\boldsymbol{t}}$ follows a controlled Markov process across the time slots. The task assignment problem can then be formulated as a Markov decision process (MDP) with the discounted reward criterion, and the optimal task assignment control policy can be obtained by solving the following Bellman's optimality equation [8],

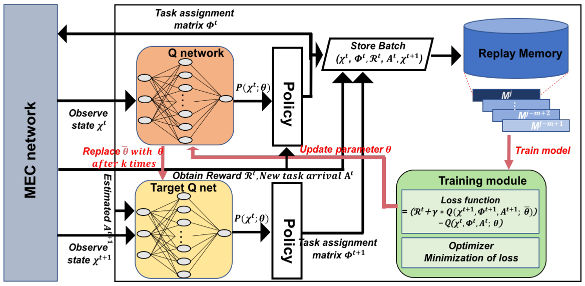
$$V^*(\boldsymbol{\chi}) = \max_{\boldsymbol{\Phi}} \{(1 - \gamma)\, U(\boldsymbol{\chi}, \boldsymbol{\Phi}(\boldsymbol{\chi})) + \gamma \textstyle\sum_{\boldsymbol{\chi}'} \Pr\{\boldsymbol{\chi}' | \boldsymbol{\chi}, \boldsymbol{\Phi}(\boldsymbol{\chi})\}\, V^*(\boldsymbol{\chi}')\}, \tag{3}$$

where $\boldsymbol{\chi}' = \{\boldsymbol{q}', \boldsymbol{s}', \boldsymbol{c}'\}$ is the subsequent MEC network state, and $\Pr\{\boldsymbol{\chi}' | \boldsymbol{\chi}, \boldsymbol{\Phi}(\boldsymbol{\chi})\}$ represents the state transition probability to the next state $\boldsymbol{\chi}'$ if the task assignment $\boldsymbol{\Phi}(\boldsymbol{\chi})$ is performed in state $\boldsymbol{\chi}$. $\boldsymbol{q}' = \{q'_n : n \in \mathcal{N} \cup n_c\}$, $\boldsymbol{s}' = \{s'_n : n \in \mathcal{N} \cup n_c\}$, and $\boldsymbol{c}' = \{\boldsymbol{c}'_n : n \in \mathcal{N} \cup n_c\}$ are the queue, task processing capability, and network delay states in the subsequent time slot.

The traditional solutions to (3) are based on value iteration, policy iteration, and dynamic programming [9, 10], but these methods require a full knowledge of the network state transition probabilities and task arrival statistics that are unknown beforehand in our dynamic network case. Thus, we seek the online reinforcement learning approach which does not have such a requirement. In previous research, we introduced an algorithm based on conventional Q-learning [6], which defines an evaluation function, called Q function, $Q(\boldsymbol{\chi}, \boldsymbol{\Phi}) = (1 - \gamma)\, U(\boldsymbol{\chi}, \boldsymbol{\Phi}) + \gamma \sum_{\boldsymbol{\chi}'} \Pr\{\boldsymbol{\chi}' | \boldsymbol{\chi}, \boldsymbol{\Phi}\}\, Q(\boldsymbol{\chi}', \boldsymbol{\Phi})$ and learns an optimal state-action value table in a recursive way to decide the optimal task assignment control policy for each time slot. However, for the cooperative MEC network, the task assignment decision-making for a node depends on not only its own resource availability and queue state, but also is affected by the resource availabilities and queue states of other nodes. The system state space and control action space grows rapidly as the number of involved nodes increases. The conventional tabular-based Q-learning process will search and update a large state-action value table, which incurs high memory usage and computation complexity.

3 Optimal Task Assignment Scheme Based on DDQN

In this section, we focus on developing an efficient algorithm to approach the optimal task assignment policy based on recent advances in deep reinforcement learning, which combines Q-learning and deep neural networks to address the state and action space explosion issue of the conventional Q learning with no requirement for a prior statistical knowledge of network state transitions and user task arrivals. Specifically, we design a DDQN-based algorithm to approximate the optimal state value function. In addition, it can be observed that the QoS reward function is of an additive structure, which motivates us to linearly decompose the state value function, and incorporate the decomposition technique into the deep reinforcement learning algorithm to lower its complexity.



Task assignment matrix Φ^t
MEC network
Q network
$P(\chi^t;\theta)$
Policy
Store Batch $(\chi^t, \Phi^t, \mathcal{R}^t, A^t, \chi^{t+1})$
Replay Memory
M^j
M^{j-m+2}
M^{j-m+1}
Observe state χ^t
Replace $\bar{\theta}$ with θ after k times
Update parameter θ
Train model
Obtain Reward $\mathcal{R}^t$, New task arrival A^t
Estimated A^{t+1}
Target Q net
$P(\chi^t;\theta)$
Policy
Training module
Loss function $= (\mathcal{R}^t + \gamma * Q(\chi^{t+1}, \Phi^{t+1}, A^{t+1}; \bar{\theta})) - Q(\chi^t, \Phi^t, A^t; \theta)$
Optimizer Minimization of loss
Observe state χ^{t+1}
Task assignment matrix Φ^{t+1}

Fig. 2. DDQN-based cooperative MEC task assignment.

Fig. 2 illustrates the DDQN-based reinforcement learning scheme for the collaborative MEC task assignment. DDQN replaces the tabular setting of conventional Q-learning with two neural networks, Q evaluation network and Q target network, to learn and approach the optimal state value function and decide the optimal action [7]. The Q evaluation network (Q-eval) is used to select the task assignment matrix $\boldsymbol{\Phi}^{\boldsymbol{t}}(\boldsymbol{\chi}^{\boldsymbol{t}};\theta)$ based on the collected network states $\boldsymbol{\chi}^{\boldsymbol{t}}$ at the time slot *t*, and the Q target network (Q-tar) is used to select the task assignment matrix $\boldsymbol{\Phi}^{\boldsymbol{t+1}}(\boldsymbol{\chi}^{\boldsymbol{t+1}};\bar{\theta})$ at the following time slot *t*+1. The parameters θ and $\bar{\theta}$ can be learned and updated iteratively. The standard DDQN algorithm outputs the state-action values and select the action with the maximum Q value. Unfortunately, the traditional DDQN approach in [7] cannot be directly applied to solve our problem because we do not know the number of the new task arrivals in a time slot at the beginning of that time slot. To solve the problem, we modified the Q-eval and Q-tar networks in the standard DDQN to output a probability matrix, which indicates the probability to forward a task from one edge node to another edge node in the slot.

The modified DDQN is used to approximate the optimal state value function in (3) and select the best action. We redefine the state value function (3) as

$$V^t(\boldsymbol{\chi}^{\boldsymbol{t}}) = \max_{\boldsymbol{\Phi}}\{(1-\gamma^t)U(\boldsymbol{\chi}^{\boldsymbol{t}}, \boldsymbol{\Phi}^{\boldsymbol{t}}(\boldsymbol{\chi}^{\boldsymbol{t}}, \mathcal{P}(\boldsymbol{\chi}^{\boldsymbol{t}}; \theta^t))) +$$
$$\gamma^t[\Pr\{\boldsymbol{\chi}^{\boldsymbol{t+1}}|\boldsymbol{\chi}^{\boldsymbol{t}}, \boldsymbol{\Phi}^{\boldsymbol{t}}(\boldsymbol{\chi}^{\boldsymbol{t}}, \mathcal{P}(\boldsymbol{\chi}^{\boldsymbol{t}}; \theta^t))\}U(\boldsymbol{\chi}^{\boldsymbol{t+1}}, \boldsymbol{\Phi}^{\boldsymbol{t+1}}(\boldsymbol{\chi}^{\boldsymbol{t+1}}, \mathcal{P}'(\boldsymbol{\chi}^{\boldsymbol{t+1}}; \bar{\theta}^t)))]\}, \tag{4}$$

where $\mathcal{P}(\boldsymbol{\chi}^{t};\theta^{t})$ and $\mathcal{P}'\left(\boldsymbol{\chi}^{t+1};\bar{\theta}^{t}\right)$ are the probability matrices calculated by Q evaluation and Q target networks, respectively. In the standard DDQN algorithm, the state value will be updated in each time slot and used to determine the optimal action. To simplify the updates, in our implementation, the state value obtained from (4) is stored in a replay memory for training and updating θ and $\bar{\theta}$ in the learning process so that the Q-eval and Q-tar can select the optimal task assignment matrices directly and accurately. The loss function for updating the parameters θ of Q-eval can be defined as

$$\mathbb{L}(\theta) = E\left[\left((1-\gamma)U(\chi,\boldsymbol{\Phi}(\chi,\mathcal{P}(\chi;\theta))) + \gamma U(\chi',\boldsymbol{\Phi}'(\chi',\mathcal{P}'(\chi';\bar{\theta}))) - V(\chi)\right)^{2}\right], \tag{5}$$

and the parameters $\bar{\theta}$ will be updated by copying θ after a predefined number of steps.

At the beginning of each time slot *t*, the MEC controller determines the task assignment matrix $\boldsymbol{\Phi}^{t}(\boldsymbol{\chi}^{t})$ based on the collected network states and informs the edge nodes of the task assignment decision. The task assignment matrix $\boldsymbol{\Phi}^{t} = [\phi_{n,j}^{t}: n, j \in \mathcal{N} \cup n_{c}\}$ at the beginning of scheduling slot *t* is determined as,

$$\boldsymbol{\Phi}^{t} = \mathcal{P}^{t}(\chi^{t};\theta^{t}) \tag{6}$$

An edge node then offloads the tasks to other nodes or receives tasks from other nodes and processes these tasks based on the task assignment decision. The new task arrivals $\boldsymbol{A^{t}}$ will be counted at the end of the time slot t and the new network state is collected and updated to $\boldsymbol{\chi^{t+1}}$ by the controller. The MEC network receives a QoS reward $\boldsymbol{U}^{t} = U(\boldsymbol{\chi^{t}},\ \boldsymbol{\Phi^{t}}(\chi^{t},\mathcal{P}(\chi^{t};\theta^{t})))$ by performing the task processing. The Q-tar network is used to calculate $\boldsymbol{\Phi^{t+1}}$. As mentioned before, the DDQN includes a replay memory that is used to store a pool of the most recent M transition experiences, $\Omega^{t} = \{\boldsymbol{m}^{t-M+1},\dots,\boldsymbol{m}^{t}\}$, where each experience $\boldsymbol{m}^{t} = (\boldsymbol{\chi}^{t},\boldsymbol{\Phi}^{t},\boldsymbol{U}^{t},\boldsymbol{\chi}^{t+1},\boldsymbol{\Phi}^{t+1})$ is occurred at the transition of two consecutive slots *t* and *t* + 1 during the learning process. At each slot *t*, the *k* previous experiences are randomly sampled as a batch from the memory pool Ω^{t} to train the DDQN online. The learning process will calculate the approximated overall state value for each experience in the batch and update the parameters θ with an goal to minimize the loss function (5). Once the state value function is converged, we can obtain the optimal parameters θ^{*} for Q-eval. The optimal policy will be

$$\boldsymbol{\Phi}^{*} = \mathcal{P}^{*}(\chi;\theta^{*}) \tag{7}$$

The MEC network QoS reward in (1) is the summation of the service delay and task drop rate satisfactions of the edge nodes, and the task arrival statistics and task processing capabilities of the edge nodes are independent each other. We can then decompose (4) into per node QoS reward and separate the satisfactions regarding the service delay and the task drops [11]. We first rewrite (6) as

$$\boldsymbol{\Phi}^{t} = \boldsymbol{\Phi}^{t}(\chi^{t}) = \{\phi_{n}^{t}(\chi_{n}^{t}): n \in \mathcal{N}\}. \tag{8}$$

n agents $n \in \mathcal{N}$ can be employed and each agent learns the respective optimal state value function through a per node sub-DDQN. An optimal joint task assignment control decision is thus made to maximize the aggregated state value function from all the agents. The task assignment related to node *n* can be expressed as

$$\phi_n^t(\chi_n^t) = \mathcal{P}_n^t(\chi_{\boldsymbol{n}}^{\boldsymbol{t}}; \theta_n^t), \tag{9}$$

where $\mathcal{P}_n(.)$ is the task assignment probability obtained through DDQN n. The state value function in (4) can be decomposed and expressed as in (10) and (11)

$$V^t(\boldsymbol{\chi}^t) = \ \sum_{n\in\mathcal{N}} V_n^t(q_n^t, s_n^t, c_n^t), \tag{10}$$

$$V_n^t(\chi_n^t) = \ (1-\gamma^t)U(\chi_n^t,\ \Phi^t(\chi_n^t,\ \mathcal{P}_n(\chi_n^t;\theta_n^t))) + \\ \gamma^t\left[\Pr\{\chi_n^{t+1}|\chi_n^t,\ \Phi^t(\chi_n^t,\ \mathcal{P}_n(\chi_n^t;\theta_n^t))\}U\left(\chi_n^{t+1},\Phi^{t+1}(\chi_n^{t+1},\mathcal{P}_n'\left(\chi_n^{t+1};\overline{\theta}_n^t\right))\right)\right] \tag{11}$$

With the linear decomposition, the problem to solve a complex Bellman's optimality equation (4) is broken into simpler MDPs and the computation complexity is lowered. In order to derive a task assignment policy based on the global MEC network state, $\boldsymbol{\chi} = (\chi_n : n \in \mathcal{N} \cup n_c)$ with $\chi_n = (q_n, s_n, c_n)$ and $c_n = \left(c_{n,j}, c_{j,n}\ :\ j \in \mathcal{N} \cup n_c\right)$, at least $\prod_{n\in\mathcal{N}\cup n_c}\prod_{j\in\mathcal{N}\cup n_c}(\,|q_n|\,|s_n||c_{n,j}||c_{j,n}|)$ states should be trained. Using linear decomposition, only $(N+1)\ |q_n||s_n|\ \prod_{j\in\mathcal{N}\cup n_c}(|c_{n,j}||c_{j,n}|)$ states need to be trained, resulting in much simplified task assignment decision makings and significantly reducing training time. The online DDQN-based algorithm to estimate the optimal state value function and determine the optimal task assignment policy is summarized in Algorithm 1.

Algorithm 1. Online DDQN-based Cooperative MEC Task Assignment

```
1.  Initialize the Q-eval and the Q-tar with two sets of $\theta^t$ and $\bar{\theta}^t$ random parameters for $t = 1$; the replay memory $M^t$ with a finite size of $M$ for experience replay.
2.  At the beginning of scheduling slot $t$, the MEC controller observes the network state, $\boldsymbol{\chi}^t = \{\boldsymbol{\chi}_n^t : n \in \mathcal{N}\}$ with $\boldsymbol{\chi}_n^t = \ (q_n^t, s_n^t, \boldsymbol{c}_n^t)$, and the Q-eval with parameters $\theta^t$ determines the task assignment matrix, $\boldsymbol{\Phi}^t = \ [\boldsymbol{\phi}_n^t : n \in \mathcal{N}]$ according to (8) and (9).
3.  After offloading and processing the tasks according to the above task assignment decision, the edge nodes will receive new tasks $\boldsymbol{A}^t = \ \{A_n^t\ : n \in \mathcal{N}\}$ at the end of slot $t$.
4.  The controller determines the QoS reward $U^t$after new task arrivals and calculates the state value $V^t$ according to (10) and (11)
5.  The network state transits to $\boldsymbol{\chi}^{t+1} = \{\boldsymbol{\chi}_n^{t+1} : n \in \mathcal{N}\}$ where $\boldsymbol{\chi}_n^{t+1} = \ (q_n^t + A_n^t, s_n^{t+1},\ \boldsymbol{c}_n^{t+1})$, which is taken as input to the target DQN with parameter $\bar{\theta}^t$ to select task assignment matrix $\boldsymbol{\Phi}^{t+1} = \{\boldsymbol{\phi}_n^{t+1}, n \in \mathcal{N}\}$ at the following scheduling slot $t$+1.
6.  The replay memory $M^t$ is updated with most recent transition $\boldsymbol{m}^t(\boldsymbol{\chi}^t,\ \boldsymbol{\phi}^t,\ \boldsymbol{U}^t,\ \boldsymbol{\phi}^{t+1}, \boldsymbol{\chi}^{t+1})$.
7.  Once the memory replay collect $\overline{M}$ transitions, the controller updates the Q-eval parameter $\theta^t$ with a randomly sampled batch of transitions to minimize (5)
8.  The target DQN parameters $\bar{\theta}^t$ are reset every $k$ time slots, and otherwise $\bar{\theta}^t = \bar{\theta}^{t-1}$
9.  The scheduling slot index is updated by $t \leftarrow t + 1$.
10. Repeat from step 2 to 9.
```

4 Numerical Experiments

In this section, we evaluate the cooperative MEC task assignment performance achieved by our derived online DDQN-based algorithm. Throughout the simulation experiments, we assume that the processing capability s_n^t, $\forall n \in \mathcal{N}$ of different edge nodes are independent of each other and evolve according to a Markov chain model, each modeled with three states characterizing the high, medium, and low with {4, 2, 1} tasks per slot. We simulated multiple MEC network scenarios with different system parameters. Due to the page limit, we present the results for several typical settings. The slot duration is set to be 30 msec. The network delay between two edge nodes, c_{nj}^t, $\forall n, j \in \mathcal{N}$, is also modeled as a Markov chain with three states, {1, 0.5, 0.2} slots. Edge nodes communicate with a cloud data center through the Internet. The network delay between the edge node and the cloud data center $c_{nn_c}^t$, $\forall n \in \mathcal{N}$ is assumed to be 10 slots. $U_n^{(d)}$ and $U_n^{(o)}$ in the QoS reward function are chosen to be the exponential functions [12] with $U_n^{(d)} = \exp\left(-d_n^t/d^{(\max)}\right)$ and $U_n^{(o)} = \exp\left(-o_n^t/o^{(\max)}\right)$.

The neural networks used for Q-tar and Q-eval have a single hidden layer with 15 neurons. We use ELU (Exponential Linear Unit) as the activation function for the hidden layer and Softmax for the output layer to output the probability matrices for the action selection. The optimizer is based on RMSProp [7]. The number of iterations for updating parameters of Q-tar is set to be 30, and the memory replay size and the batch size are also set to be 30. The training process will be triggered when the system collects enough samples and it will pull out all samples to train. There are other sampling optimization techniques, e.g. prioritized experience replay, which will be included in our future work.

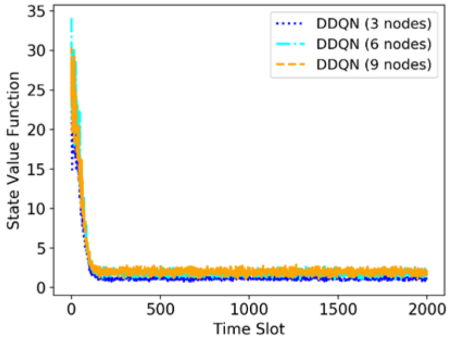


Fig. 3. Convergence of the proposed DDQN-based learning process.

We first investigate the convergence performance of the proposed online DDQN-based cooperative MEC task assignment algorithm under dynamic stochastic MEC network environments with different number of MEC edge nodes. As shown in Fig. 3, we can observe that the proposed algorithm spends a short time period to learn and then converges to the global optimal solution at a reasonable time period which is less than

150 slots. In addition, the network size does not have noticeable effects on the convergence time of the algorithm.

Next, we evaluate the QoS performance of the proposed online DDQN-based cooperative task assignment scheme. For the purpose of comparison, we simulate four baselines as well, namely,

1) No Cooperation: An edge node processes all the tasks it receives from its associated users by itself. There is no task offloading.
2) Cloud Execution: An edge node offloads all its received tasks to the cloud data center for execution.
3) One-shot Optimization: Like the scheme in [5], at each scheduling slot, the task assignment is performed with the aim of minimizing the immediate task service delay. Note that the power efficiency constraint is not considered here because we assume the edge nodes have sufficient power supply.
4) Q-Learning: Task assignment optimization based on conventional Q-learning.

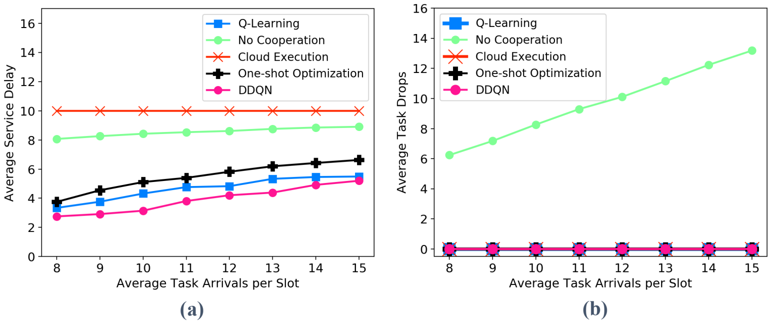

Fig. 4. (a) the average task service delay and (b) the average number of dropped tasks per slot versus the average task arrivals per slot for different algorithms.

Figures 4 (a) and (b) show the average task service delay and the average number of dropped tasks per slot, respectively, for the proposed scheme and baselines, with three edge nodes and one cloud data center as the task arrivals per slot at the edge nodes follow independent Poisson arrival process. The delay is measured in the unit of the time slot duration. We can observe that the DDQN-based and conventional Q-learning based task assignment schemes perform better than the other baselines such as No Cooperation, Cloud Execution, and One-shot Optimization schemes. This is because they not only consider the current task processing performance but also take into account the QoS performance in the future when determining the optimal task assignment matrix under time-varying stochastic task arrivals and network states. Their task drops are zero because the algorithms tend to minimize the task drops, and the edge nodes will forward the tasks to the cloud data center when their buffers are full. For the No Cooperation scheme, an edge node does not send the unprocessed tasks to the cloud and other edge nodes, so that there are tasks drops when the node's buffer becomes overflow. For the Cloud Execution scheme, a large network delay is always incurred to ship the tasks to the cloud data center for processing over the Internet. The One-Shot Optimization scheme performs relatively well. However, it makes task assignment decisions to minimize the immediate task service delay in a slot and may cause shipping many tasks to the cloud data center for processing under fluctuating task arrivals and non-stationary node process capabilities, with such tasks incurring a large network delay.

Fig. 5 shows the memory usage of DDQN- and Q-learning task assignment schemes. The traditional tabular Q-learning consumes much higher system resources than the DDQN scheme and cannot scale well due to the explosion in state and action spaces, making the solution unviable. On the other hand, the memory usage by the DDQN-based task assignment scheme scales well as the number of edge nodes in the network increases.

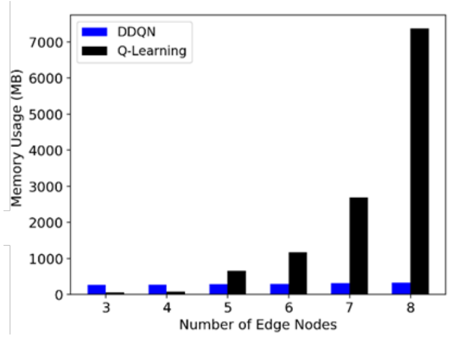

Fig. 5. The memory usage of DDQN and Q-learning task assignment schemes.

5 Conclusions

In this paper, we have investigated the task assignment problem for cooperative MEC networks, which enables horizontal cooperation between geographically distributed heterogeneous edge nodes and vertical cooperation between MEC edge nodes and remote cloud data centers to jointly process user computational tasks. We have formulated the optimal task assignment problem as a dynamic Markov decision process (MDP), and then proposed an online double deep Q-network based algorithm to obtain the optimal task assignment matrix. A function decomposition technique is also proposed to simplify the problem in DDQN learning. The proposed online DDQN algorithm does not require for a statistical knowledge of task arrivals and network state transitions. The evaluation results validate the convergence of the proposed algorithm and demonstrate that it outperforms the traditional schemes that optimize the immediate task service delay with no consideration of the impacts of network dynamics to the expected long-term QoS rewards. In addition, the proposed DDQN scheme can scale reasonably well, and requires much less memory than the conventional Q-learning based algorithm.

Systems security assurance as (micro) publishing

Declarative markup for systems description and assessment

Wendell Piez

Abstract

Markup technologies are very general purpose, as reflects their generality of conception. They become interesting as well as useful as they are applied to accomplish goals in the real world. Since principles of generic declarative markup were first applied to accomplishing publishing-related goals in information management, design and application, 25 or 40 years ago, they have repeatedly demonstrated both their generality – they really do work – and their demand for applicability. Get one thing wrong, or leave it out, and the effort sits on a shelf. Design and deploy it carefully and sensitively, and even an inexpensive initiative can pay dividends for years. These systems become sustainable in the context of the sustainable operations of which they are a part.

Decades of experience have shown us how to use declarative markup to sustain publishing operations. Now we have to deal with similar problems of information description, management, reuse across contexts, referencing, tracing, and authentication, only at even larger scales than before, both in size and complexity. This paper proposes some lessons and insights we can bring from our experience with publishing technologies, and suggests how they might be applicable in the growing domain of systems security assurance.

Practical successes of declarative markup

In the form of XML (Extensible Markup Language), for twenty years we have had systems exploiting the principles of declarative markup on a standards basis, with commodity tools. If you count XML's predecessors including both SGML[1] and applications of other technologies that are or can be “declarative” in their approach (such as LaTeX),[2] this history is much longer. This is no accident inasmuch as the roots of these technologies are in typesetting, among other requirements, which presents problems difficult enough to demand we factor out and “layer” solutions addressing challenges in functionality, configurability and maintainability. The layered solution to the problem of maintaining multiple publishing streams from complex aggregated sources, it turns out, is the layered solution to much else as well.

What has not happened? Whether considered as a standard processing stack based on the W3C (Worldwide

Web Consortium) XPath/XQuery Data Model (XDM xdm2017), or only as a data format, XML has not become the single and sufficient solution to all problems. Perhaps it was never, indeed, meant to be, at least not seriously – let us distinguish advocacy from marketing – yet in 2020, even as the broad domains of digital information stretch far beyond what visionaries of 20 years ago imagined, XML or even "layered", declarative approaches considered more generally, are by no means predominant. This is in part because other solutions have emerged to other problems, which have seemed more exigent or demanding than the long-term problems solved by descriptive markup or XML, and which do not entail its overhead. Those of us who work with it know that XML (or the more important principle it stands for) has not "failed"; yet at the same time, it has not altogether taken the field either. Sometimes its successes have been ambiguous. (War stories could be told.) It is probably closer to say that XML has been remarkably, even spectacularly successful in some ways – while in other ways, the future we imagined has not come to pass, or if it has, it appears in a form quite unlike what we expected. (People edit wikis. They use Markdown! War stories could be told.)

What is publishing? challenges of documentation in systems security

Into this ambiguous context we step with a new set of problems, unprecedented and yet (in many respects) familiar at the same time. Systems security assessment, assurance, authorization. Information exchange around systems security – this is not publishing exactly, in anything like the common sense (of making materials available to a public), yet it entails all the same problems of information gathering, organization, exposition, design and presentation for the consumption of readers and consumers, both sentient (people) and automated (machines).

In particular, systems security assessment or RMF-based security assurance activities[3] are not publishing in the sense that they entail creating productions for a general audience. Few of the documents produced by security professionals in their work are "published" in a normal sense. But the size of the audience, or even whether a document is released or disseminated to a public, are not the only defining features of what is "publishing". Perhaps we could refer to this (formal and informal) circulation of formatted office documents as "micropublishing" or targeted publishing. A PDF or Word document, that is, prepared at considerable trouble and expense by dedicated professionals, and submitted for review, whether it be by potential customers, regulatory authorities, or partner organizations, might never be "published", while it is nevertheless subject to all the same functional requirements in information creation, production, management, and tracking – and most especially, for revision cycles and quality control.

Compared to more normal sorts of publishing, this set of activities might work at a higher order of complexity, over faster – and also more extended! – time frames, with larger and more articulated information sets. Even how this is to be done adequately, much less at its best or in its ideal form, has hardly been defined, and its definition is itself dynamic, a moving target, as we learn more about systems and risk migitation and management. At the same time at a certain level we have no choice: this is work that will and must be done, at some level, the only question being how well. In this respect, "publishing" serves as shorthand for an entire range of activities entailing data collection, composition, analysis, review, formatting for presentation and finally the production of "artifacts" for consumption, be they "reports" or "proposals" or "reviews", "specifications" or "assessments" in whatever form - paper, PDF, Office or word-processor formats, web pages, or any other form. In these forms, these artifacts are disseminated to recipients that are able to make use of them for their own processes..

In a paper delivered to Balisage 2019, some of the special challenges of the (so-called) "system security" application domain – as seen from the point of view of a relative newcomer – were described at some length. Additionally, Joshua Lubell's companion paper to this one frames in much greater detail the questions of security assurance processes as a specifically *documentary* activity, and one in which (moreover) the questions of authority, knowledge, sources of knowledge, trust, accountability, traceability and transparency – all issues that have been implicit in every publishing system ever built (whether digital and networked, or by any analog media) – become especially salient. For purposes of this paper, this background is assumed as context.

Indeed, insofar as systems security may also entail both "marketing" and "customer relations" – even while it entails much else – we can recognize that even when it is not formalized to the extent that we see with the United States Federal Government's Risk Management Framework – as one approach to security among others – it is always based in the *appropriate transmission and communication of information between points*. In other words, it always comes down to a kind of publishing, albeit, as noted, a kind of targeted micropublishing. The details are always different. But a principled approach to the design of information technologies, which works to address one set of thorny problems in information exchange, should provide similar advantages when dealing with another.

What have we learned from technology in publishing?

Your system is someone else's subsystem

Self-similarity across scales - Information ecosystems or ecologies, as noted at Balisage 2018 (Piez 2018), are fractal in organization; one way we know this is by the way we find similar organizations and patterns of organization appearing at many levels of scale. In particular, with publishing workflows we can see a great range of scales and indeed nested scales. Every system is made of systems, with more or less articulated boundaries within the subsystems; and this is true of subsystems too. Essentially, all systems are hybrid systems, and the way to look at any one of them (whether at a "system" level or that of a component) is to consider its interfaces and externalities (including operational and technical dependencies) and especially the way these affect its capacity for maintenance, adaptation and scaling.

Consider for example the banal case of a scientific or scholarly journal. Its communications are carried forward for the sake of producing articles and making them available to a readership. Each article entails a complex choreography of data exchange, as the text of the article is submitted to the journal by its author, reviewed, revised (or rather: rejected in favor of revision), finally accepted and then "processed" (the means varies) for publication. Each of these steps entails one or more communications between parties to accomplish. These communications include the article itself but also the coordination and meta-commentary around it.

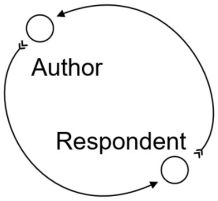
In principle this is measurable. A typical small journal might publish four or six issues per year; each of these issues might contain four or six articles, averaging 20 to 30 articles per year. Each of these articles requires a varying (small) number of peer reviews – which we can also count, yielding another number – say, between 50 and 100 peer reviews, per journal, per year. Circulating these peer reviews – and, more importantly, ensuring that documents are revised accordingly – constitutes much (though, not all) of the work of the journal editor perhaps with the help of staff. Since many or most peer reviews will then be returned to an author, for each peer review, there are at least three or four participants in the workflow (author, editor, peer reviewer, staff). To the extent there is attrition, as not all peer reviews and article revisions are carried through successfully, we could quantify this as well. In any case, even without numbers and figures (elapsed time per peer review, to edit it and return it to the author), it becomes clear how the work associated with such circulation is probably the largest limiting factor preventing a journal (on this model) from scaling up to a larger run. Essentially this means that due to the centrality of the editor in the worflow (if only as "peer review conductor") – there is a limit to the effective size of a journal. Making a journal bigger (in terms of production, not circulation) is much harder than spinning off a new journal.

One gating factor here is the relative difficulty of not just peer review, that is, but all the coordination around it. Author, editor, managing editors, peer reviewers: as long as they share no simple platform or standard for the handling of peer reviews, their peer reviewing system is essentially made up of the combination and intersection of all their personal systems, and maintaining communications this way is costly (even while regarded as normal and regular). Migrate peer reviewing to an online system, for example, that consolidates the effort of reviewing and tracking, and the numbers shift. Scaling is now easier – albeit other limiting factors such as availability or motivation, might remain.

Similarly, further along the lifecycle, once journals start being aggregated together, peer review is no longer a limiting factor. Once articles enter "post publication", they are more like black boxes, identifiable by metadata but not requiring intervention for particular cases (as peer review might). So publishers or aggregators of published information can pull together multiple issues of multiple journals, and the scaling bottleneck posed by peer reviews (or again more precisely, by the interventions they require), does not apply. Similarly – but differently – this particular bottleneck does not apply to other sorts of publishing such as trade or monograph publishing, where peer review and the revision process are done and managed differently.

These differences and distinctions between systems and the industries they serve, are driven and defined by their information processing requirements, and the difficulty and expense of those requirements – most of which are the expenses of time and expert attention. What we do not have, to take account of all this, is a science of workflows,[4] which is to say a set of principles and governing ideas for how workflows actually work: a branch of sociology and economics, but with a technical aspect insofar as workflows lend themselves to quasi-formal definition, once (for example) we start to specify the details of inputs and outputs.

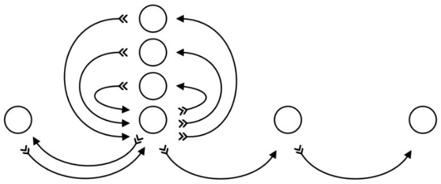
Figure 1: Elements of workflow



One principle of a science of worflow should be the concept of exchange. A party gives something to another party, who gives something in return. This response typically triggers another action, perhaps an iteration with a modified input. Such exchanges might be the "elements" or conceptual primitives of a systematic accounting.

When the parties are reciprocal and co-equal, and contents of the exchanges are equally contributed by both, we have a basic "Correspondence" pattern.

Figure 2: Peer review pattern



"Peer review" is one pattern in a (potential) pattern language to describe information workflows. Others might be "bundle"; "enhance" (e.g., provide metadata); "test" or "confirm"; "publish" (maybe both "push" and "pull") and so forth.

What a science of workflow would enable us to see would be the articulated joints of these related processes – where there are hand-offs in responsibility, and where there are requirements and capabilities for (what should be called) *transformations*, in that their outputs (results, what is "produced") are modifications, translations and enhancements of their inputs (their sources and raw materials). These can be and typically are very specific operations to very local sets of requirements. Nor is this a bug or a problem, in that these particularities are often the entire point of the exercise. (The reason we send an article to a peer reviewer, is that we would like to see what comes back.)

Without such a science, however, there are still things we can know from experience. One reason it is useful to work through a mundane example such as a peer review exercise in a hypothetic journal, is that it dramatizes the underlying reasons why, for example, rates of technological evolution are so uneven. It remains an open question, for example, in 2020, what format or formats are best used to share draft articles (or more precisely, the raw materials of what is to become an article) in a peer review process. Externalities (such as the ubiquity of certain tools or toolkits) push one way, while functional requirements – or even cultural considerations – in the system itself may push another. Thus there is no perfect solution – journals accept documents created with proprietary word processors because that is all their authors are prepared for. When an unusual consistuency is able to provide a journal with something better (perhaps a community of scientists, or academic scholars with text encoding skills, has tools they prefer) they will often take that. *This is all because the system of the journal is just a subsystem for each of its authors.*

In a fractal landscape, scales are relative, we should expect the same problems or versions of them to turn up in more than one place, albeit differently. While by definition and design, technologies of automation can support scaling, the fact that they also need to be *fitted* so closely – that two cases (say, two journals, or two research articles in a journal) are so similar without being alike – frustrates and even prohibits a cookie cutter approach.

What is true in one domain of information processing, might well be true in others. In publishing, especially technical publishing (however defined), things are always the same except where they are not. Precisely to deal with this variability, experience shows, only a well-defined, openly-specified, and non-proprietary technology can serve as the basis for (open-ended) “solutions”, which can be adapted to serve a heterogeneous and changing set of organizations, with their interlocking goals. Experience with academic, scientific and technical publishing indicates that such a technology will be declarative in form. For machine-readable data to be useful “for the duration” (that is the lifecycle of the information, not the system it currently sits in or the form it currently takes), it must systematically and consistently address and characterize the data itself as both artifact and “mechanism”. What that mechanism is or should be, is relative to the uses to which we put this information and our needs for handling and processing it.

Declarative markup adds value

As noted, it is possible for a scholar, researcher or “information professional” in 2020 to be entirely on a digital platform, where all the works apart from some odd print artifacts, consumed as well as produced, take digital form, and indeed in which XML, standards, declarative markup and open systems (perhaps broadly including wikis, git repositories, and assorted other forms of hybrid hypertext media on line) are central to the system, while word processors and other page-oriented tools are secondary.

But those are outliers, and almost everyone involved in “authoring” or “research” phases of publishing today still uses word processors, spreadsheets and document formats along with email – almost necessarily a one-off format with little potential for data reuse – for passing their information across systems. “Office documents” as we broadly call them, are the assumed basis for data interchange. Although they exist, journals or publishers that readily work with other kinds of data inputs, even nominally standard formats, are indeed quite rare, and the cases that do so are illustrative. Similarly, despite all the demonstrated advantages of “single source” publishing, publishers that produce anything but pages first (albeit in digitally encoded form, which is to say digital artifacts in PDF or Postscript®), are also quite rare; any web version or archive version is treated as a secondary production. The possible efficiencies to say nothing of the more outlandish potentials of an XML-first workflow, are simply not perceived to be worth it. And indeed they may not be, if the trouble, expense and disruption are certain while the gains are hypothetical.

On the other hand, to claim that markup technologies have had no impact would be to entirely misconstrue what has happened in 25-some years. While to some it may appear that XML's day has come and gone, it keeps coming back and proving its usefulness: indeed it might be said that the larger-scale activities now happening routinely in the publishing space enabling both access, and long-term stability, for collections of unprecedented size and complexity – all of these would be for practical purposes impossible without strategies of declarative (descriptive) markup and the principle of open lingua franca that can be established on its base. Even if markup technologies have not made their way explicitly into the work practices of writers, researchers and editors, it still cannot be said – most especially in the case of HTML (Hypertext Markup Language) and the web, but this is not the only case – that these technologies are not significant. Indeed, the reasons we invest energy in producing these representations (indexable, retrievable, massable, filterable, stylable – in ways their word processor documents are not), is because they prove to be so valuable.

To a great extent, this is because the principles themselves are sound. Of course there is nothing especially “XML” about cleanly layered separation, and an architecture that reflects and responds to the requirements of its users not to “paint” information to appear one way or another, but to expose and maintain the information *as information* – which interestingly we do by describing it. XML, with its associated technologies, is a means to this end.

Data acquisition is hard

Perhaps we all agree already that rich, clean declarative markup is by far the preferred form not only for archiving but for production. Even if we do (and I am not sure I do), the question remains of where that rich information set comes from: how does the XML get there in the first place? By XML, here, we mean of course not XML itself, but a particular kind of XML, as exemplified by documentary formats with descriptive tag sets. For reasons that will become clearer later, I also mean (paradoxically) an “XML” that is not XML at all (in that, as I will discuss, the JSON Javascript Object Notation] variants of OSCAL formats seeks to share the same advantages offered by the XML variants). (OSCAL, the Open Security Controls Assessment Language, is discussed further below.)

In the real world, the answer to the problem of how do we acquire the data to start is generally, with difficulty. When information sources are created and first transmitted as “office documents” (meaning any of a species of word processor, spreadsheet software, whether proprietary or open-standard), conversion into XML can be done (with care, by a skilled operator) “by hand”, or it can be semi-automated. Either way it will require additionally a skilled human operator for supervision, definition of data quality, assessment. Given these challenges, automation is expensive, becoming cost-effective only when rates of production are large enough – and rules are clear enough – to reward economies of scale.

In general, as well, while large-scale data conversions supported by externalized providers is a way of making XML, this approach is only affordable or sustainable for certain kinds of information. Systems security and assessment is actually characterized by a great heterogeneity of information formats, including data sets produced by machines as well as by people. This great heterogeneity, plus requirements for sensitive handling of private or confidential data, together make it difficult to outsource the task of data description to a third party or external provider. Data security questions aside (how do you shop for a conversion vendor to reformat your most sensitive and proprietary strategic information?), the combination of high data complexity and distinctiveness (at the levels of subdomain, markets and enterprise) may make for no “sweet spot” for outsourcing data conversions, across the domain of systems security. Partner organizations may need to be able to do this for themselves and each other, without always relying on external expertise.

Other methods of acquiring XML markup also present opportunities along with their own challenges. For example, we can bring XML tools such as structured editors earlier into the workflow; similarly, we can design systems with user interfaces (wizards, forms interfaces) that abstract the structure and its encoding away from the view. Both of these have the effect of providing support for the human operator (writer or editor), while permitting the information to be “XML native”; and the advantages of such system, where they can be used, can be considerable. *Where they can be used* here is the operative qualifier – since this is by no means everywhere: both development and deployment require a level of engagement with both goals and technical means. Generally speaking it is only the more agile and more technically-minded organizations that have been able to take advantage of such opportunities.

Yet there may also be a narrow and somewhat arduous path forward to structured data that goes *through* office documents, not around them. The key here may be templates, which already have the advantage of being the preferred method for much of the industry for capturing their information – largely because the promises of templates *are*, in many respects, the promises of structured data, while the deployment architecture (documents layered with so-called styles) is the same or similar, albeit in proprietary form. In some cases, it may be possible to design combinations of templates, rule sets, transformations and document validations (dynamic checks and feedback) that together can help with the job of data conversion, from a representation internal to the word processor, into an externalized form. For certain very regular and generalizable species or subspecies of documents, in certain organizations, this approach might serve as a useful accelerant to getting structured information into the mix. Word processor as structured editor.

While such a solution is possible, who is going to build the solution, for whose use? Will it have to be producers of the data themselves (which would demand an extraordinary combination of disparate skills), or can there be a market for such development and innovation? If the model of the third-party data conversion vendor does not serve for addressing the need here, what does?

Moreover, it can be expected that this question will remain acute until we have both adequate specifications for shared data description (to whatever level of “standard” possible), and working systems that respect and implement these standards. Until then, cumbersome data conversions will remain an impediment. Organizations who can insulate themselves at the boundaries, defining for their partners what the specifications of these formats will look like, will have an advantage.

This brings us to incentive structures.

Activities are supported by incentive structures

> “‘When I use a word,’ Humpty Dumpty said in rather a scornful tone, ‘it means just what I choose it to mean — neither more nor less.’
>
> ‘The question is,’ said Alice, ‘whether you can make words mean so many different things.’
>
> ‘The question is,’ said Humpty Dumpty, ‘which is to be master — that’s all.’”

One key to understanding these articulations – and how they implicate practical matters such as the serialization format of a data exchange – is to see how the lines and arrows in a diagram demarcate lines of authority and responsibility in a complex system of exchanges, whose most important considerations are not in the details of any single exchange, but rather in the operational context in which all of them take place together, as an orchestrated set.

By “exchange” here we mean more than simply an exchange of data. Certainly, some of these transitions entail data being copied from one system to another. (As a journal article is sent as an email attachment from its authors to the issue editors.) However, exchanges also happen as data transitions in other ways. An editor who assigns to an assistant, for example, a task such as copy editing, may “move” nothing, except assign access control rights in the system (so the assistant can make changes to the copy). Yet to exchange access control is to exchange much else, namely the custody of the article, entirely or in part. (In our example, the assistant may know that some corrections are in scope while others cannot be executed without conducting another loop outward, with the author.)

As an example of the signification of such an exchange, over and above the communication of the exchange itself: a young scholar publishing an article in a leading journal, assumes and acquires thereby some of the authority and credibility (as it were by proxy) of the journal. The published article becomes a line item in a *curriculum vitae* and eventually a tenure application, and as such might be worth as much as or more than the article itself. Of course, this is of no direct interest to readers of the article, who benefit from the scholarship despite the necessarily mixed motives behind it. Indeed in principle, the combination produces a mutual benefit even if not a perfectly symmetrical one. (The journal, and its readers, get the good scholarship. The author gets a shot at tenure.) In any case, several exchanges occur following on the central one (the article's publication) at several levels: exchanges of authority and reputation, as well as notice of interests and alliance.

This kind of thing matters since it shows how these structures are built on and around incentive structures, which is to say combinations of mandates, structured choices, and agreements to cooperate that condition how these systems are built and maintained. (One such agreement to cooperate takes the form of “I will do this task if you employ me and make it part of my responsibility” – which is at one level a significant commitment. And yet some kinds of tasks, it seems, are not routinely accomplished without it.) At question is always not only in what *form* does a data exchange occur (an email, a Word document, a piece of registered mail with a signature, a spreadsheet – or an XML document, valid to a schema?) but also *by what rule is that form determined*, *who makes that rule*, and *whose interests are served* (immediate or long-term) by that rule and its rule set, both actually and apparently? (“Make it a `docx` file because that's what I know how to use.”) In our example, the young scholar may happily take on the work of formatting the bibliography, as the journal submission guidelines demand, because she understands this exercise is both valuable in itself (or she wouldn't be asked to do it, presumably), and, in a sense, the price of admission, the cover charge for the club; a demonstration and proof of her willingness and ability to play by the journal's rules and pitch in to the common effort. (It is not entirely uncommon for scholars to find bibliographies in particular as rites of passage.)

Or alternatively (to work this example further) maybe the journal discovers that it can't get good enough bibliographies from its authors no matter what it does. So the work of reformatting bibliographies is handed to an in-house assistant. The workflow for handling the article is thus articulated, at the point of the bibliography. Custody shifts, with respect to an isolable (rules-bound, thus also “typical”) chunk of data, namely that part of the article (the bibliography or works cited section) with its links or bindings to the rest of the system (conceived in large terms). The workflow becomes more complex and the bibliography becomes a special focus. Submitted to a more stringent set of rules, by an agent or operator who can specialize in them, the bibliography can now be enhanced in ways otherwise impossible, normalized for integration. So the bibliography of the paper is made by this effort to merge more easily with the larger bibliography of the journal or publisher's holdings, not only this bibliography but all of them. The benefits of having such a mega-bibliography grow exponentially as the number of entries grow, so it is worth building as largely as possible if you're going to the trouble at all. However, this comes at a cost: someone must pay for the expert assistance and the technical stack to support it. Someone must learn how to do it. In the real world, someone has to volunteer to take on this responsibility, or there must be a budget to pay someone to do it.

It is not difficult to find examples of such phenomena, which are indeed at the heart of publishing activities or more largely, of business in general. Exchange happens, we can stipulate, when a data set in some form or representation (a “document”, an “article”, a spreadsheet, some sort of formal submission on a template), shifts from one party to another, for an operation to be performed. Submitted to such a process, there may be a new record created, and/or an original record or document may be altered or amended: in any case there is a before/after relation; in a way of speaking, each discrete step can be considered an operation, function or filter.

For each of these, whether machine aided or entirely motivated and performed “by hand”, there is some investment (cost), and some reward. In return for providing its value to the operation, the function or filtering operation must be paid for. Standards-based automation pays for itself when we can make these costs linear (by factoring out costs of design and development), while the benefits remain exponential, whenever we can operationalize such functions or filter to the point that they can be automated.

Quality is defined within context

Another key is to see how, within these transmissions, the question of *quality* is both construed (defined and determined) and maintained. Again within the context of journal publishing, a (nominally) “high-quality” author submission might well take the form of a word processor or “office”document. (Whether it is Microsoft Word, Google Docs or whatever a journal editor might consider acceptable these days.) In this case, the criteria of quality are not in its formatting – how pretty is the research laid out on the page – but rather in its instrinsic properties of argument, evidence and exposition, relating it as subject matter to other subject matter. (Is it original or novel research in its field? Does it relate to the literature in its field in some other meaningful way?) As such, the entire purpose of a produced artifact such as word processor file is to represent its author's work adequately for the purposes of the journal to “publish” it, a complex process that entails among other things (and again, because criteria of quality are extrinsic to this), that the document will be translated into a new form – for example, a PDF for page display, even eventually ink on paper.

In its new form, the reformatted document has “quality” (or one might more properly say “value”) that the original document does not, and is judged accordingly – now, not only for its argument and evidence (its nominal “content”), but also for its aesthetics and accessibility (for example).

In other words, it is worth looking at the before and after states when considering appropriate criteria of evaluation. Before publication, as submitted, we might like the document to look nice on the page; but it is not the page layout by which we judge it. This matters because part of what we intend to do, indeed, is reformat it so it looks different. In other words, we fully expect that the article or work we accept for publication, will be changed in that process, if not in essence (as FRBR “work”[5]) then in representation. Yet as publishers (to say nothing of the production designer), we expect the work to look “better” or more polished (than the author could make it). The publishing enterprise is designed to support such activities through processes that work not simply by adding value but by doing so within the context of new and more stringent criteria for evaluation, changing the definition of “quality” itself.

Moreover, this shift in what might be called the *evaluation context* for determining quality is entirely the point of the workflow, the “refinement” to which the work is subjected. Significantly, this can happen irrespective of how the worflow's participants constituent – the various players in the exchanges – are more or less oblivious to it. The young scholar is rewarded by publishing the article in the leading journal. Part of the reward is that the article is now listed in indexes; it pops up in searches. Other researchers are led to the scholar's work through these links. The links were made not by the scholar who wrote the article, but by the staff who provided its metadata and aggregators who followed after to consume the refined works (journal articles, issues and volumes) made from the raw word processor documents collected from scholars in the field. The very existence of these links, and the aggregators who make them, may be unknown to the scholar whose paper is being cited. Yet they serve a purpose, and the scholar benefits from them indirectly without knowing about it.

In a way, this is to note again that the plan or design of the “machine” of a publishing enterprise is already larger and more complex than the various machines, people and processes that are embedded in it, sometimes even larger than the participants appreciate. The special opportunities of automating document workflows, where we can do this – which is to say, the opportunities and promise of information technologies to enable things that go beyond what could have been done with ink and paper or even telegraph and telephone – will have to *accommodate* these larger systemic requirements, not work against them. Or they will simply not be viable.

The good news is that we are now at a point where we know that these systems can work, and indeed work well, when their various parts are adequate to their needs and where, just as importantly, contributors to the effort know and understand something about how the system works, and why it takes the form it does. (Even if they cannot see everything all the way to the edges.) Enough documentation projects have subsisted long enough, at various and very different levels of scale and complexity, that we can be confident of what we know about this.

Evolution works by little revolutions

A technological system exists until the day it stops being used. After that day, its relics may subsist, but the system itself does not. But a system can also be renewed over time from the inside, shedding parts of itself (since a system is made of subsystems) and replacing them, as its users continue to use the system, but modify it while using it. At one level of the organizational hierarchy, a system is brought down or replaced; it comes to an end; it is switched out for another. This same activity, seen from the next level up – from the point of view of the larger system in which this subsystem works – the switch out constitutes renewal, not death. Maybe there was a day when you used Eudora or Pine for your email, and now you do no longer. Has your email system died? Or merely migrated? Depending on how we define the system: both.

Just as your system can be someone else's subsystem, all their systems can be subsystems of yours, to the extent that you rely on them to do things for you, that you do not do for yourself. The boundaries in the system are not determined so much by extrinsic factors such as the software or platform on which it runs (especially when so much runs on the cloud), as they are by agency and scopes of responsibility – who is responsible to do what – and the interfaces and functionalities that support this.

New systems do not successfully replace old systems except (ipso facto) when they answer the needs met by the old system, and this can happen in only two ways: either the new system grows out of the old system, as it were within the context of its interfaces, and therefore replaces it organically. Or the new system is engineered to replace the old system by offering the same capabilities, perhaps along with some other definitive advantages such as scalability or ease of use. Again, this might be a single process, looked at from two directions.

So we might consider the way email has replaced sending paper through the post (mail), for most routine transactions. A publisher that once collected stacks of paper manuscripts, now pulls together file sets culled from email attachments. This development happened organically, but it would not have occurred if email had not been designed and extended to serve some of the basic (or “essential”) functions of paper mail, even while it is crucially different in other respects. It is worth recalling one of Marshall McLuhan's adages, that the content of any medium is another medium.[6] It is not quite a drop-in replacement – email promised and offers new capabilities beyond what the paper post ever did – but it is capable of many of the same functions and operations.

Any disparity of perspective here tends to be not a disparity of kind but of scale, that is again, of the level of hierarchy at which the problem is viewed. To return to the journal example, to an editor as email user, for example – `editor@journal.edu` – correspondence with contributors and readers is an ongoing and essential process, which must occur for the journal to subsist, somehow or other. This volume of information (correspondence, manuscripts, edited copy, reviews, in-process transcriptions), as a kind of information matrix, is the medium out of which the medium of the journal itself (through a kind of alchemical distillation) is made. From the point of view of the journal – a fish looking at an ocean – the case of its correspondence is distinctive, unique and special to itself. (The editor does not care for anyone else's journal correspondence, nor are they expected to.) As a team, the journal staff undertakes the responsibility of supporting this exchange with the people they wish to reach. (This is what it means to produce a journal.) Does this mean they need to develop their own postal service or messaging platform? No: in the real world, what they do is necessarily what their correspondents and partners in exchange (authors, readers) already do. In other words they do not and indeed cannot invent something new, instead, adopting as an externality a shared platform or system (the post, or email on the Internet, or a package delivery provider) already available (an externality) and indeed designed and engineered as a system, working at a higher scale, for a more general purpose than to join this journal with its authors and readers (namely to enable any such journal, and many others as well, and many activities and enterprises beyond journals). From this point of view, this journal's particular problem (as a "user", we might say) becomes only another instance of a more generalized problem – not maintaining a correspondence with readers and writers, but only an email system (or, before email existed, a postal system) among others.

It might be an interesting debate to discuss whether and in what respects the journals we produce today, with the support of electronic communications such as email and file exchange over the Internet, are "better" or "worse" than journals once produced on platforms we have long ago migrated away from. (A science of workflow might interestingly also be an archaeology of workflow.) Certainly the volume and rapidity of information exchange today is greater by orders of magnitude. There may also be shifts in who is able or permitted to participate, and for what presumed as well as actual purposes. However, we do not now prefer email, or our digital platforms of choice, to paper and postage, because they enable better work, so much as because the *scale* at which we now work – the number of partner exchanges we have, of what quality, and of what kinds of information codified in what forms – would simply not be achievable (much less sustainable) without the capabilities of the digital machine for information storage and manipulation.

We have seen a similar migration in the progression in "camera ready copy" for production of both print, and print surrogates, from literal image files, through printer instruction sets (such as PostScript ™) to today's PDF transmissions. All of these systems had to be engineered, but almost no one who adopted them paid much attention to the engineering itself. Each successive system merely met the need better than its predecessor. Today we have something far superior to what was ever possible without the networked exchange platform we now have (the Internet) and all the standards developed to support it. But no one exactly noticed much as our means of sending "pages" improved – as one subsystem replaced another. It simply happened.

Of course, it did not simply happen by itself, and the emergence of superior means (or at least, more capable means at scale) for maintaining business correspondence (email) or producing materials for the eyes of readers (camera-ready copy) reflected significant efforts by their developers and early proponents. The efforts were not made by the eventual users, however. Similarly, our users should not have to design their own technical solutions. A new platform emerges because we work at several levels of the system at once – and because we exploit emerging opportunities.

If our aim is to provide any "downstream user" with the kinds of capability and leverage one gets from external control, specification and testability of the kinds of regularities – at multiple levels of "semantics" – that can be usefully discovered or introduced into our data. We do this by working at different layers, providing users and indeed application developers not with solutions, but with the foundations and technical infrastructure on which their solutions can be constructed; but once that has been done, the solutions themselves "just work". In other words, what from one point of view, is an engineered solution, must be from another, just a better way to do the same thing.

Yet in a world where processes are already well defined and described, this is a challenge, since application design must in some way come first – at least insofar as engineers must build to specific problems, not just general ones, to motivate the efforts. Solutions will emerge – someone will put effort into building them – if the base works well enough to enable and streamline these efforts. With a combination of good data, and good data description, we believe this is possible and necessary in a domain as complex and semantically rich as this one.

How do we know we need (something like) OSCAL?

As pointed out in a 2019 paper for this conference, many or most of the functional requirements for data capture and relation (linking) that we face in systems security could be achieved, with only a bit of stretch, by extant markup technologies. The reason we need OSCAL is not because existing technologies including DITA, ISO/NISO STS, HTML microformats, XBRL, or even TEI, not capable of representing the data adequately (just to mention a few reasonable candidates[7]). Indeed if we assume that any of these has such capability, the question becomes why documents relating to systems security, and their exchange, remain firmly locked into proprietary technologies of production such as word processors and spreadsheets, given their well-understood limitations for systems working at scales beyond the enterprise. Why, in other words, has this migration not long ago happened?

One answer to this question is in plain view in the form of a common office document feature, namely templates, and the simple fact that an Office document (whether Microsoft Word or Excel, or a similar application on or off the web), for all its limitations, is the most flexible, powerful and accessible tool available (to one definition of “accessible”) to a security professional, for data modeling. And data modeling – the definition, collection, management and deployment of structured, semantic data – is indeed at the core of their work. Available encoding standards all assume one thing: that the schema that adequately describes the document for its intended application, can be known ahead of time, indeed is not only known, but anticipated and accounted for by the general-purpose schema in question.

But every new structured document and every spreadsheet implies a model, and usually one (assuming a good designer) whose outlines are readily discernible to an informed reader. Indeed frequently, documents in use must conform to a “type” and follow rules for that type – evidence of the model again – with templates used as one (not the only) criterion for measuring conformance to the type (considered informally). Now, these new models are not made just for the enjoyment of it (although that could play a factor). On the contrary, we invest the effort because we can see the benefits (in higher quality, better and more throughput – that is, data processing capacity and capability) of doing so. The rules are not an impediment but a track to follow.

Many data professionals understand the shortcoming of office documents (considered as a genre) for truly widespread data, secure data exchange. But even they have no choice but to use them, since document templates are also what their own downstream users can use – while XML application stacks and libraries of stylesheets (or even the functional equivalent for JSON) are not.

Indeed it might be said that the essence of our problem is to make it possible for data professionals to do more than encode their information optimally for exchange (only) with their *immediate* partners – however necessary this is, and great the benefits of doing so. A workable standard for active information exchange is a *sine qua non*, but beyond it is another essential, since the requirements for exchange themselves in this domain are so local and so particular to processes, and defined and mandated at several levels at once.

This meant that whatever language we adopted or developed to address the needs, its own extensibility model would be crucial. (This is not an unfamiliar problem to the designers of documentary encoding standards.) Ideally, extensibility features would be free to users in the sense that no work in a schema or formal layer should be necessary for local applications to define and then enforce their own semantics (for example, by offering features enabling extension by restriction). But mechanisms for them to introduce such enforcement are also essential. We found a solution to this issue in our Metaschema technology (as described in the 2019 paper).

From this point of view, OSCAL (the Open Security Controls Assessment Language) should be regarded not as a solution, so much as a process for developing solutions. This process is technical and entails the definition and specification of information models as means to and end (successful, meaningful data exchange). But it is also very granular, and happens “on the ground”. Like any documentary standard, OSCAL may be able to provide for 80 % of what is needed for its "normal" cases, and what constitutes a normal case for it, as all technologies, will be a direct reflection of its capabilities. What is most important, however, is how OSCAL permits its users to deal with their 20 %.

It is not the aim of this paper to describe in any detail the OSCAL models or how they address requirements: a certain amount of background information on the project might be a prerequisite for much of what follows. It is too early to say whether and to what extent any adoption of OSCAL may change or improve the actual practice of security assurance. But it is not too early to reflect further on the challenges that could impede its success. And if the basic premise of OSCAL, like other markup technologies, is in declarative markup and descriptive encoding, it seems necessary to consider what problems or issues we might watch out for.

The OSCAL Approach

This paper is for two audiences at once: information technologists who specialize in open data formats and the standards that sustain them; and systems and information security professionals who bring an understanding of the requirements of their domain, not necessarily deeply informed of available approaches or solutions (in the form of available technologies), but who bring an interest to this topic because they know or sense enough about it, to understand the significance of their impact. If anything, what makes our project interesting to the first of these audiences, is our relation with the second. Briefly, we are hoping to change the practice of systems security and its documentation, by presenting its stakeholders and practitioners with better ways of doing things. While we have some ideas (or we would not be making the attempt) of what these better ways look like, we must assume, however (quality is defined in context) that they are in a better position than we are to know what "better" will be. This means our primary challenge is to listen, with the goal of empowering them (users, stakeholders, the community, the market) to do what we would do for them, if we knew what they know.

In view of this, it may be worth considering briefly what OSCAL (the Open Security Controls Assessment Language) is, and is not. OSCAL is:

- A set of related and interlocking data models
- A data description language for a domain, and thus defined by that domain: systems security assurance and related documentary activities, as defined by IT (information technology) practice and statute.

As described in Piez 2019, these models are defined by a schema back end or *Metaschema* technology that permits us to provide support for these models in multiple syntaxes, specifically (to date) XML, JSON and YAML syntax.[8] This support takes the form of schemas for validation, conversion utilities and much else (documentation, starter stylesheets for designing representations, code generation, etc.). Together, these offer the platform for a stack of capabilities for data description, application and interchange. In this it is analogous to many other standard or common encoding technologies (XML-based and not), as they address their respective domains.

What then is OSCAL *not*?

- It is not a markup language.

  While OSCAL has an XML expression, and is designed for use in and with markup-based systems, it is also not a substitute for DITA, JATS/BITS, NISO STS, HTML[9] or any other extant markup technology, which are considered to be (from the OSCAL perspective) not alternatives (since they do not address the same set of functional requirements for data representation), but rather as complementary technologies and (as such) exploitable assets.
- OSCAL is also not an attempt to engineer a workflow or "solution" to the problem of data management in this complex domain. Rather, it is intended to provide the foundation or groundwork for the development of workflows and solutions.

  Again, existing workflows might be regarded as externalized assets and as opportunities, insofar as to the extent they can be "OSCALized" (enabled with and by OSCAL), they can work together with other systems more seamlessly, acquiring new capabilities via network effects.

So what about those functional requirements? The core concept is close to that of standards-based markup languages, albeit scoped within the particular domain of a specialized information set: we wish to enable better system security and security assurance by providing a foundation for rich (semantic) data exchange among partners and organizations. If we succeed, we will *lower the costs to organizations and users* of participating in such exchanges, by helping to *define and apply the rules* that enable it.

So how are the requirements we are addressing unlike requirements for publishing systems?

- When publishing for an audience of no more than three or four parties, requirements for production values are different, and economies of scale in production will not benefit in the same ways. Return on investment still comes from economies of scale, but not to the same (exponential) degree. At this time, achieving superior results, arguably, is as important as lowering costs. (This is not always true in publishing, which has been subject to economic stresses for much longer.)
- With respect to the data sets themselves, the granularity of description they require is (as compared to many applications of markup languages) relatively *rough*. This is reflected in the fact that OSCAL applications do not need much functionality at the word and phrase level – the data models is seeks to capture generally do not require it – and that when it comes to discursive contents ("prose"), it does not need much beyond some inline formatting plus a generalized insertion or transclusion mechanism (somewhat analogous to DITA **key/keyref**) working at the phrase level. Since these together can be accommodated using a near-subset of HTML or Markdown, the information can also (with some compromise) be constrained to representations that fit well within the limitations of JSON or similar object notations. In the terms I used in my Balisage 2018 paper Piez 2018, the data is higher on the "semantic stair".

  The flip side of this is that at a higher level of granularity – groupings of prose and structured data – the requirements for what might be called "hypertext" are comparatively intricate . Documents and their parts and components present complex interlinkings, both to one another and to similar or different parts of similar or different but related documents. For example, System Assessment Plans must make targeted references from their parts, to parts of system descriptions given in System Security Plans. Those references are "semantic" in the sense that they must be distinguished by type according to intended use and the kind of relations they encode; and when the links break, the documents break.
- Above all, OSCAL's users are different from the users of publishing systems or even from operators of documentary-production workflows.

  Most importantly, OSCAL's users will not only be CMEs (content matter experts) who use OSCAL-based systems to acquire and represent data to do their security assessment jobs, but also developers of systems and software to use it. While we do not expect that most OSCAL data will be published widely (the exception being canonical documentation such as the catalogs and baselines to which other OSCAL documents refer), we do expect it to be useful within organizations and between partners, in multiple unforeseeable ways. This means that developers need to be able to build to it.

  In order to win their support as well as maximize the chances for their success, we do not wish to constrain, any more than absolutely necessary, those developers with any encumbrances with respect to formats, software platform(s), or technical dependencies in general. Because we expect and rely on them to take us places we cannot go, we must trust them to use the means that seem most appropriate to them.

  In our experience, most dev/ops professionals become literate in multiple different formats for information interchange. However, it is also important to meet them where they are, and to enable them to use tools they know (while opening opportunities to use tools they do not yet know).
- This means that while we are free to define, demonstrate and promote models that enable functionality to be delivered, we are not free to stipulate that only XML may be used. Today, it is either JSON and other formats (including but not limited to XML), or JSON only.

  And indeed, since the information in our domain is not only documentary and not only suited to XML, having the capability to work in either format is a huge advantage. And designing from the start to be able to support and address either, also positions us over the longer term – as adding support for yet more alternatives (YAML, for example) becomes easier to do.

Notwithstanding these differences, both the complexity of the requirements, and the "documentary" and "fractal" nature of the data sets themselves – they exhibit regularities, but they are not entirely regular – necessitate the layered approach to systems design. As stated at the outset, we believe that a layered system that relies on declarative, descriptive encoding of data structures, with a separation from both underlying platforms (operating systems, storage media etc.) and from application logic, is the only practical approach to dealing with information management this complex. Indeed, the problem presented by systems security (planning, analysis, implementation, documentation, assessment) – whether considered as "micropublishing" or not – might be described as similar to the problem of designing robust, sustainable (platform-independent) publishing systems, except "on steroids": perhaps an order of magnitude more complex. The only way we have of managing that complexity is to factor it out into separate interrelated sets of requirements, which can be addressed separately as well as together.

If we have built and operated successful systems on that basis, the next question becomes what that experience teaches us.

Applying the lessons: conclusions and expectations

To state that there is a way forward is not to say that it will be easy. Considering the lessons of XML in publishing, with its challenges, can help us reflect on the challenges we also face:

- **Your system is someone else's subsystem**

  This is even more true in the realm of RMF-based security assurance activities than it is in mainstream publishing. By design, an OSCAL document produced in and for one system, will be used, worked and integrated within another. An OSCAL system component description, for example, can be encoded once in one resource, then referenced by many systems plans that integrate that component. These documents will all be composed, produced and shared in different organizations (such as when the component in question is developed by one vendor and then used as a platform by another); and the links must hold together.

  One of the keys to scaling within the publishing domain is that an article, monograph or any published “artifact” is conceived as, in principle, a self-contained and self-sufficient entity, which can be written and produced for publication separately from others of its kind. Of course (as discussed above), this self-containment is partial and qualified, as much of the work of publishing is the integration of such an entity with other such entities within a larger structure – articles are integrated into a journal and even monographs are anchored into larger infrastructures for purposes of marketing, distribution, cataloging and so on. This is achieved through the application of two principles: (1) distinguishing “kinds” or classes of publication that can be treated alike within larger systems; and (2) associating metadata with each publication that can distinguish the instance among the members of the class.

  A primary goal of OSCAL is to begin to do this, and to provide a foundation for continuing to do so, within the domain of systems security documentation. Of course, the idea of kinds or classes of documents brings us to declarative markup.

- **Declarative markup adds value**

  The layering that is characteristic of systems based on declarative principles has been well explored at this conference and elsewhere. This layering enables separation of concerns between the production of data content (information sets), and its subsequent management, processing, rendering (presentation) and downstream application. When applied to publishing, this principle works.

  Again, however, the fact that there is a principle we can follow, does not make the design problem easy. In this case, distinguishing meaningful classes of information according to their nature, purposes and uses, depends on a clear and articulated sense of both commonalities across, and boundaries between different information sets, as well as their complex relations. Shared documentary structures that reappear throughout OSCAL's models reflect these commonalities; rules on their use reflect the boundaries. But both the shape of those structures and the rules applied to them, must make sense in terms of the data set as the practitioner sees it.

  And because our view of this is partial and evolving, we have also made efforts to enable the modeling to be agile and flexible and adaptive, most especially in the back end (Metaschema) technology we have developed to enable modeling across the gap between XML and object notations (see Piez 2019).

- **Data acquisition is hard**

  If only because it is so challenging in other domains, we should be ready to place special focus on developing means to convert relevant data sets into well-structured, well-described OSCAL.

  Multiple methods and approaches could be explored, using an “all of the above” strategy: structured editors; forms interfaces; semi-structured resources such as wikis or “issue” (ticket) systems; office document conversion pathways. Different methods or strategies may be appropriate for different parts of the system.

- **Activities are supported by incentive structures**

  The incentive structures within this domain are very different from publishing, and positive incentives are arguably scarce. Historically, activity related to systems security (beyond the functional minimum) has too often been a low priority, a kind of optional insurance policy for cases where the implicit security model of “trust your neighbors and leave the door unlocked” has failed. Similarly, the second-order benefits of well-documented systems security (exposure of latent issues; traceability; assurance; contingency planning) have been considered at best as “nice to haves”. Without the heavy hand of regulation, security typically gets little if any attention from designers or developers until after a system is implemented and stakeholders are happy with its functionality and performance.

  In order for RMF-based activities to be fruitful, we need to keep incentive structures in mind, and look for opportunities to provide positive as well as negative incentives. To be sure, impediments must also be removed for positive incentives to come into play – thus for the OSCAL project we have done our best to address non-negotiable operational requirements (such as “XML versus JSON”) in ways that make it possible for deployed systems to actually start to realize benefits in data interchange.

Noteworthy positive incentives should include, first and foremost, improved capabilities: more and better risk management at less expense. The more substantial positive incentives might take the form of better and more secure systems – that is, not only the documentation, but the systems themselves will be more secure, while also easier to develop, test, reuse and adapt in a “security first” mindset.

Additionally there are important secondary incentives, such as a more efficient use of time invested in assessment when the overhead of manual operations is reduced. Given that there is always more to assess, it is difficult to imagine how security assessments themselves can become cheaper. But with the aid of machining, and given better and more consistent, more easily consumed artifacts to represent the subjects of their assessment, one could expect assessments in general to be better, even to the point that “light touch” assessments (of well-documented, well-vetted systems) might be deemed to be adequate.

There are perhaps some further benefits of automation and automatability that might become incentives, to the extent that it can be recognized how achievable they are given appropriate investment. Much of the design of OSCAL is intended so that the considerable efforts of authors at lower layers – people who define and publish catalogs and baselines – can be better leveraged and exploited by the consumers of their information whether that be planners, assessors or others responsible for defining policy. This could become an incentive were it possible to monetize or otherwise feed back that benefit. (Pay a license to use an especially good baseline?) More likely, it becomes an incentive to the extent that such use and reuse of one's catalog (or baseline) is itself considered a criterion for success.

Finally, it is worth stressing that a significant factor in getting work done – to say nothing of good work – is inevitably in the imponderable aspects of pride and satisfaction with good work that good workers cultivate. It may be possible, by developing good tools, to build in “micro incentives” in the form of opportunities for good work, which serves as its own reward for those who see how consistency, transparency and integrity of the data they produce can contribute to the soundness of the system as a whole.

- **Quality is defined within context**

  With respect to security-related activities in general, or even RMF-based activities in particular, because operational context is hard to define and open-ended, no single solution will be a comprehensive solution. In the publishing domain, we have learned that the high degree of requirements for local adaptation and customizability has been critical to the success of the standard encoding formats. This is likely to be even more true for us.

  Tolerance of variation – and recognition of variation as a source of information – is an important characteristic of these systems. It being difficult to distinguish in general where variation is meaningful – where it is signal, and where it is noise – these systems need to be well defined, well managed and transparent, but also flexible and adaptable, with extension mechanisms that permit local adaptation without unnecessary “forking”.

  Although it is outside the scope of this paper, the design of OSCAL's schemas and validation infrastructure permits addressing this set of issues in ways already familiar to designers and users of publishing systems: namely, by deploying not a single “one size fits all” validation regimen, but rather by supporting a layered or tiered approach, “mix and match”. This permits organizations to define their own rules and rules sets and gain leverage over their own data, for their own (and partners’) processes, even while they also conform to a more general set of rules shared by everyone.

- **Evolution works by little revolutions**

  Everything we have learned about the application of information technologies to publishing suggests that in this domain as well, progress towards better practices and more capable systems will be incremental before it is systemic. With a view to this likelihood, OSCAL aims to offer early rewards for users who can adopt it for solving problems, whatever those problems are, without imposing a requirement for any top-down overhaul. Even when OSCAL is never used at the core of a documentary system, it might be useful at its interfaces. And if it is useful at the edges of any system, it will eventually be useful at the core of others.

  Yet experience also suggests that developers and stakeholders must “get it”, for progress to happen at all. There is no substitute for understanding, and thus for data transparency to the extent practical and possible. A commitment to open, non-proprietary declarative encoding – even within a secure operational context – is crucial, if only because a monoculture is not secure. But it is not only because of its long-term security, that the system must be open; it is because its success will depend above all on who understands it and how well, and how well they can adopt it for appropriate and intended use.

Within this context, one final principle might be recognized: *the platform is not the capability*. This might, indeed, be considered to be a core insight, in the sense that the entire enabling paradox of declarative markup is based on it – by defining the encoding in a way *independent of and abstracted from* its local application, we enable applications not only locally (any application must be local) but in general. While a technical platform (considered in the broadest sense) is necessary for a technical capability, this practical dependency is a reflection of the fact that the logical dependency is the other way – unless it enables a meaningful capability, a platform or technical means remains inert and ineffective. A platform that offers no useful capability, will soon be abandoned. Conversely, while it is necessary for developing and demonstrating a capability, the very fact that a requirement can be described without commitment to a platform, is an indication that no platform or technical solution is a *sine qua non*. The different strengths of different technologies (whether XML/XDM, Javascript/JSON, comma-delimited values exported and imported into spreadsheets, or anything else) give them comparative advantages – and these can be exploited. Thus a platform that is developed to enable capabilities we already understand – and already have the means to accomplish – can also be a springboard.

Effect of Amplitude Mismatch on Entanglement Visibility in Photon-Pair Sources

Paulina S. Kuo
Information Technology Laboratory, National Institute of Standards and Technology, 100 Bureau Drive, Gaithersburg, Maryland 20899, USA
paulina.kuo@nist.gov

Abstract: Entangled photons produced by parametric down-conversion effectively have two down-conversion paths. Ideally, amplitudes of the two paths are matched. We show that the entanglement visibility is, to first order, insensitive to amplitude mismatch. © 2020 The Author(s)

Entangled photon-pair sources are typically based on spontaneous parametric down-conversion (SPDC). In a type-II SPDC polarization-entangled source, the generated entangled state is

$$|\psi\rangle = \alpha|HV\rangle + \sqrt{1-\alpha^2}|VH\rangle, \tag{1}$$

where α is the amplitude ratio parameter, $|HV\rangle$ refers to horizontally polarized signal and vertically polarized idler, and $|VH\rangle$ refers to vertically polarized signal and horizontally polarized idler. The two terms in Eq. 1 correspond to two different biphotons that can be produced by two different physical paths [1], two different crystals [2], two different quasi-phasematching periods [3], or two different down-conversion paths in an aperiodically poled crystal [4, 5].

In an ideal polarization-entangled state, the amplitudes of the two terms are equal. When measuring coincidence counts in the diagonal/anti-diagonal bases, in order to get zero coincidences (required for high entanglement visibility), there must be perfect destructive interference of the $|HV\rangle$ and $|VH\rangle$ photon paths (assuming no background noise). If the amplitudes in Eq. 1 are unequal, then this destructive interference is not possible. In several of the SPDC techniques mentioned above, the amplitude ratios are fixed during fabrication and it seems that good entanglement visibility can still be obtained even if the amplitudes are unbalanced [3–5].

High entanglement visibility requires high indistinguishability between the two possible down-conversion paths. We can quantify this indistinguishability by considering Hong-Ou-Mandel (HOM) interference between the two down-conversion paths. Imagine interfering the two down-conversion paths (or two biphotons) on a beam splitter. If the paths are indistinguishable, then no coincidences will be observed between the two outputs of the beam splitter, resulting in the well-known HOM dip. The closer the HOM dip is to zero, the better the indistinguishability and the better entanglement visibility we expect.

We can calculate the depth of the HOM dip by considering the joint spectral intensity distribution of two photons exiting opposite ports of a beam splitter, which is given by [6, 7]

$$I(\omega_1,\omega_2) \propto \frac{1}{2}\left|C(\omega_1,\omega_2)e^{i(\omega_1 t_1+\omega_2 t_2)} - C(\omega_2,\omega_1)e^{i(\omega_2 t_1+\omega_1 t_2)}\right|^2, \tag{2}$$

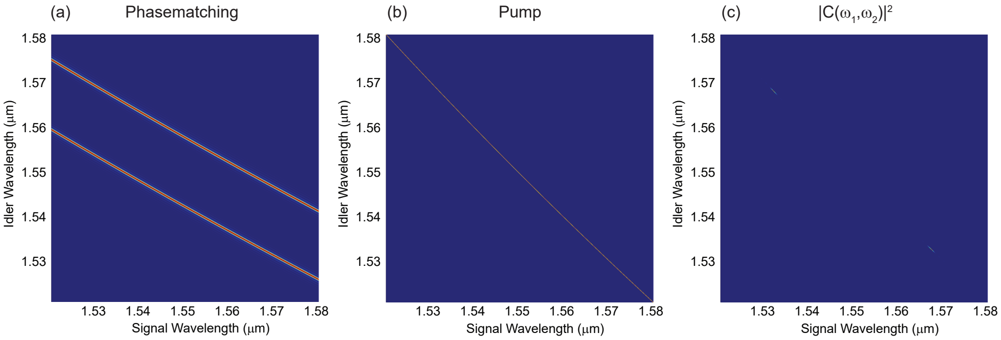

Fig. 1. The (a) phasematching and (b) pump functions are multiplied to produce (c) $|C(\omega_1,\omega_2)|^2$. The case of equal amplitude is shown.

Kuo, Paulina. "Effect of Amplitude Mismatch on Entanglement Visibility in Photon-Pair Sources." Paper presented at Integrated Photonics Research, Silicon and Nanophotonics (IPR), Montreal, CA. July 13, 2020 - July 16, 2020.

where $C(\omega_1,\omega_2)$ is the joint spectral amplitude of the two photon wave-function incident on the beam splitter, ω_1 and ω_2 are the frequency of the two photons, and t_1 and t_2 are their corresponding arrival times. The coincidence detection rate for obtaining counts in both output ports of the beam splitter, R_c, is [6]

$$R_c \propto \iint d\omega_1 d\omega_2 I(\omega_1,\omega_2). \tag{3}$$

When the photons arrive at the same time ($t_1 = t_2$) and $C(\omega_1,\omega_2)$ is symmetric (i. e., $C(\omega_1,\omega_2) = C(\omega_2,\omega_1)$, then $R_c = 0$ and we expect perfect indistinguishability of the two down-conversion paths.

As a specific example, we studied the down-conversion process presented in Ref. [5]. A domain-engineered, lithium niobate crystal is designed to simultaneously phasematch both $|HV\rangle$ and $|VH\rangle$ processes for the wavelengths 775 nm $\longrightarrow$ 1533 nm + 1568 nm. We used a narrowband pump that constrains the idler frequency, ω_2, to be related to the pump, ω_p, and signal, ω_1, frequencies by $\omega_2 = \omega_p - \omega_1$. The $C(\omega_1,\omega_2)$ function is the product of the phasematching and pump functions, as shown in Fig. 1. The phasematching function has two lines for the two simultaneous down-conversion processes.

Using Eq. 3, we calculated the coincidence rate as a function of the mismatch in amplitudes the two down-conversion paths. Figure 2 plots R_c as a function of peak ratio, which is equal to $(1-\alpha^2)/\alpha^2$. R_c is normalized to 1 as the peak ratio goes to zero. We see that when the peak ratio is near 1, R_c is near zero and is to first order independent of the peak ratio. This indicates that the two down-conversion paths are nearly indistinguishable and that entanglement visibility is not sensitive to small mismatches in amplitudes of the two down-conversion processes.

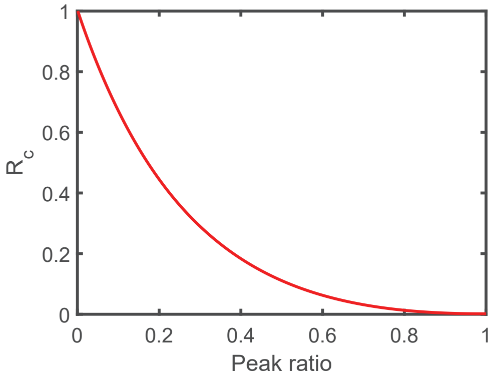

Fig. 2. Coincidence rate as a function of peak ratio.

In conclusion, we quantify the indistinguishability between two down-conversion paths by considering an analogy to HOM interference. We observed that mismatches in amplitudes between the $|HV\rangle$ and $|VH\rangle$ states do not significantly affect R_c and in turn, do not significantly degrade the polarization entanglement visibility. This observation explains how SPDC sources whose properties are fixed during fabrication can still have high polarization entanglement visibility even in the presence of fabrication imperfections.

Effect of Amplitude Mismatch on Entanglement Visibility in Photon-Pair Sources

INFORMATION TECHNOLOGY LABORATORY

Paulina S. Kuo (paulina.kuo@nist.gov)
Information Technology Laboratory, NIST, Gaithersburg, MD 20899

Introduction

Entangled photon pairs are a key resource for quantum information systems. Entangled photon pairs are typically produced by spontaneous parametric down-conversion (SPDC). High entanglement visibilities are obtained for many SPDC sources even when there are non-ideal fabrication or experimental conditions. In this work, we consider how amplitude mismatch in the SPDC process can still lead to high entanglement visibility.

Entangled Photon Pair Generation

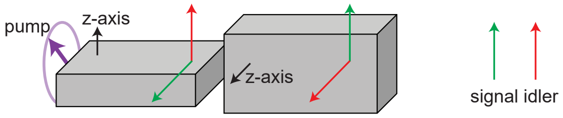
- In a Type-II, polarization-entangled SPDC source, the generated wavefunction is

$$|\psi\rangle = \alpha|HV\rangle + \sqrt{1-\alpha^2}\,|VH\rangle \qquad (1)$$

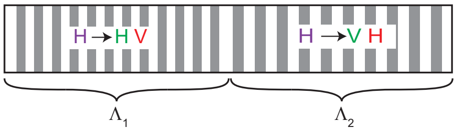
where $|HV\rangle$ refers to horizontally (H) polarized signal and vertically (V) polarized idler, $|VH\rangle$ refers to vertically polarized signal and horizontally polarized idler, and α is the amplitude parameter.

- When $\alpha^2 \neq 1/2$, the amplitudes are mismatched
- A state such as shown in (1) can be produced many ways including:

Two co-rotated SPDC crystals



Two quasi-phasematching (QPM) periods

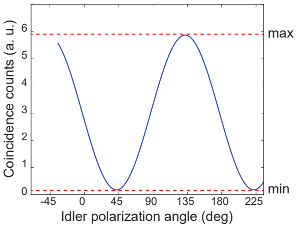


or using dual-periodically-poled or domain-engineered SPDC; see

C. Sun, et al., Opt. Lett. **44**, 5598 (2019)
P. S. Kuo, et al., OSA Continuum **3**, 295 (2020)

- The two terms in Eq. (1) correspond to two biphotons that take two different down-conversion paths (through two crystals, two QPM periods, etc.)
- In several schemes to generate Eq. (1), α is fixed during fabrication. In these cases, experiments have shown good entanglement visibility even when $\alpha^2 \neq 1/2$.

Entanglement Visibility and the HOM Interference Dip



- In a typical polarization entanglement measurement, coincidence counts are recorded while rotating the idler polarization and holding the signal polarization fixed
- The visibility, V, is calculated by

$$V = \frac{\max - \min}{\max + \min} \qquad (2)$$

- Maximum visibility (V = 1) is obtained when min = 0
- Neglecting noise, in Type-II SPDC, when the polarization analyzers for signal and idler are both H, there are no coincidences (min = 0)
- To get min = 0 when the signal is diagonally polarized, there must be perfect destructive interference between the two idler down-conversion paths, akin to perfect Hong-Ou-Mandel (HOM) interference

→ Examine the HOM interference dip to understand visibility

Spectrally Resolved HOM Interference

- HOM interference is a measure of indistinguishability. The HOM dip allows quantification of the effect of mismatch
- The joint spectral intensity distribution of two photons exiting opposite ports of a beam splitter is[1]

$$I(\omega_1, \omega_2) \propto \frac{1}{2}\left|C(\omega_1, \omega_2)\exp[i(\omega_1 t_1 + \omega_2 t_2)] - C(\omega_2, \omega_1)\exp[i(\omega_2 t_1 + \omega_1 t_2)]\right|^2 \qquad (3)$$

$C(\omega_1, \omega_2)$ = Joint spectral amplitude of the two-photon wave-function incident on the beam splitter
ω_1, ω_2 = Frequencies of the two photons
t_1, t_2 = Corresponding arrival times of the two photons

- The coincidence detection rate, R_c, for obtaining counts in both output ports of the beam splitter is[1]

$$R_c \propto \iint I(\omega_1, \omega_2)\, d\omega_1 d\omega_2 \qquad (4)$$

[1] T. Gerrits, et al., Phys. Rev. Lett. **91**, 013830 (2015)

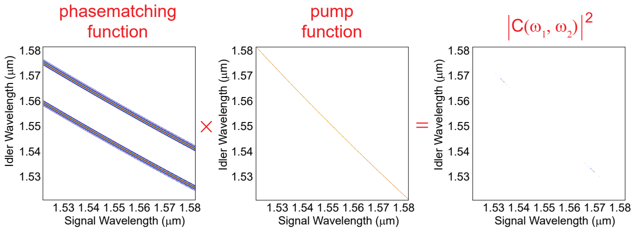
- Plotting R_c vs. $t_1 - t_2$ traces out the HOM dip

Joint Spectral Amplitude

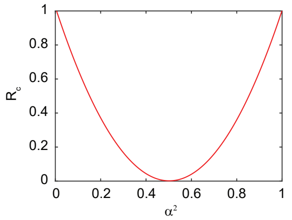
- We modeled Type-II SPDC in periodically poled lithium niobate having two QPM periods and a narrowband pump

775 nm ⟶ 1533 nm + 1568 nm

- The joint spectral amplitude, $C(\omega_1, \omega_2)$, is the product of the phase-matching and pump distributions



HOM Dip when $\alpha^2 \neq 1/2$



- Using Eq. (3) and (4), we calculated the minimum of the HOM dip (given by R_c with t_1=t_2) when α^2 is varied
- At $\alpha^2 = 1/2$, there is perfect destructive HOM interference and $R_c = 0$
- Near $\alpha^2 = 1/2$, R_c varies quadratically with α^2, which means that to first order, the HOM dip minimum is independent of changes in α^2, i.e. amplitude mismatch

→ By the previous arguments, the entanglement visibility is to first order independent of the amplitude mismatch

Conclusions

- We quantify the indistinguishability between the two down-conversion paths by considering the analogy to HOM interference
- The HOM dip and the entanglement visibility are robust to small amounts of amplitude mismatch (deviations from equal amplitudes)
- Small mismatches in amplitudes, such as those caused by non-ideal fabrication or experimental conditions, do not seriously degrade the entanglement visibility

Abstract. Providing the business context has a potential to become a powerful mechanism for the interoperable usage and efficient maintenance of message standards. In the literature, there are multiple techniques for its representation and application. Industry use cases have identified multiple issues that come with currently used techniques, which can represent that context. Initial assessment of a logic-based technique for doing so has been conducted and showed that some of the identified issues can be resolved. This paper presents plan for validation of the logic-based technique where proposed algorithms will be assessed in realistic integration scenarios. The paper gives details of the validation steps, goals that need to be met, and indicates issues that guide our future research plans.

Keywords: Business context, Services integration, Enterprise interoperability.

1 Introduction

Distributed and autonomous services are increasingly becoming components of the manufacturing and logistics enterprises. To achieve efficient integration of these services, message standards are needed. Messages (i.e., payload or business document specifications) define types of transaction-related information that need to be exchanged among different services. Messages are necessarily standardized because of the wide variety of inputs to those services. Inputs come from numerous business sectors, business processes, business contexts, and business representatives.

However, traditional message standards have been only partially successful. We have identified four major issues inhibiting the adoption of messaging standards. First, "out-of-the-box" message standards are necessarily generic, making them difficult to adapt to specific use cases. Second, the standards are typically documented in text form to facilitate human interpretation and do not have a computational form that can be processed by validation tools to assure integration and interoperability. Third, over time

Ivezic, Nenad; Jelisic, Elena; Kulvatunyou, Boonserm; Nieman, Scott; Oh, Hakju; Marjanovic, Zoran. "Towards inter-operable enterprise systems - graph-based validation of a context-driven approach for message profiling." Paper presented at APMS 2020 International Conference Advances in Production Management Systems (APMS 2020), Novi Sad, RS. August 30, 2020 - September 03, 2020.

the standards become large supersets of duplicative data elements contributed by various industries making the standards difficult to implement. And, fourth, as more elements are added, detailed refinement or profiling of a message standard is necessary to recapture the original business intent and business context.

On-going work by the Open Application Group [1], industry, and National Institute of Standards and Technology (NIST) [2] continues to explore the concept of using business context to improve 1) the enablement of new syntax-neutral message standards and 2) the resolution of the identified issues [3, 4, 5]. Some of the currently implemented context schemas and management approaches, however, have proved to be inadequate [6]. On the other hand, some newly proposed, promising approaches are introduced [7] but must be tested with realistic industry situations to establish their capability and feasibility. Yet, such testing is resource-intensive and requires commitment and engagement of industry and standardization communities.

We have started to validate a newly proposed approach using existing scenarios already contributed to OAG-i by industry stakeholders [1, 6]. Further industry adoption of the proposed context management approach depends on its capability to address all real-world use cases. Accordingly, the theme for this paper is our proposed approach to validate a promising, context-management technique for cross-industry use cases. Since the outcome of our approach depends on the validation process, this paper provides a detailed description of that process. That description identifies the goals and steps needed to achieve those goals. To the best of our knowledge, there are no research papers that deal with validation of a proposed, business-context-management approach.

In the following, Section 2 introduces background information about important concepts that are used in the paper, Section 3 describes the validation process through steps needed to achieve identified validation goals, Section 4 describes validation domain, and, finally, and Section 5 discusses the expected results and future research steps.

2 Background

Message standards are expressed in terms of message components. Message components are developed and offered as parts of a message standard suite where they are used to form multiple types of messages. An important, international standard, Core Component Technical Specification (CCTS), has been proposed to enable uniform and consistent development of message components and message standards. The goal of CCTS is to advance interoperability among applications and services [8].

A key concept in CCTS is *business context*, which is used to describe the business intent of using a message component or message profile, which is a subset of a corresponding message standard. In our view, capturing that intent is essential to finding and reusing the right message components and profiles, which will enable interoperability of corresponding data and services. Following CCTS, a specific business context is represented as a set of context values that are associated with their corresponding context categories (e.g., business process party profiles, geo-political location, tasks with a business process, resources available, and industry).

While the business context can indeed identify situations in which some components will be reused, we found this to be insufficient for interoperability. This is because semantic interoperability must also consider what happens in the background (e.g., transformation of the data into the database). Hence, in this paper, we assume that business context must also provide semantic definitions and validation rules that may be triggered when choosing the components in the business context. Providing those definitions and rules requires business-context knowledge.

Business-context knowledge can be represented using multiple, modeling techniques including graphical, object-oriented, logic-based, and ontology-based. For the purpose of this paper, we will employ a logic-based modeling technique - Enhanced UN/CEFACT's Context Model (E-UCM) [7]. E-UCM represents business-context knowledge using decentralized, directed, acyclic graphs. Each business-context category has at least one such graph that represents a list of possible values (or nodes) in the corresponding category. Then, a specific business context for a specific, information-exchange situation corresponds to a collection of nodes belonging to specific categories in the E-UCM graph.

E-UCM methodology for creating these graphs has two main parts. First, there is an infrastructure for (a) business-context presentation and expression and (b) contextualization of existing message profiles. Contextualization is supported by algorithms that can detect message components that are either relevant or irrelevant for a *Requested business context*. Second, there is a set of algorithms that can be used to generate the structure of new message profiles using existing message components that are relevant for *Requested business context* of a new message profile.

To determine a business context for a specific, information-exchange situation, we identify a collection of graph nodes that make up that business context. A list of specific nodes can be identified from E-UCM graph using E-UCM-provided expressions that are built using available operators and predicates. Every message component and profile has an associated E-UCM expression that captures its usage intent. This expression is called *Assigned business context*.

Along with the *Assigned business context*, E-UCM introduces terms *Overall* and *Effective business context* and provides directives for calculation of these terms for all situations and components, ultimately resulting in *Effective business context* for each component. The *Overall business context* can be understood as cumulative business context of some compound message component, while the *Effective business context* should reveal message component's relevancy in a *Requested business context*.

The process of assigning contexts to a message profile and its components, and calculation of *Overall* and *Effective business contexts* is called *contextualization.*

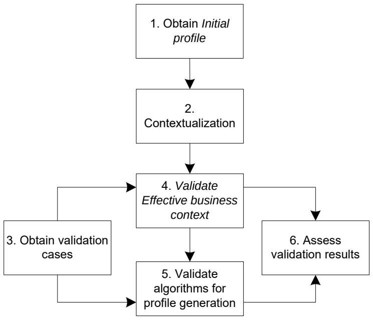
3 E-UCM Approach – On-going Validation

Our initial validation [6] concluded that E-UCM methodology provides a powerful mechanism for business context presentation and expression. Our goal in this paper is to validate the algorithms that E-UCM proposed for both *contextualization* of existing message profiles and profile generation. Our approach to achieve that goal involves two steps. The first step is to assesses *Effective business context* as sufficient evidence of message component's relevancy or irrelevancy in the defined business context. The second step assesses the algorithms for message profile generation as capable of constructing a valid, message profile for a *Requested business context*. The key difference between those two goals is whether message profile structure is available or not. If it is available, profile refinement occurs for new integration scenarios. Otherwise, message profile structure should be generated using E-UCM algorithms on the basis of existing message profiles.

We made two important assumptions in completing the validation study. First, we assumed *contextualization* would be realized by a specialized service provider. Such a service provider would need domain knowledge needed for the development (or selection from an existing standard library) and use of message components. Such domain knowledge would typically be obtained through 1) business analysis of existing business processes and 2) information exchanges that rely on documentary standards and standard operating procedures.

Second, we assumed that there is one contextualized *Initial profile* upon which all others are based. To obtain the *Initial profile*, a service provider would construct a special kind of domain knowledge that contains an *initial collection of document components* and a *set of business rules* that govern the usage of those components. Using this domain knowledge, the service provider would generate an output in the form of a contextualized *Initial profile* with its components assigned intended business context, corresponding to the business rules.

Our validation process is shown in Figure 1. First three steps are prerequisite and the same for both validation goals, fourth and fifth steps reveal our validation goals, while the sixth step is an assessment of validation results. The third step gathers validation cases that will be used to accomplish our, two, identified, validation goals. Each validation case is described using *Requested business context*.



1. Obtain *Initial profile*
2. Contextualization
3. Obtain validation cases
4. *Validate Effective business context*
5. Validate algorithms for profile generation
6. Assess validation results

Figure 1 Validation process

3.1 Validation of *Effective business context*

The input for this validation step is semi-contextualized *Initial profile* with defined *Assigned business context* and calculated *Overall business* context and a set of validation cases. The output is a set of identified message profiles obtained through refinement of an *Initial profile*. The first step in our validation approach is to put the *Initial Profile* to use in a variety of validation cases, both boundary and normal, where business context is adequately and precisely expressed. For each validation case, *Effective business contexts* for each component will be calculated in order to identify irrelevant components. *Effective business context* is calculated as intersection between component's *Overall business context* and business context in which corresponding component is supposed to be used (*Requested business context*). Intersection is conducted for each business context category separately.

In general, there are three possible outcomes: *Effective business context* is equal to null, *Effective business context* is narrower than component's *Overall business context* and *Effective business context* is equal to component's *Overall business context*. *Effective business context* can be equal to null if intersection of the *Overall business context* and *Requested business context* expressions across any of their business context categories gives an empty set. This outcome informs us that the corresponding component or field is not relevant for the *Requested business context*. Other two outcomes inform us that the corresponding component is relevant, but it might undergo additional considerations (because *Effective business context* of the component is narrower).

The refinement of an *Initial profile* results in the identification of new message profiles for a specific set of integration scenarios, where only components that are relevant for the *Requested business contexts* are included. Message profiles' refinement results in recalculation of *Overall business contexts*. New message profiles will have *Assigned business context* equal to *Requested business context*. Figure 2 presents a reusable Contextualization and profile refinement subprocess that can be applied to any domain. Since the calculation of *Overall business context* depends on message component's type it is represented currently as a subprocess and details are neglected.

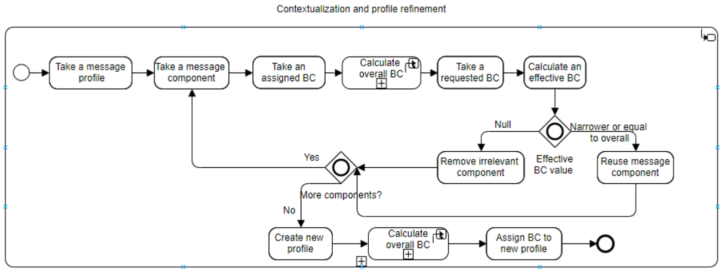


Figure 2 Contextualization and profile refinement process

3.2 Validation of algorithms for message profile generation

A set of refined message profiles, obtained from the previous step, and a set of validation cases provide the input for this validation step. An output is a set of generated new message profiles constructed using E-UCM proposed algorithms. In this validation step, we will take one by one validation case, and compare *Requested business context* with business contexts assigned to existing profiles that we got as the output from the previous validation step. If there is a match, we will reuse it, otherwise, we will employ E-UCM algorithms to obtain components, from the repository of contextualized ones, that are relevant for a new validation case. E-UCM proposes an algorithm with five processing steps. The first step gathers all components from an existing standard component library, while each of the next steps has the goal to filter message components applicable to the *Requested business context* regarding different matching indexes, such as complete or partial matching. Details of this algorithm are out of scope of this paper and will be discussed in our future work.

3.3 Results assessment

To achieve the identified goals, the structure of resulting profiles, both from the first and the second step, will be compared with expected outcomes by consulting human expert or developer. Important remark is that the fifth validation step is conducted under assumption that the output of the fourth step is valid.

4 Validation domain

We demonstrate our validation process using a case study from a Visa application domain. Afterwards, all conclusions will be verified in other domains, such as a Small-and-Medium-Enterprise (SME) and its procure-to-pay scenarios. We have identified three variables in Visa application domain: *Issuance country*, *Visa type* and *Applicant's country*. Moreover, we use these three variables as our business-context categories. Associated message profiles can include different combinations of these three. To simplify the complexity, we have fixed the *Issuance country=New Zealand* and *Visa type =Visitor*, respectively.

Since each country has its own, specific visa policies, we used a two-step process to construct a set of validation cases. First, for *New Zealand*, for *Visitor visa type* we identified a list of eligible countries whose citizens can apply for a visa. Second, for the same issuance country, for the same visa type we have identified a list of visa waiver countries. After these two steps are conducted, we can identify possible visa application submissions.

In the real life, New Zealand has one Visa Application Form (VAF) for Visitor visa type and this VAF, with the same structure, is offered to all applicants, no matter their country. According to our validation methodology setup, this *initial collection of document components* will be analyzed by the service provider, along with the set of New Zealand's specific business rules. As the output, we will get the contextualized *VAF Initial profile*. By studying the structure of visa applications for different visa types and different countries, we have concluded that there is a great chance that irrelevant fields will be proposed to a certain applicant. Korean application form has the field *Kanji Name* that is applicable for a few applicants' countries only. New Zealand's application form has the field *SWITCH card* which is the United Kingdom-specific credit card type, to name a few. These examples clarify the purpose of our first goal - to approve *Effective business context* as enough to identify relevant fields from the *VAF Initial profile*.

The output of this validation step would be a set of *VAF profiles* that would contain only components relevant to the *Requested business contexts*. Consequently, each applicant would get a customized VAF that contains only relevant set of fields, which will ultimately lead to less error-prone application process.

When a new visa application is recorded, first, we will compare *Requested business context* with business context assigned to existing profiles using the E-UCM business-context, matching algorithms. If there is a match, we will reuse it; otherwise, we will employ the E-UCM algorithm to construct a new message profile. That construction is based on relevant, obtained components from the repository of contextualized ones. The structure of resulting *VAF profiles* will be compared with expected outcomes by consulting human expert or developer. These conclusions contribute to the identified validation goals.

5 Discussion and Future Work

So far, first three validation steps have been conducted. Analysis of *Initial profile* and validation cases show that, in most situations, *Effective business context* can be used to identify irrelevant components from existing message profiles. However, there are some boundary scenarios where *Effective business context* is insufficient to make conclusions. We have identified the following types of unsuccessful validation cases. They justify the purpose of our validation process. From those example scenarios, E-UCM validation must be conducted prior to its industry adoption.

Time-dependent - Values assigned to business-context categories denote the current state of an object. We identified scenarios where it was necessary to remember the history, not just the current state. For example, keeping history of applicant's country transitions might be important to decide whether some field is applicable to the integration situation at hand. In this case, *Applicant's country* business-context category would be used to denote transition of the applicant's country, not just his current citizenship. Example transitions include changes in citizenship, holidays, temporary work, and student-exchange programs. In practice, this means that the result of *Effective business context* might vary through time. Hence, considering only one state, without considering history of change, may not be sufficient to communicate needed information for the relevant integration situation.

Unpredictable - There are scenarios that lack the logic needed to determine whether some field is relevant to the applicant or not. For example, field *Passport book number* can often be found in VAFs. The *Passport Book Number* may appear in a passport in addition to the *Passport Number*. Some countries may have this detail in some versions of their passports, while others may not. There is no traceable guideline that will inform us which passport versions contain this detail, so defining *Assigned business context* for such component would be a challenge. Further, it means that calculation of *Effective business context* might be impossible.

Insufficient - There are scenarios where business context does not give us enough information. For example, *Applicant's country* may not be enough because applicant's current residence or applicant's nationality, to name a few, may also affect appearance of some field. This means that the business-context categories that are chosen to describe business context are not enough; and, other relevant categories should be introduced. In practice, *Effective business context* can be calculated, but it can lead to conclusions that are inadequate for the specific integration situation.

If our validation process proves *Effective business context* as insufficient, which we believe is the case, future research will be needed. We plan to consider using new context categories and employing data mining techniques for business context definition to resolve those failing scenarios and enable adequate calculation of *Effective business context*. These approaches may help identify combinations of context categories expected to adequately define a specific business context [4]. Also, there is a possibility for extension of E-UCM methodology to capture history data through business context categories. A possible solution would be introducing state-machine diagrams for business context definition that would enable capturing multiple states (values for specific business context category) through time.

The described on-going validation covers algorithms that can be employed for profiles' generation when there is only one document type considered. Also, E-UCM offers other algorithms that can be applied for profiles' generation when there are two, or more, paired document types. Future research will consider validation of this aspect of E-UCM methodology as well.

ABSTRACT

We demonstrate that single-gated, commercially-sourced, field-effect transistors (FETs) operated with a lock-in amplifier (LIA) under closed-loop control can achieve an average pH resolution of 9×10^{-4}. This performance represents an ≈8-fold improvement over previous FET measurements[1]. The pH sensitivity was found to be ≈56 mV, consistent with the Nernst potential at room temperature. The precision of our approach makes it ideally suited for sensitive bioanalytical measurements. We show that the technique can be applied to measure the therapeutic efficacy of small polypeptide molecules that regulate enzymes implicated in Alzheimer's disease.

KEYWORDS: Single-gate FET, pH measurement, PID controller, Lock-in amplifier, TiN, Sensitivity, Resolution

INTRODUCTION

The demand for high-performance biochemical measurements has dramatically increased to support applications such as biomanufacturing, marine ecology, and DNA sequencers[2]. Electronic measurements that leverage the field-effect are particularly attractive because they allow real-time signal detection without the need for specialized labeling of biomolecules. Their small size, low-cost, and scalability by leveraging foundry processes can allow a straightforward route to commercial deployment. FET-based biochemical measurements can allow the direct measurement of ions concentration (H^+ or OH^-) in a solution when paired with an appropriate sensor. As an example, measurements of pH can allow rapid quantification of enzymatic activity[3]. Improving the resolution of these measurements will allow the sensors to operate under physiological conditions. Therefore, many biochemical research groups are actively developing devices and methods to improve the sensing performance. Here, we demonstrate that commercial single-gate FETs combined with novel signal processing can allow nearly an order of magnitude improvement in pH resolution over conventional FET measurements.

EXPERIMENTAL

A single-gate commercially sourced n-channel FET was soldered onto a printed circuit board. The initial electrical characterization of the devices was performed with a semiconductor parameter analyzer. The pH measurements were performed in a remote configuration by connecting a TiN pH sensor connected to the top-gate metal contact using a shielded coaxial cable. The pH sensor was comprised of tungsten needle coated with 100 nm TiN thin film using sputter deposition[4]. The measurements were performed using two configurations. Figure 1a shows the schematic of single-gate FET measurement with a proportional-integral-derivative (PID) controller, operated in a constant current mode[1]. The PID controller was operated to maintain the drain current, I_D, at a constant value by continuously summing the controller voltage (V_{PID}) with the voltage from the pH sensor (V_{pH}). Figure 1e illustrates the schematic of single-gate FET measurement that combines a PID controller with phase sensitive detection using a lock-in amplifier (LIA). Similar to the measurement setup in Figure 1a, the FET operated in a constant current mode. The LIA allowed improved measurements of weak signals at a specific reference frequency and phase to improve the overall signal-to-noise ratio (SNR).

RESULTS AND DISCUSSION

Figure 1a describes single-gate FET measurement with PID control. The pH sensitivity (dV_{PID}/dpH) was determined to be ≈58.7 mV (R^2=0.99), consistent with the Nernst potential of 59 mV at room temperature from the time-series measurements shown in Figure 1b (*inset*). The time-series measurements also allowed the estimation of the pH resolution to be $\Delta pH = (7.2 \pm 0.3) \times 10^{-3}$ at a bandwidth of 10 Hz. This value was 3 times higher than when the single-gate FET operated in an open-loop without PID controller[1]. The improved pH resolution allowed high-resolution measurements of the effect of a polypeptide therapeutic, p5, on the regulation of the pathological enzyme complex, Cdk5/p25, shown in Figure 1c. Importantly, the measurements were made under physiological conditions with appropriate buffering conditions. As seen from Figure 1d, upon addition of the 24 amino acid polypeptide p5 we observed a significant inhibition in Cdk5/p25 activity as is evident from the change in V_{PID}. The observed p5-based inhibition of Cdk5/p25 activity had a threshold of [p5]=0.7 µM, consistent with literature values[5]. The performance of the measurements were improved by using a LIA in conjunction with PID control. In this configuration, the sensitivity of the FET was ≈56 mV (R^2=0.99) as seen from Figure 1f. The average resolution of FET extracted from the time-series measurements in Figure 1g improved 8-fold to an average of 9 x10^{-4} (Figure 1h). This improved resolution will allow enzymatic measurements at sub-physiological concentrations, allowing new tools for drug discovery and diagnostics of neurological disease.

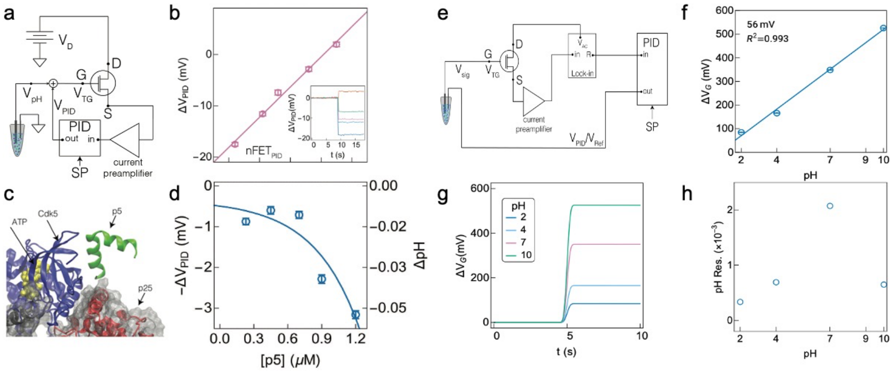

Figure 1: (a) Biochemical measurement using FET with PID control. (b) Response of ΔV_{PID} under different pH conditions. (inset) Time-series data as a function of pH. (c) p5 interactions with the Cdk5/p25 complex. (d) Response of ΔV_{PID} as a function of p5 concentration ([p5]). (e) Schematic of oprating a FET with a LIA and PID controller to improve measurement resolution. (f) Response of ΔV_{PID} uder different pH conditions. (g) Time-series under different pH condition relative to a reference potential. (h) pH resolution under a wide range of pH conditions.

CONCLUSION

We show that FET-based biochemical measurements can be substantially improved by combining commercially-sourced devices with PID and LIA techniques. The observed pH resolution was found to be ≈8-fold higher than conventional measurements where the FET was operated in an open-loop. The substantially improved resolution demonstrated by our results can lead to new tools for robust therapeutic development and diagnostic tools for use in neurological disease research.

"It's the Company, the Government, You and I": User Perceptions of Responsibility for Smart Home Privacy and Security*

Julie Haney$^{\alpha}$, Yasemin Acar$^{\alpha\beta}$, and Susanne Furman$^{\alpha}$,

Abstract

Smart home technology may expose adopters to increased risk to network security, information privacy, and physical safety. However, users may lack understanding of the privacy and security implications. Additionally, manufacturers often fail to provide transparency and configuration options, and few government-provided guidelines have yet to be widely adopted. This results in little meaningful mitigation action to protect users' security and privacy. But how can this situation be improved and by whom? It is currently unclear where *perceived responsibility* for smart home privacy and security lies. To address this gap, we conducted an in-depth interview study of 40 smart home adopters to explore where they assign responsibility and how their perceptions of responsibility relate to their concerns and mitigations. Results reveal that participants' perceptions of responsibility reflect an interdependent relationship between consumers, manufacturers, and third parties such as the government. However, perceived breakdowns and gaps in the relationship result in users being concerned about their security and privacy. Based on our results, we suggest ways in which these actors can address gaps and better support each other.

1 Introduction

While early adopters of IoT smart home technology have typically been more technically savvy, smart home devices are increasingly being purchased by non-technical users [31] who may not understand the technology's privacy and security implications. Within the current dynamic threat and technology environment, the uptick of smart home technology adoption may expose users to increased risks to their network security, privacy of their information, and quite possibly their physical safety [26]. In addition, global surveys have identified that security and privacy are significant concerns among both IoT adopters and non-adopters [9, 49], and that consumers would like more information about security and privacy when purchasing devices [33]. Therefore, it is imperative that smart home consumers be empowered to protect the security and privacy of their devices while still being able to enjoy the benefits of the technology. This would result in consumers feeling more comfortable with their devices and encourage additional adoption among those who currently have concerns.

Unfortunately, smart home devices may fail to provide transparency of privacy and security protections and may lack adequate security and privacy controls [24], while manufacturers may be unsure as how best to implement these [25]. Generally, third-party guidance on desirable privacy and security controls has not yet entirely converged and is not currently widely adopted since many of these efforts are nascent and reflect in-progress work.[1] In combination with users' lack of in-depth understanding of smart home device technology, privacy, and security, the result is limited meaningful mitigation actions being taken to protect consumer security and privacy [1, 32, 42, 49, 66]. For example, some users leave the room to have sensitive conversations out of earshot of the technology, unplug devices, or tape over cameras.

In order to create meaningful and effective privacy and security controls, interfaces, guidelines, and other resources to support users, it is important to understand who users believe are the responsible parties for privacy and security. Responsibility can be viewed as being active: "the state or fact of having a duty to deal with something."[2] A better understanding of perceptions of responsibility and framing within the context of duty/obligation might shed further light on what actions users are willing and able to take on their own versus

Haney, Julie; Acar, Yasemin; Furman, Susanne M. "It's the Company, the Government, You and I: User Perceptions of Responsibility for Smart Home Privacy and Security." Paper presented at USENIX Security 2021, Vancouver, CA. August 11, 2021 - August 13, 2021.

which functions they feel are the duty of or would be better suited to others. Knowing the will of the consumer may then put more pressure on others to take action. We also consider that responsibility may be perceived in a more negative light as "the state or fact of being accountable or to blame for something."[3] Viewing responsibility through this lens may reveal areas of discomfort. These areas of discomfort could illuminate gaps that need to be filled in order to provide a more private and secure smart home experience and make adoption more palatable. However, it is currently unclear where users think responsibility for smart home privacy and security lie.

To address this gap, we uncovered perceptions of responsibility during a semi-structured interview study of 40 smart home users by seeking to answer two research questions:

RQ1: Who do users believe is responsible for the privacy and security of their smart home devices?

RQ2: What is the relationship, if any, between perceptions of responsibility, concern, and taking mitigative action?

Our study revealed that user concerns about the possibility of undesirable security and privacy situations (e.g., as found in [56,66]) can stem from the perception of insufficient controls on manufacturers and inadequate user support. We found that users primarily assign privacy and security responsibility to three actors or a combination of those - smart home owners (personal responsibility), manufacturers, and government/regulatory bodies - with manufacturers being most frequently held responsible. Responsibility is often viewed as being an interdependent relationship between those actors in the pursuit of robust smart home privacy and security. Part of this relationship relies on actors taking voluntary action (e.g., users configuring security options) and supporting the others in their goals (e.g., a manufacturer providing security tips to consumers). However, when a user is either unwilling or unable to take necessary action, participants desired better information and built-in protection by manufacturers, facilitated by the government. When manufacturers do not use privacy and security standards or support privacy/security controls, standards or guidance can help them target a privacy/security baseline, with "checks and balances" (e.g., regulations, certification) enforcing action.

Our study makes several contributions:

- We provide novel insight into where smart home users place responsibility for the privacy and security of their devices and how those perceptions may relate to concerns and implementation of mitigations. We identify a theme of an interdependent relationship between users, manufacturers, and the government/third parties.
- Our findings extend prior literature related to perceptions of privacy/security responsibility for conventional technology into the smart home domain.
- We give practical guidance for how users, manufacturers, and government/third party organizations might support each other by filling current gaps.
- We suggest future research directions to address how best to enhance the interdependent relationship necessary for smart home privacy and security.

2 Background

To help frame our smart home privacy and security study, we describe prior research and background information related to privacy/security perceptions, smart home privacy/security, responsibility, and third-party efforts.

2.1 Related Work

2.1.1 Privacy and Security Perceptions

Prior research on privacy perceptions can serve as a foundation when exploring user beliefs and opinions of smart home privacy. Researchers have suggested the existence of a "privacy paradox" [2,7] in which, although users often state that they care about privacy, they may fail to mitigate privacy risks and choose to use privacy-violating technology. Users may also willingly or reluctantly trade privacy and security for convenience and perceived benefits [2,47,48]. One study suggests that users value privacy more when they have it than when they do not, i.e., efforts to re-establish privacy may be less spirited than staying private in the first place [3]. Default settings and hard-to-navigate configuration options also contribute to behavior that does not preserve privacy [46]. Furthermore, privacy policies are often mistakenly assumed to contain the promise to respect user privacy or understood as implicit recommendations [41]. The concept of "privacy resignation" in response to repeated privacy violations has also been identified [52].

We also turn to prior literature on perceptions and security mitigations employed with traditional information technology (IT) and online applications as a potential basis of comparison. Typical, non-technical end users rarely view security as a primary goal when interacting with technology, often lack security knowledge, and have low self-efficacy when it comes to taking security-related action [54]. This is opposed to security experts who have very different ideas of which actions help with online security [39,58]. Wash and Rader [62] surveyed U.S. internet users and found that those with weakly held beliefs about viruses and hackers were the least likely to take protective actions. Stanton et al. [54] discussed "security fatigue," a weariness towards security when it becomes too burdensome. Herley [36] similarly claimed that users may ignore security advice due to being overwhelmed by the sheer volume of advice, viewing security as being a high cost to themselves, and because they perceive security actions to be

[3] Ibid.

inadequate in the face of myriad threats. West et al. [63] examined why people make poor security decisions, finding that the tendency to satisfice, cognitive biases, time pressures, and inattentional obliviousness contribute to this.

In this paper, we explore whether users' general views of privacy and security found in the literature are reflected in the perceptions of privacy/security responsibility for a specific technology (smart homes).

2.1.2 Smart Home Security and Privacy

In recent years, many researchers have examined smart home privacy and security from a user perspective. In this section, we highlight several relevant efforts that identified user perceptions and experiences that can be confirmed or extended in our own study. Early work pointed out a lack of transparent privacy controls in smart home devices [61]. A subsequent study identified additional challenges and tensions in smart home hubs, including security and privacy issues [44].

Research and industry surveys have shown that security and privacy concerns can be barriers to adoption of smart home devices [11, 21, 57, 64]. For example, Lau et al. [42] found that some non-users are privacy conscious and distrustful of privacy and security of smart home devices and their manufacturers, and that smart home devices generally cross these non-users' privacy thresholds.

Even adopters have privacy and security concerns. For example, Sanguinetti et al. [51] found that owners of smart home devices were just as concerned as those who chose not to purchase the devices. Malkin et al. [43] observed that users express concern about smart home speaker recordings and reject the use or sharing of recordings for purposes other than voice commands because of a violation of contextual integrity (i.e., not adhering to user expectations of how data flows and is used for a specific service). Users also have complex, but incomplete threat models, which include a general sense of being surveilled by manufacturers or the government and the possibility of being attacked by hackers, while lacking awareness of botnets and the sale of inferred data [1, 21, 67]. Users were generally more concerned when the privacy of children was at stake [4, 43].

Smart home users also express that they lack information to evaluate device privacy and security features. Emami-Naeini et al. [21] found that, although participants ranked privacy and security as important factors when purchasing IoT devices, information was difficult to find. This was also confirmed by researchers at the U.S. National Institute of Standards and Technology (NIST) who found that open-source security information for smart home devices often lacked specificity or was unavailable [24].

Multiple studies found a lack of substantive mitigation actions to address security and privacy concerns for various reasons, including lack of agency, lack of option availability, and trust in other entities to take action [1, 32, 42, 56, 66]. Adopters may also fail to take action because they typically have higher tolerances for privacy violations, willingly or reluctantly accept the trade-off in exchange for the convenience and utility offered by smart home devices, and often express that they have "nothing to hide" [42, 56].

Other researchers identified privacy and security options desired by users. In a co-design exercise, Yao et al. [65] found that data localization and a private mode were among desired items for privacy protections. Haney et al. [32] identified wishlists for both privacy and security mitigations, which included more transparency about data collection and use and easy-to-configure options. However, availability of options must be balanced with usability, as expressed by Colnago et al. [12] who found that, while participants desire more control over their data and privacy settings, they are concerned about being overloaded with configuration options and "notification overload."

Several studies investigated the use of smart home devices in multi-user homes, finding power imbalances in that secondary users often have less agency in purchase and configuration and use decisions, which creates a potential for abuse [28, 42, 66]. These findings are corroborated by Huang et al. [37], who observed that users of multi-user devices adopt all-or-nothing mitigation strategies similar to mitigations against external actors, and desire more control options over their data. Tabassum et al. [57] found that users desire sharing options with people outside their home to increase their security. Based on a 2018 online study, He et al. suggested that smart homes need granular configuration options based less on device type and more on user type (e.g., neighbor vs. spouse) [35]. On the manufacturer side, Chalhoub et al. interviewed smart camera designers, and found that user experience (UX) is considered important in communicating privacy configurations, but is under-utilized when it comes to security [10]. While prior studies identified smart home privacy and security concerns and mitigations, to the best of our knowledge, none explored *perceptions of responsibility* in detail. This is a gap our research hopes to address.

2.1.3 Perceptions of Responsibility

As a possible comparison point to our findings related to responsibility of *smart home* security and privacy, we look to prior work addressing general security and privacy responsibility. Past research has shown that consumers often feel that security is the responsibility of a third party (for instance, the government, vendors, or IT professionals) and may delegate security decisions because they feel they lack knowledge and technical skills to take action [27, 30]. From a privacy perspective, Renaud at al. [50] explored why end-to-end email encryption solutions have not been widely adopted. They found that, although participants were privacy aware, they were often not overly concerned enough to take additional action, partially because they abdicated responsibility to service providers that they felt were better equipped. Bandyopadhyay [5] proposed a theoretical framework to explore factors influencing privacy and security concerns of consumers who use the internet. He suggested that there is a consumer trust problem which necessitates increased assurance that security and privacy are being protected. Therefore, the responsibility of assurance was viewed as three-fold, falling on governments, vendors, and, to a lesser degree, consumers. Dogruel and Joeckel [19] interviewed U.S. and German smartphone users and found that most felt the responsibility for privacy protection lies primarily in their own hands. While some participants assigned third party responsibility to government and commercial entities, most believed both carry at least some responsibility for privacy. German participants were much more likely to desire government intervention in the case of privacy, for example by setting minimum privacy standards and establishing legal frameworks. U.S. participants, however, were more likely to place accountability with commercial entities.

A global Mozilla survey of close to 190,000 people asked "Who is most responsible for protecting the online safety, privacy, and security of the connected apps and devices you own?" [9]. Thirty-four percent of respondents placed responsibility on the makers of apps and devices, with roughly the same percentage saying that it was up to them. Twenty percent selected government. The survey also revealed variances in responsibility perceptions among different countries. For example, respondents from Mexico and the U.S. were much more likely to claim personal responsibility (41% and 43%) and less likely to put most responsibility on the government (13% and 12%) as compared to those from other countries.

While these prior studies examined perceptions of responsibility, none focused on smart home devices. It is unclear as to whether responsibility for smart home devices is viewed differently than traditional online or information technology, potentially because of inherently unique characteristics of the devices, such as them being always on and collecting data within highly personal and private spaces. Our study begins to address this unknown.

2.2 Third-Party Efforts

Government, regulatory bodies, non-profits, and other certification authorities have demonstrated initiative in protecting consumers' digital privacy and security, with differing levels of success. Recent developments in privacy-protecting laws reflect that some responsibility for keeping user data private is being shifted from users to corporations via government intervention. For example, the European Union (EU) enacted the General Data Protection Regulation (GDPR) [60], which provides individuals with rights related to the collection and storage of their personal data and requires that developers implement privacy by design. In the U.S., the state of California recently implemented the California Consumer Privacy Act (CCPA) [55], a statute that addresses online privacy and states that a consumer has rights regarding transparency of data collection and the right to request that their data not be sold and be deleted. Reactions and implementations for these regulations have been mixed since privacy may be viewed as a conflict between allowing the free market to trade data as a commodity and empowering end users to control their own data. With respect to GDPR, while some vendors have added configuration options, many are still difficult to navigate for average users. Other vendors block access to their services when accessed from within the EU to avoid having to comply [16].

With respect to IoT, several industry, government, and non-profit organizations have issued voluntary security guidance for manufacturers, most of which is too new to have been widely adopted. Recent government guidance includes NIST's *Foundational Cybersecurity Activities for IoT Device Manufacturers* [23] in the U.S., the European Union Agency for Cybersecurity (ENISA)'s *Good Practices for Security of IoT - Secure Software Development Lifecycle* [22], and the United Kingdom (U.K.)'s *Code of Practice for Security of IoT* [17]. Industry consensus groups have also provided privacy and security baseline resources for manufacturers, for example, the Internet of Things Privacy Forum [38], IoT Security Foundation [40], and the Council to Secure the Digital Economy [14]

Recently, there has also been considerable attention and advocacy for IoT product security and privacy labels as both an aid to consumers and way to increase manufacturer transparency and accountability [18, 33, 53]. For example, the Underwriters Laboratory (UL) now provides an IoT security rating backed by a standardized process to evaluate security aspects of smart products [59] and the wireless industry association implemented the CTIA IoT Cybersecurity Certification Program [15]. Carnegie Mellon University proposed IoT security and privacy labels based on studies of consumers and experts that suggested that labels could aid in consumer purchase decisions while holding manufacturers accountable for product privacy and security implementations [20, 21].

3 Methods

Between February and June of 2019, we conducted an exploratory, semi-structured interview study of 40 smart home users to understand their perceptions of and experiences with the devices. This paper describes a subset of collected data which is novel to prior smart home research and centered on user perceptions of privacy and security *responsibility*. The study was approved by our institution's research protections office. Prior to data collection, participants were informed of the study purpose and how their data would be protected. Data were recorded without personal identifiers (using generic identifiers such as P10_A) and not linked back to individuals.

3.1 Participant Recruitment & Demographics

To be eligible for the study, participants had to be adult users of smart home devices. We hired a consumer research company to recruit general public participants, who were compensated with a $75 prepaid card. Prospective participants were members of the consumer research company's research panel, a database comprised of over 6,000 participants located in the Washington, D.C. metropolitan area in the U.S. who had agreed to be contacted about consumer research opportunities. The recruitment company emailed a subset of 444 members of the research panel, selected for demographic diversity. They also recruited via social media posts and requested direct referrals.

To determine eligibility, those interested in the study first completed an online screening survey about their smart home devices, their role with the devices (e.g., administrator, user), professional background, basic demographic information (age, gender), and number of household members. After reviewing the screening information, we purposefully selected participants for interviews if they had two or more different smart home devices for which they were an active user (as opposed to being a bystander). We did this to engage with users who actually had *smart homes*, which we define as using multiple, diverse smart home devices, as opposed to those with only one individual smart home device. Smart TVs were not included in this initial count (but were addressed in the interviews) because most TVs now come with smart functionality and do not necessarily represent a deliberate choice to purchase a smart device.

We ultimately selected and interviewed 41 individuals. Despite a review of the screening questionnaire, during the interview, one participant (P5) was found not to have any smart home devices, so was removed from the study.

We defined smart home devices as being networked devices in the following categories, which were developed after consultation with IoT experts in our institution and used in the screening survey to focus responses. Number of participants with each type of device is indicated in parentheses.

- **Smart security (n=35):** e.g., security cameras, motion detectors, door locks
- **Smart entertainment (n=38):** e.g., smart televisions, speakers, streaming devices, connected media systems
- **Home environment (n=38):** e.g., smart plugs, energy consumption monitors, lighting, thermostats, smoke and air quality sensors
- **Smart appliances (n=15):** e.g., smart refrigerators, coffee pots, ovens, washing machines
- **Virtual assistants (n=36):** e.g., voice-controlled devices such as Amazon Echo/Alexa and Google Home

Initially, although not a major focus of this project, we also wanted to examine potential differences between smart home users living in the same household. Therefore, the survey was administered over the phone to another household member if interested. This recruitment only yielded four additional participants, so we ultimately decided not to pursue this vein of comparison. Since few participants were recruited in this way, it is unlikely that their opinions caused undue data bias, especially since most had different perspectives from their housemates.

Of the 40 participants, 32 had installed and administered the devices (indicated with an A after the participant ID), and eight were non-administrative users of the devices (indicated with a U). Twenty-two (55%) were male and 18 (45%) were female. The majority (70%) were between the ages of 30 and 49. Participants were highly educated with 18 (45%) having a master's degree or above and another 20 (50%) with a bachelor's degree. Thirty-four participants lived in multi-person households, with four couples among the participants (interviewed individually). All but one participant had three or more individual smart home devices, with 34 having devices in three or more categories. Refer to Appendix A for detailed participant demographics.

3.2 Data Collection

In addition to the screening survey responses, our data consisted of transcripts from 40 in-person, semi-structured interviews lasting on average 41 minutes. All interviews were audio recorded and then transcribed by a third party service provider. We chose semi-structured interviews over other methods, such as surveys, due to the exploratory nature of our investigation. Interviews afforded a greater richness of data, the ability to ask follow-up questions to more deeply explore participant responses, and the opportunity for participants to add other relevant information not explicitly targeted [13].

To develop our interview protocol, we conducted an extensive review of prior literature and market research up through 2018 to understand recent research, trends, and the state-of-the-art in smart home technologies. We also examined existing smart home devices ourselves to understand their usage. Based on these investigations, we crafted questions to address research gaps and explore multiple aspects of smart home device ownership and usage, including privacy and security. We asked an IoT domain expert to review our interview questions to ensure we were using correct terminology and considering appropriate facets of smart home ownership and use. We then piloted the interview protocol with four smart home owners from our institution (two device administrators and two non-administrators/users) to determine the face validity of questions and language. Pilot participants were not compensated. We made minor adjustments to the interview instrument based on feedback from the content expert and the pilot experience. Because modifications were only minor to improve clarity and comprehension, the pilot interviews were included in the final data set.

Interview questions addressed several areas in the following order: understanding of smart home terminology; purchase decision process; general use; general concerns, likes, and dislikes; installation and maintenance; privacy; security; and safety. Interview questions can be found in Appendix B. During the interviews, we differentiated between privacy and security by giving the participants definitions and examples of what each term meant. Security concerns relate to safeguarding of data/devices while privacy is safeguarding user identity (which can be gleaned from certain types of data). In this paper, we focus only on collected data pertaining to privacy and security *responsibility* since this topic has not yet been explored in detail by other researchers. Note that participants may have mentioned privacy and security responsibility concepts throughout the interview (for example, when asked if they had any hesitations prior to device purchase), not just during the designated privacy and security sections.

We interviewed until we reached two conditions. First, we monitored for theoretical saturation, the point at which no new ideas emerge from the data [13]. We also wanted to ensure we had a participant sample with a diverse set of smart home devices to account for potentially different experiences depending on the types of devices.

3.3 Data Analysis

Data analysis included both deductive and inductive coding practices, which allowed for an emergence of core concepts. Analysis of the interview transcripts began with the development of an *a priori* code list based on the research questions. Using the initial code list, each of the three research team members individually coded a subset of four interviews (4936 lines, 214 minutes of audio), then met as a group to discuss code application and develop a codebook. The final codebook addressed all data concepts (e.g., purchase, installation, usability, privacy, security, safety). All codes were "operationalized," which involves formally defining each code to ensure understanding among all coders. The codebook for privacy and security concepts informing this paper are included in Appendix C.

Using the codebook, we then coded the remaining interviews independently, with each transcript coded by two researchers and one primary coder (the first author) coding all interviews. Each pair of coders then examined and resolved differences in code application. In accordance with the recommendation of qualitative methodologists (e.g., [6, 45]), we focused not just on agreement but also on how and why disagreements in coding arose and the insights afforded by subsequent discussions. This focus was especially valuable in pursuing alternate interpretations of the data given the diverse perspectives of our multidisciplinary research team. When disagreement occurred, we discussed as a group to reach consensus. In rare cases where agreement could not be reached, the primary coder made the final decision.

Throughout the data analysis phase, we progressed to the recognition of relationships among the codes and examined patterns and categories. We met regularly as group to discuss our interpretations and emergent ideas. This process allowed for the development of central concepts, including the topic of this paper: perceptions of privacy and security responsibility as an interdependent relationship.

3.4 Limitations

As with any interview study, participant responses are subject to recall, self-report, and social desirability biases. In addition, our study only captures perceptions of smart home adopters of multiple devices, so does not adequately capture those of limited adopters or non-adopters. The participants, who were generally highly educated professionals in a high-income metropolitan area, may not be fully representative of the smart home user population in the U.S. However, our sample appears to mirror smart home adopters characterized in prior industry surveys [29]. We also acknowledge that U.S. smart home users may have different privacy and security attitudes from those in other countries, for example, due to political or cultural factors related to privacy expectations and tolerance. However, since other regions in the world, such as Europe, lag behind North America in terms of smart home market penetration and maturity [8], our findings may identify potential areas that other countries may want to consider as adoption increases. These limitations could be addressed with replication of this study in other countries or a global quantitative survey informed by the results of our study.

Since the smaller sample common to qualitative research does not lend itself to generalizability, we did not perform analysis to identify differences based on demographics (e.g., gender, age). We also did not differentiate responsibility based on device type but rather asked about general perceptions. We plan to explore the effect of demographic characteristics as well as per-device differences in a follow-up quantitative survey administered to a larger sample.

4 Results

In this section, we report results about perceived responsibility for smart home privacy and security. Example quotes from participants are provided throughout. Counts are provided in some cases, not as an attempt to distill our qualitative data to quantitative measures, but rather to illustrate weight or unique cases.

We first provide a brief overview of the privacy and security concerns and mitigations voiced by participants during the interviews. Although these concerns and mitigation strategies are not novel as compared to those identified in several of the studies cited in Section 2.1.2, we summarize our own

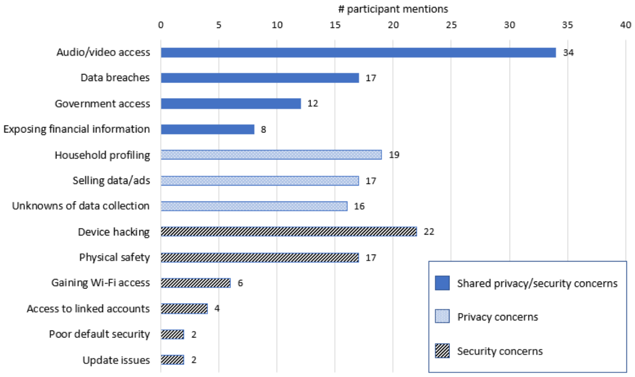

Figure 1: Participant concerns.

findings here in order to contextualize the focus of the paper: the assignment of *responsibility* for security and privacy.

4.1 Concerns and Mitigations

Early in the interview, we asked participants a general question, “What concerns, if any, do you have about the devices?” We later asked, “What are your concerns, if any, about how information is collected, stored, and used and who can see that information?" and “What are your concerns, if any, about the security of your devices?” In some cases, participants were personally concerned about privacy or security (28 for privacy and 26 for security) but to varying degrees. Several participants mentioned concerns that were expressed by others (e.g., family members, friends, media) but not personally held (4 for privacy, 6 for security). The most frequently mentioned concerns for both privacy and security in our study are summarized in Figure 1.

We also found evidence of lack of concern. In 24 cases, participants did not value the information collected by smart home devices, believing they would not be a worthwhile target. Therefore, they felt that there was a low probability that their devices would be hacked (5 participants). In addition, unconcerned participants often demonstrated privacy resignation [42] in which users believe that their data is already publicly available via other means and that there is nothing they can do about it (8 participants).

Privacy and security mitigations enumerated by participants were often simplistic or non-technical. Examples of simplistic mitigations include: setting a device app password, password-protecting the Wi-Fi network, and disabling the option to order items via virtual assistants. Non-technical mitigations included: not having sensitive conversations near virtual assistants, not placing devices with cameras or microphones in private rooms of the house (like bedrooms), or unplugging the device when not in use. Figure 2 shows the most frequently-

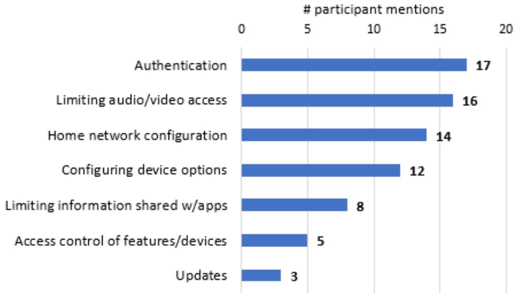

Figure 2: Shared privacy and security mitigations.

mentioned mitigations. Note that all of these were discussed at least once within both the privacy and security contexts.

We observed that being concerned about smart home privacy and security did not always translate into action. This inaction was due to several reasons. First, smart home device ownership was often viewed as a conscious choice to accept risks in exchange for perceived benefits, described as *“willful ignorance”* by P1_A. This same participant commented, *“It’s a trade-off. . . I know that it’s collecting personal data,. . . and I know there’s the potential of a security leak, but yet, I like having the convenience of having those things” (P1_A)*. Second, users may not be aware of available options or were not given options by the manufacturer. For example, one smart home user commented, *“I’ve been given very little methods to alleviate the concerns. Usually the description of the controls aren’t specific enough for me to alleviate my concerns” (P13_A)*. In addition, some do not have enough knowledge to be able to select and implement mitigations, especially security ones (8 participants). A participant said, *“I know it is password protected. That’s as far as my knowledge. I don’t know more than that. I’m not certified with cybersecurity” (P41_U)*. As with concerns, we also observed the influence of resignation as well as loss of control and fatalism, which are characteristics of security fatigue. One participant exhibited this resignation when he said, *“I just kind of assume if it exists, there’s a way to hack into it” (P18_A)*.

4.2 Responsibility

Participants were asked “Who do you think is responsible for protecting the privacy of information collected by your smart home devices?” and, later in the interview, “Who do you think is responsible for the security of your devices?” Participants may have also discussed concepts related to responsibility in response to other questions, e.g., those pertaining to concerns and “What kind of things would you like to be able to do with your devices, but haven’t, don’t know how, or are not sure that you can?” (see Appendix B for contributing questions in bold).

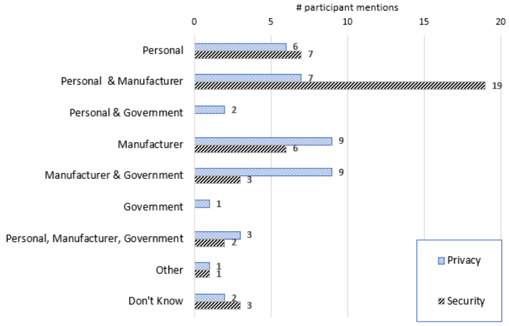

Figure 3: Perceptions of responsibility for smart home privacy and security.

Most responses fell into one of three categories or a combination of those: personal responsibility (smart home owners), device manufacturers, and government/regulatory bodies (see Figure 3). Two participants did not have an answer for privacy, and three did not have a response for security. One owner of a smart thermostat thought the power company was responsible for privacy, and one participant said internet service providers were partially responsible for security.

4.2.1 Personal Responsibility

Eighteen participants claimed at least partial personal responsibility for **privacy** (6 of those with sole responsibility). For example, P1_A expressed, *"It starts with us. We're bringing this device into our home."* Twenty-eight participants claimed some personal responsibility for **security** (7 with sole responsibility): *"It's on you to either put extra restrictions in place or just be okay with the fact that [a breach] is going to happen" (P8_A)*. Note that several participants placed responsibility on a housemate or spouse who was more involved with the devices. However, we considered personal responsibility as being that of smart home owners in general.

Eleven participants viewed personal responsibility as holding themselves accountable for accepting risks. For instance, personal privacy responsibility was often described as being implicit with device purchase and continued use. When asked who was responsible for privacy, a participant said:

> *"The owners. In my opinion, if you don't want stuff exposed, you shouldn't have those devices in your house to begin with. You're accepting a risk by taking those on in your home" (P35_A).*

Another commented, *"You buy the device and realize what you're getting yourself into… Buyer beware. Operate at your own risk" (P26_A).*

We also observed that viewing responsibility as personal could also be a justification for inaction in taking mitigation actions, even if privacy and security were concerns. In these cases, participants accepted personal blame for their own perceived deficiencies, such as not looking into what options were available, having incomplete threat models, or not taking the time to learn more about how to secure their devices or home networks. For example, P14_U believed device owners are to blame if they do not adequately secure their devices: *"I think that's probably a shared thing… A lot of people don't put secure passwords and stuff on their systems… People don't use the tools that are out there, like VPNs,… I think that's all responsibility of you."* Although P8_A believed he is solely accountable for the security of his smart home devices, he did not take many substantive mitigation actions because *"I'm not going to educate myself on network security… This stuff is not my forte. I'm very accepting to the fact that it is what it is."*

Conversely, participants who approached personal responsibility as an active, obligatory role were those who implemented mitigations above and beyond setting a password at installation and incorporated security and privacy considerations into their purchase decision-making process. Regarding the obligation to configure privacy settings, a smart home owner remarked, *"I feel like the default is always full access, so you have to really look for and pursue stricter settings" (P18_A)*. Especially in the case of security, responsibility was viewed as requiring some effort on behalf of users. For example, P15_A addressed most of his concerns by doing extensive research on the devices prior to purchase. He then only selected those he felt adequately implemented security and privacy protections, including *"good authentication, encryption, secure protocols being used."*

Some participants did not mention taking personal responsibility for smart home privacy and security (22 for privacy, 12 for security). We note that most of these participants did not explicitly deny responsibility, but rather assigned responsibility to other actors when asked. An older smart home user was one of the few to overtly abdicate responsibility when she said, *"I'll leave that to the next generation" (P38_U).*

The study results also revealed a disconnect between being concerned and accepting responsibility. Among those participants who accepted personal responsibility, the majority did express personal concern (13 concerned vs. 5 unconcerned for privacy and 20 concerned vs. 9 unconcerned for security). However, privacy concern did not necessarily mean that participants accepted responsibility (15 concerned did not accept responsibility for privacy vs. 13 that did). Being concerned with security was more likely to be associated with personal responsibility (20 accepting responsibility and 6 who did not).

4.2.2 Manufacturer Responsibility

As the most frequent response, 28 participants believed manufacturers share some responsibility for **privacy**, with nine of those assigning sole responsibility to manufacturers. For example, a participant remarked, *"Any single person who was involved in the creation of the product is responsible for what it does, including collecting information" (P30_U)*. Another felt that manufacturers *"have a responsibility to make sure that information is where it's getting sent to, who's getting it, and that it's safe, and it's not going to get taken away or stolen" (P32_A)*.

Thirty participants said manufacturers have at least some responsibility for **security** (only 6 for solely responsible). For instance, one participant who thought manufacturers are solely responsible said, *"I would say the manufacturer. I don't think they can expect all of us to be cybersecurity experts. That's why we bought the product" (P29_A)*. Another commented,

> *"[Manufacturers] are the prime people who are responsible for things they're making because we're not putting all the time, and energy, and money on building that stuff. So, we really don't know what is inside of this" (P9_A).*

The data revealed an attitude that manufacturers have an obligation to the buyers of their products to adequately protect their privacy and security, with this being part of an unstated manufacturer-consumer contract put in place at time of device purchase. One participant remarked, *"They need to do everything [since they are] taking so much money for all that" (P9_A)*. Another commented, *"If I'm going to buy your product, I think you owe it to me to not abuse that. I did give you money for it" (P29_A)*.

However, there were differing levels of confidence in whether manufacturers could adequately uphold this obligation. Participants who put their trust in manufacturers to protect their privacy and security often did so based on a perceived competence due to company size or reputation. For example, a user trusted larger companies to build secure devices: *"Maybe that's why I'm feeling a little more secure than not because I'm like, oh, this is a big company. If something happens, hopefully, they have the money to figure it out" (P6_U)*. One participant felt that it was beneficial for manufacturers to implement strong privacy and security measures because *"If they have a bunch of massive security breaches, people are going to stop buying their products. So our interests are aligned there" (P17_A)*.

Even though they placed responsibility on manufacturers, others expressed varying levels of distrust. Only 11 participants relied on manufacturer-supplied information when researching potential products, while 34 looked at other, often subjective online sources, such as customer reviews. While 10 participants believed data was sent to manufacturers for beneficial reasons (e.g., product improvement and tailoring to consumer habits), others felt that they were at the mercy of manufacturers who do not have consumers' best interests in mind, for example, believing manufacturers were purposely vague in terms and conditions statements so that consumer data could be more easily monetized. When asked if he ever reads any of the privacy agreements, P10_A said, *"I don't have much trust in what companies say they collect and don't collect. I think they collect what they can and use it."* Others felt that manufacturers were powerless to prevent data breaches and device compromise when up against a determined adversary. For example, a participant commented, *"I would say that I think they try to do a good job of being secure, but we see hacks all the time... I think that sooner or later they will get hacked" (P26_A)*.

In all of these cases, participants felt that manufacturers *should* have a duty to implement adequate security and privacy mechanisms but were not certain they *would* or *could*. However, manufacturers were still not exempt from being accountable or blamed if something should go wrong.

4.2.3 Government Responsibility

Fifteen participants thought that the government or some regulatory body was at least partially responsible for smart home **privacy**, with only one viewing government as being solely responsible. In general, participants viewed the government as having an obligation to protect its people from harm from security and privacy breaches. For example, a participant saw government regulation of smart home privacy as being associated with consumer safety:

> *"I think the other half of the responsibility goes on the government to protect your citizens... There's other safety precautions put in other industries. I don't see why that shouldn't be something applied to this industry as well" (P29_A).*

P31_A did not think the government would do the best job, but felt regulation had some benefit:

> *"We've got to do something to protect people's information, or at least make them more aware of what exactly is being utilized and sold, and having opportunities to opt-out, taking at least some steps."*

The assignment of government privacy responsibility was at times ironic because several participants also expressed that they believed the government was performing surveillance of citizens via smart home devices. Potential surveillance bothered some, but others were not concerned because they felt they were not doing anything illegal or of interest to the government. Even though P26_A thought the government was partially responsible for privacy, he remarked:

> *"I'd like to regulate our government, but that's not gonna happen. Right? I don't mean to sound so flippant, but I wish they would stop watching and collecting data, but that's not going to happen. It is what it is."*

Interestingly, while over a third of participants allocated at least partial responsibility for privacy on the government, there was less expectation that the government should regulate **security** (5 participants, none holding the government solely responsible). Among those five, P32_A thought the government's duty was in *"setting guidelines, enforcing them."*

P7_A felt that a regulator's role was not about constant auditing but rather holding manufacturers responsible if they were to *"mess up"* with respect to security.

4.2.4 Shared Responsibility

Responsibility for **privacy** was often viewed as being shared by some combination of consumers, manufacturers, and government (21 participants). For instance, one participant thought both she and the manufacturer are obligated:

> *"I think I'm partially responsible in making sure that I don't put too much out there. But I think that the companies that control and own these, they need to make sure that people's information is not being put out there. Because at the end of the day, it affects us" (P37_A).*

Twenty-four thought responsibility for **security** was shared, mostly between user and manufacturer. A tech-savvy participant talked about this mutual obligation:

> *"If you have stronger security features that the device offers the user doesn't use, that's kind of the user's fault. If it doesn't offer certain level of security, that's the manufacturer's fault" (P10_A).*

We observed that participants perceived each actor (consumer, manufacturer, government) as having a role in filling in the gaps when other parties cannot or choose not to enact strong privacy and security measures. In the remainder of this section, we present the different combinations of responsible actors discussed by participants and how they viewed each actor as balancing the others.

Personal and Manufacturer. Most responses about shared responsibility for **security** were between device owners and manufacturers (19 participants), with much fewer (7) for **privacy**. From our analysis, we observe that the difference may be due to a recognition that both the device itself and the environment in which it is placed need to be secured, with only users themselves having the ability to secure the home network and set strong passwords on device companion apps. However, some acceptance of personal responsibility and mitigation implementation did not abdicate manufacturers, since there are aspects of security and privacy that users will never have control over (e.g., secure code, security of cloud services, protection of stored data and data in transit). Therefore, responsibility was often viewed as being shared, as expressed by a participant:

> *"I need to protect my passwords and things like that. But at the same time... you don't know what security features are built in, you don't know what any potential vulnerability might be. I think it's certainly a shared responsibility" (P24_A).*

As another example case, P1_A assumes personal responsibility both in purchase decision (*"It starts with us. We're bringing this device into our home"*) and by taking some simple mitigative actions (e.g., taping over cameras, not placing devices in more private areas of the home like bedroom). Yet, she also expects the manufacturer to do what she is not able to do with respect to managing data *"appropriately and securely"* and producing secure devices.

Given that smart home users may not know how to protect their devices and data, they look to manufacturers to provide them with more usable and transparent options. A smart home administrator commented about the need for better usability:

> *"I think the ability to control that data should be simpler than a multistep process, especially because the smart homes are very popular with people who don't know how to use technology" (P29_A).*

P3_A placed partial responsibility on herself for privacy (*"To the extent that you can do something about it, you should"*), but also felt the manufacturer should be more transparent:

> *"There's a certain responsibility to be transparent about what you're doing with people's data, protect personally-identifiable information, and to make it clear how you will use it up. I would want to know what their rules are about law enforcement, state access, and how they deal with data brokers and other companies."*

Even technology-savvy, advanced smart home users wanted manufacturers to fill in current gaps in available options. For example, when asked who he thinks is responsibility for the privacy of data collected by his smart home devices, P15_A commented: *"My personal perspective on it is that it's up to the user to be aware of what the device is doing and configure and use them appropriately according to your own needs."* However, he did not believe that consumers were given enough control:

> *"I think it would be ideal if the companies running the back end systems for these devices would give you either a little bit more control or be a lot more transparent about what they do with it and show themselves to be more responsible with that data."*

There is also a tension in that users do not always trust manufacturers' motives and ability to implement strong security, so they feel the need to take personal action. For example, P15_A viewed himself as being responsible in order to fill a gap left by manufacturers who fail to produce secure products:

> *"I'd like to see the vendors take more responsibility and take more action to secure their own devices. But because they don't always do that, and I don't always necessarily trust them to do that, I take it upon myself to be responsible for the security of these systems" (P15_A).*

Personal and Government. Only two participants thought that they and the government were responsible for **privacy** (none for **security**). One of those two, P31_A, discussed, *"We haven't even begun to really go down the road what the EU has as far as protecting privacy, but it's the government... and you personally, as much as you can to the extent practical."*

Manufacturer and Government. Nine participants thought manufacturers and government were jointly responsible for **privacy** but only three for **security**. Assignment of responsibility to the government or other regulatory bodies was usually rooted in response to lack of trust in manufacturers and belief that manufacturers were monetizing and selling smart home data. Government intervention was viewed as a standardizing construct that provides *"all the checks and balances" (P3_A)* on manufacturers so they do not circumvent privacy protections. For example, one participant commented:

> *"Voluntary consensus on privacy issues is almost impossible to get from the commercial sector... I think they need privacy guidelines at least from the government in order to adhere to them" (P13_A).*

Another participant claimed that companies are

> *"supposed to respect your privacy... If they fail,... next jurisdiction would be a government. The government has to watch them to make sure information is used for the right purposes" (P36_A).*

Personal, Manufacturer, and Government. Five participants viewed responsibility for **privacy** as being shared amongst themselves, manufacturers, and the government: *"It's the company... It's the government. But ultimately it's you and I" (P26_A).* Two participants viewed **security** as being shared among all three actors. A participant viewed privacy responsibility as being *"three-pronged... A third as a consumer, I should be aware, a third the company, and a third regulators and the government" (P25_A).* Another had a more in-depth explanation of his view of privacy responsibility:

> *"I think the company is responsible for it... in terms of government oversight, the government is in some way, shape, or form... Ultimately - and we're talking about accountability - you are responsible for your information because everyone else doesn't really care about you any more than you care about you" (P8_A).*

5 Discussion

In this section, we situate our results within prior literature on smart home privacy/security and IT responsibility. We then discuss the interdependent relationship between users, manufacturers, and third parties, and identify gaps and recommendations for how each actor can support the others.

5.1 Advancing Smart Home and Responsibility Research

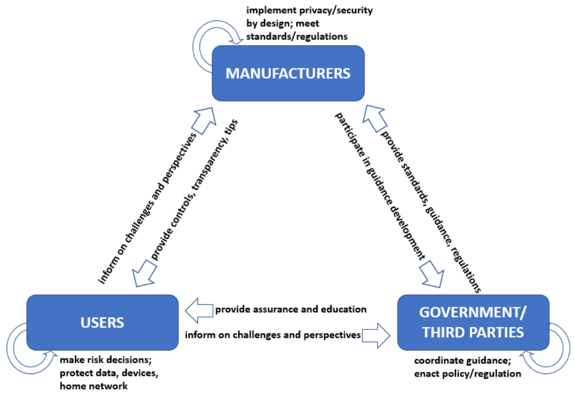
In our study, we confirmed results of prior smart home studies indicating that well-known concepts in privacy and security translate into perceptions of smart home devices (cf. 2.1.1). As demonstrated in past studies [2, 47, 48], our research showed that users may have concerns, but they accept the risk in favor of perceived benefits. They choose to adopt privacy-violating technology and rarely take mitigative action, while accepting accountability for purchase and subsequent use. These behaviors reflect the privacy paradox [7]. This inaction may be due to several reasons. Users may have low security and privacy self-efficacy and experience security fatigue [54] and privacy resignation [42]. In addition, we found that taking action may be complicated due to hard-to-navigate configuration options or lack of any options at all (e.g., [34, 46]).

We advance research on responsibility by extending the investigation into the smart home domain, which has unique attributes as compared to traditional online and IT technology. For example, in our study, we observed that smart home devices are perceived as intrusive—always on and collecting sensitive data with ties to physical safety. Unfamiliarity with a new technology and the potential for many more devices in the home as compared to traditional IT devices adds complexity and vulnerability to the home network.

Similar to prior responsibility research (cf. 2.1.3, (especially [5]), we identified that users view smart home responsibility as being shared. We observed both active and passive responsibility, a perceived interdependent relationship, and, when necessary to motivate, a desire for a system of checks and balances for positive privacy/security outcomes. Although our participants felt that they bear some personal responsibility (as also discovered previously [5, 9, 19]), they often delegate responsibility to other entities (like manufacturers and government) when they do not feel equipped or incentivized to take action [27, 30, 50]. Tension may arise when users do not always trust the actors to whom they relegate responsibility, so they then look to others (government, industry oversight) to provide extra assurance [5]. Conversely, users may be resigned to having to take personal responsibility as a stopgap for lack of meaningful action on the part of manufacturers and government.

Moving beyond these similarities, we also identified differences from previous work. In prior smart home research (cf. 2.1.2), manufacturers and government are portrayed more as risks and bad actors [56, 66]. While some participants in our study did see these entities in potentially negative lights, they also recognized them as active partners in finding holistic solutions for smart home privacy and security. In addition, compared to prior findings that U.S. consumers rarely assign responsibility to their government for the protection of their digital assets [9, 19], we observed an appreciable number of our participants (roughly 37%) who thought government had responsibility for protecting smart home device privacy. This difference may be due to several potential reasons. First, the prior studies did not focus on smart home devices, rather connected devices in general, and may have lumped security, privacy, and safety together. Second, as compared to closed-ended survey choices, in our study, participants were able to organically assign responsibility in open-ended discussion. In addition, our study population was located in an area where the U.S. government is a major employer and more familiar.

Haney, Julie; Acar, Yasemin; Furman, Susanne M. "It's the Company, the Government, You and I: User Perceptions of Responsibility for Smart Home Privacy and Security." Paper presented at USENIX Security 2021, Vancouver, CA. August 11, 2021 - August 13, 2021.



implement privacy/security by design; meet standards/regulations
MANUFACTURERS
inform on challenges and perspectives
provide controls, transparency, tips
participate in guidance development
provide standards, guidance, regulations
USERS
provide assurance and education
inform on challenges and perspectives
GOVERNMENT/ THIRD PARTIES
make risk decisions; protect data, devices, home network
coordinate guidance; enact policy/regulation

Figure 4: Perceived relationship between smart home users, manufacturers and third parties.

Progressing responsibility research into the smart home domain allows for identification of areas where users voiced the desire for immediate improvement (as described in the next section). The identification of perceived gaps is particularly valuable, given that this is a fledgling industry that currently lacks the maturity and full spectrum third-party support and guidance currently afforded to traditional IT.

5.2 Addressing Gaps

An overarching theme was the perceived interdependency between users, manufacturers, and government in a triad of responsibility. Through the eyes of smart home users, we observed disparities between the status quo and what consumers think should be happening. Disparities can point to future directions where researchers and practitioners should focus attention. As an example, if users accept responsibility but lack the ability to take action, discomfort with their smart home security and privacy may warrant action and investigation into how manufacturers can better support users or where third-party guidance or regulation may be beneficial.

In this section, we summarize problem areas and provide suggestions on how each actor can better be empowered to contribute to smart home security and privacy. The desired interdependent relationship identified by participants in our study is illustrated in Figure 4. Note that participants had a narrow view of oversight only coming from the government. However, recognizing that other, non-governmental organizations (e.g., non-profits, industry groups, standards organizations) may also be able to provide manufacturers and users with support, standards, and evaluations, we expand the government/regulatory actor into a broader third-party role. Our study also motivates future work related to each actor's potential contribution and needed support.

5.2.1 Problem Areas and Gaps

Users. We observed inconsistent relationships between being concerned, accepting personal responsibility, and taking privacy and security mitigative actions. Concerned participants did not always take action because of lack of knowledge, accepting trade-offs, and not valuing data collected by smart home devices (4.1). Those with privacy and security concerns did not always accept personal responsibility, and, sometimes, those who did not express concern still accepted responsibility (4.2.1).

There was also a marked disconnect between *feelings* of personal responsibility and *ability* to take active responsibility. While users may blame themselves for not actively protecting their security and privacy, they feel essentially powerless, resulting in a sense of privacy resignation and security fatigue. Most participants therefore believed that the privacy and security of their smart home should be a shared responsibility. Unfortunately, most of the burden is currently put on the user.

In order for users to be able to take *informed* personal responsibility, they need to better understand the risks, be given the opportunity to take action, and be educated about what steps they need to take. They also require reliable, objective information from manufacturers or trusted third parties to aid in purchase decisions. However, when researching smart home privacy and security, a minority relied on manufacturer-supplied information, with most participants trusting other online sources more.

Users who did not mention that they felt personally responsible mostly assigned responsibility to other actors, and not without reason. Concurrent research agrees that users' security and privacy needs in smart homes should go beyond what users can do (or are willing to do) and should be extensively supported by more powerful actors, like regulators and manufacturers (cf. Sections 2.1.2 and 2.2). This is complicated by users sometimes not trusting manufacturers or the government even when expecting support.

Manufacturers. Some participants believe manufacturers are competent with respect to privacy and security, often based on manufacturer reputation as opposed to transparent communication. Others doubt the willingness of manufacturers to implement strong privacy and security measures. They believe that manufacturers may not be incentivized to spend extra time/money on privacy and security for relatively inexpensive and disposable devices. Plus, added privacy restrictions may be counter to their business model of monetizing data, so participants believe that manufacturers may be purposely vague in what they reveal about data collection and use. Even though participants viewed manufacturers as being responsible, the reality is that some manufacturers may not know how to properly implement privacy and security, partly because many are new to developing smart products [25]. In addition, manufacturers may be unsure of what third-party guidance to follow since smart home privacy and security guidelines have not yet converged into widely agreed-upon standards.

The notion of manufacturers may also extend beyond those who develop smart home products. Third-party cloud and internet service providers and makers of the devices upon which smart home companion apps reside (e.g., smartphone and tablet manufacturers) may also hold some responsibility for security and privacy.

Government and Third Parties. While participants did not necessarily trust the government, they voiced a desire for third parties (including government) to develop smart home privacy and security regulation and guidelines to uphold and support manufacturer responsibility in a system of checks and balances. Participants were less understanding of how government guidance and regulation could help with security. This might be because participants were less clear about what security of smart home devices and data would mean for them.

While general privacy and security regulation is slowly being rolled out (e.g., CCPA and GDPR), few authoritative government regulations or guidelines for IoT/smart home privacy and security are available or widely adopted. Even though manufacturers sell devices globally, individual government organizations may create their own guidance or regulation that they want manufacturers to follow. (We note that none of the participants in this study lived in an area covered by any of the new privacy laws). In addition, industry groups may issue their own recommendations. Various guidelines from these organizations may or may not be consistent, which could result in manufacturer confusion on which to follow.

From a legal perspective, there is also debate on who should protect data and the boundaries of protection. Considering the newness of mandates in this area, legal constructs and interpretations will likely evolve.

5.2.2 Opportunities for Improvement

Based on identification of actions participants are willing/able to take and what they desire others to do, we offer the follow suggestions for strengthening the three-pronged, interdependent privacy/security relationship. We refer back to Results sections that inform our recommendations where appropriate.

What users can do. While manufacturers have a substantial responsibility to ensure smart home devices are privacy-respecting and secure, they cannot do everything and require users to be willing and active partners.

- ***Protection of data, devices, and home networks -*** Participants in our study thought they have some responsibility for configuring device options and setting strong passwords on device apps (4.1, 4.2.1). Recognizing that manufacturers have no control over the environment in which smart home devices are placed, users also need to protect their home networks, control device placement, and understand device capabilities and how those may impact or be used for privacy/security (4.1).
- ***Due diligence in understanding and accepting risks -*** Smart home users make privacy and security tradeoffs (4.1). Although they should be better supported in making these decisions and understanding risks, they are ultimately responsible for making informed decisions in line with their own privacy and security expectations and needs (4.2.1).

What third parties can do. Third parties, including oversight, government, and consumer-focused organizations, can provide support and guidance for smart home users and manufacturers. Users seem receptive to some government oversight and outside guidance for manufacturers, especially in the privacy area (4.2.3).

- ***Oversight and development of standards and guidelines for smart home privacy and security -*** Government bodies can protect consumers' privacy and security and aid manufacturers by issuing voluntary guidance or regulations when appropriate on recommended privacy and security implementations and options (e.g., [22,23]). Non-profits, industry forums, standards organization, etc. can also contribute to building a more universal consensus of what constitutes minimum privacy and security measures in smart home devices, for example via baselines [14,40] and product labels/ certifications [15,21,59]. Because users often lack the knowledge to take action on their own (4.1), recommendations should take user considerations into account, for example, with suggestions on how manufacturers might consider user limitations throughout the entire product lifecycle [23].
- ***Consumer education -*** Third parties can provide resources that educate users on smart home privacy and security issues and provide actionable configuration tips (4.1).

What manufacturers can do. Because smart home users may not be technology- or security-savvy (4.1), we found that users often want to rely on manufacturers (4.2.2) to fill this gap in several ways:

- ***Usable privacy/security interfaces -*** Provide an interface that makes it easy for users to configure privacy/security options (e.g., opt in/out), while not overburdening users with too many options.
- ***Transparent privacy and security practices -*** Be more forthcoming about what privacy and security options are available, which features are built into the products, and options/features that are not available but may be expected. To address user's distrust of manufacturer motives (4.2.2), make this information easier for consumers to find (e.g., on vendor websites or device help/support screens). Also provide more readable and accessible privacy policies that transparently communicate how data is collected, stored, and used.

- ***Privacy and security by design -*** Alleviate user burden of having to configure extra privacy and security options (4.1) by making an honest effort to provide strong "out-of-the-box" privacy and security features. Care should be taken, however, to ensure these features do not impact usability. Follow privacy/security guidance provided by reputable third parties, for example, practicing data minimization principles by only collecting data that is required to fulfill functionality and not violating contextual integrity (e.g., Alexa transmitting audio to find answers, but not storing voice recordings).

- ***Standards and guidance participation -*** In conjunction with our participants' desire for third parties to develop privacy/security guidance and standards (4.2.3), manufacturers should actively engage in coming to consensus on minimum smart home privacy/security recommendations. These recommendations can then be used in evaluations that contribute to product labels and certifications.

- ***Consumer education -*** Via app interfaces and help/support documentation, give consumers objective tips on how to best configure their devices with privacy/security in mind to account for users' uncertainty on what to do and how to do it (4.1).

5.2.3 Research Opportunities

Our exploratory study motivates future research direction into product labels, privacy/security education and communication efforts for users and smart home device manufacturers, interface design for configuring privacy and security features, and suggested standards for smart home privacy/security. There may also be value in more exploration into who should be responsible for implementing these improvements as well as receptivity and ability to take on additional duties. For example, little research has been done to capture the smart home manufacturer perspective. As such, future research may be warranted to determine where manufacturers are most challenged and how to best provide support and value. The practicalities of manufacturers implementing our proposed security/privacy recommendations also need to be better understood, (e.g., whether certain features can be implemented on devices with limited memory and processing power). Exploration of appropriate incentives that might frame the production of secure and private devices as a competitive advantage would also be valuable. We acknowledge that responsibility perceptions may be influenced by cultural, national, and political factors, so there is a need for extending current research into broader populations, including those outside the U.S. We also see an opportunity for increased real-world transfer of the knowledge gained from user-centered research efforts in this area to inform manufacturers and guideline developers. This study has already informed some of the user-centric considerations in NIST security guidance for manufacturers [23].

6 Conclusion

In a qualitative research study of 40 smart home users, we expand the discourse on smart home security and privacy by investigating where users perceive responsibility for their smart home security and privacy. We find a theme of an interdependent relationship in which participants assume some personal responsibility but also assign responsibility to manufacturers and government/third parties when they cannot or are not willing to mitigate their concerns. We identify areas needing improvement in the current smart home privacy and security domain and distill how actors can take steps to fill these gaps. Achieving a more balanced relationship may take some of the burden off of users and provide better support to manufacturers, leading to less vulnerable systems and greater adoption of smart home technologies.

Acknowledgements

We would like to thank the anonymous reviewers, our shepherd Marshini Chetty, and our colleagues Sascha Fahl, Adam Aviv, Michael Fagan, Kevin Mangold, and Brian Stanton for their helpful comments on drafts of this paper. We would also like to thank Mary Theofanos for her input during initial study design.

Table 1: Participant Demographics. ID: A - smart home administrators/installers, U - smart home users; Gen (Gender); Ed (Education): M - Master's degree, B - Bachelor's degree, C - some college, H - High school; Device Type: Sec - Home security, Ent - Home entertainment, Env - Home environment, Appl - Smart appliance, Asst - Virtual assistant. Interviewed couples: P6_U and P7_A, P29_A and P30_U, P38_U and P39_U, P40_U and P41_A.

B Interview Questions

NOTE: Questions yielding responses that contributed to this paper are in **bold**.

SECTION A: TERMINOLOGY

1. You may have heard the term “internet of things,” or IoT for short. Can you talk a little about what you think the internet of things is?
2. You may have heard the term “smart devices.” What about devices makes them “smart?”
3. What does it mean to have a smart home?
4. What do you think is the relationship, if any, between the internet of things and smart devices?

SECTION B: PURCHASE & GENERAL USE
[Review list of smart home devices before beginning this section.]

5. Who was involved in the decision to purchase the smart home devices?
6. **What are the reasons the smart home devices were purchased?**
   - **How did you (or a household member) learn about the devices before buying them?**
7. **What hesitations, if any, did you have about getting the devices prior to purchase?**
8. For what purposes do you use your smart home devices?
9. How do you access the devices – remotely with an app, while physically in the home, or both?
   - *If using a virtual assistant:* How do you access your devices using [insert assistant name]?
   - *If using a hub:* Do you use the hub app to access your devices, or do you use an individual app specific to each device?
10. How do others in your household use the smart home devices?
11. What do you like most about the devices? What are the benefits, if any, of having these devices?
12. **What do you like least or dislike about the devices?**
13. How have your opinions or expectations of the devices changed, if at all, from the time you first used them until now?
14. **What concerns, if any, do you have about the devices?**
15. **In what ways, if any, have you changed your behaviors because of your smart home devices?**
16. **In what ways, if any, have you become reliant on your smart home devices?**
17. What do the other members of your household think about the smart home devices?
18. Have you had visitors to the home who have had to use the smart home devices?
    - *If yes:* How did they use the devices? What did they think?
19. What smart home devices, if any, have you had in the past, but are no longer using?
    - **What are the reasons for no longer using this device?**
20. **What kinds of things would you like to be able to do with your devices, but haven’t, don’t know how, or are not sure that you can?**
21. What devices would you like to get in the future? For what reasons?

SECTION C: INSTALLATION/TROUBLESHOOTING

22. Who installed the smart home devices?
23. Who administers (configures or maintains) the smart home devices?

For Installers:

24. In general, what was your experience with the installation of the devices?
    - What went well?
    - What didn’t go as well?
25. Have you ever had to reinstall a device? If so, what were the reasons for the reinstallation?
26. *If have more than one device:* What has been your experience adding additional devices to the home?

For DIYers:

27. In the screening questionnaire you indicated you build your own or create extensions for your smart home devices and platforms. Can you briefly summarize what you’ve done?

For Administrators:

28. What configuration changes, if any, have you made to the devices since installation?

- *If participant makes configuration changes:* How often do you make changes?

29. How do you know that updates are available or needed?

30. How are updates done on your device - automatically or do you have to initiate them?

    - *If manual initiation:* How often do you check for updates?
    - How do you decide whether to update or not update?

For Everyone:

31. How do you try to figure out how to do something new with your devices?

    - What sources do you consult or use?
    - *If have a voice assistant:* What has been your experience, if any, adding new skills to your voice assistant?

32. What kinds of problems, if any, have you encountered while using your smart home devices?

    - How did you go about trying to resolve those problems?

SECTION D: PRIVACY

33. **What type of information, if any, do you think the devices are collecting?**

    - **Which of this information, if any, would you consider to be personal?**

34. **Where do you think the information goes?**

35. **In what ways, if any, does your device or the device manufacturer provide a means to control or manage what information is collected and how it is shared?**

36. **What are your concerns, if any, about how information is collected, stored, and used and who can see that information?**

    - **In what ways, if any, have you acted to minimize or alleviate some of those concerns?**
    - **What kinds of actions would you like to be able to take to address your concerns, but haven't, don't know how, or are not sure that you can?**

37. **Who do you think is responsible for protecting the privacy of information collected by your smart home device?**

SECTION E: SECURITY

38. **What are your concerns, if any, about the security of your devices?**

    - **In what ways, if any, have you acted to minimize or alleviate some of those concerns?**
    - **What kinds of actions would you like to be able to take to address your concerns, but haven't, don't know how, or are not sure that you can?**

39. What restrictions, if any, are placed on who in your home can use the devices and what they can do?

40. How do you authenticate to or get into any apps associated with the device?

    - What issues or problems, if any, have you experienced with authentication?

41. Does more than one person in your household use an app to access the same device?

    - Does more than one person use the same account and authentication to access the app?
    - What concerns, if any, do you have with multiple people having access to the app?

42. **Who do you think is responsible for the security of your smart home devices?**

SECTION F: SAFETY

43. In what ways, if any, do you think the devices contribute to safety?

44. **In what ways, if any, do you think the devices might pose a safety risk?**

SECTION G: CONCLUSION

45. Is there anything else you'd like to add related to anything we've talked about?

C Codebook for Privacy & Security Concepts

Code	Description
Privacy	Related to (potentially sensitive) data collected by smart home devices
Attitudes	When a participant talks about their mindset or point of view with respect to privacy
Concerns	When a participant talks about some worry they have about how their smart home data is collected, used, and protected
Audio/video recording	Exposure of data from devices that record
Data breach	Data being stolen from manufacturers
Financial	Financial information and accounts being exposed by devices/apps
Government access	Data being exposed or devices being hacked by domestic or foreign nation states
Habits/profiles	Data or the aggregation of data revealing information about the household and occupants
Lack of concern	Evidence of participants not having worries about smart home device privacy/data
Selling data/ads	Manufacturers selling data to third parties and/or data being used for targeted advertising
Unknowns	Discomfort with not knowing what data is being collected by devices, who has access to the data, or how the data is used
Information collection/use	When a participant talks about the collection and use of their smart home data
Control options	Mentions of options or lack thereof for managing data collection and use
Info collection	The types of data devices are collecting
Info destination	Where data goes
Info use	How data is used
Personal information	Which data is considered to be personal
Privacy policies/EULAs	Perceptions of and experiences with privacy information provided by device manufacturers
Mitigations	How participants tried (or didn't try) to lessen the privacy impact of their smart home devices or alleviate their privacy concerns
Access control	Limiting who/what devices can connect to or use the smart home devices/apps
Authentication	Setting passwords or biometric authentication for smart home devices/apps
Choosing devices that protect privacy	Taking privacy into account when selecting devices for purchase/use
Configuring options	Setting available privacy-related controls on the device
Lack of mitigations	How/why participants do not implement privacy-related mitigations
Limiting audio/visual	Restricting or being careful about what audio and video is recorded by the devices
Monitoring data	Inspecting network traffic entering/leaving the home network
Network configuration	Settings and actions taken on the home network, including Wi-Fi
Updates	Implementing patches or upgrading products/versions
Responsibility	When a participant talks about who is accountable for the privacy of data collected by smart home devices
Manufacturer	Responsibility assigned to the makers of smart home devices
Personal	Responsibility assigned to the participants themselves or smart home owners in general
Shared	Responsibility assigned to more than one actor/entity
Third-party	Responsibility assigned to governments or other non-manufacturer entities/organizations
Wishlist	What participants would like to have to increase the privacy of data collected by their smart home devices

Code	Description
Security	Related to how smart home devices and data are protected against unauthorized use or modification
Attitudes	When a participant talks about their mindset or point of view with respect to security
Authentication	Related to how participants establish or validate their identity when using smart home devices
Concerns	When a participant talks about some worry they have about the security of their smart home devices/data
Audio/video recording	Unauthorized exposure of data from devices that record voices or images
Data breach	Data being stolen from manufacturers
Exploitation of devices	Devices being hacked
Financial	Financial information and accounts being exposed by devices/apps
Government access	Data being exposed or devices being hacked by domestic or foreign nation states
Lack of concern	Evidence of participants not having worries about device security
Linkage to other accounts	Compromise of one account/device can lead to compromise of other accounts
Lack of out-of-the-box security	Devices are not secure when purchased
Physical security/safety	Related to potential harm of occupants or household items
Updates	Issues caused by installing patches or upgrading devices
Wi-Fi access	Unauthorized access to devices leading to compromise of Wi-Fi network
Mitigations	How participants tried (or didn't try) to alleviate their security concerns or improve security of their devices
Access control	Limiting who/what devices can connect to or use the smart home devices/apps
Authentication	Setting passwords or biometric authentication for smart home devices/apps
Choosing secure devices	Taking security features into account when selecting devices for purchase/use
Configuring options	Setting available security-related controls on the device
Lack of mitigations	How/why participants do not implement security-related mitigations
Limiting audio/visual	Restricting or being careful about what audio and video is recorded by the devices
Limiting information	Only sharing necessary information with device apps or using false information
Network configuration	Settings and actions taken on the home network, including Wi-Fi
Physical security	Actions that protect the physical device or prevent physical tampering
Updates	Implementing patches or upgrading products/versions
Responsibility	When a participant talks about who is accountable for the security of their smart home devices
Manufacturer	Responsibility assigned to the makers of smart home devices
Personal	Responsibility assigned to the participants themselves or smart home owners in general
Shared	Responsibility assigned to more than one actor/entity
Third-party	Responsibility assigned to governments or other non-manufacturer entities/organizations
Wishlist	What participants would like to have to increase the security of smart home devices/data
Household member disparities	Differences or inequalities in smart home security/privacy knowledge among those living in a house
Sense of control/agency	Perceptions of feeling in charge of their smart home devices
Trust	Perceptions of confidence in the smart home devices or the manufacturers to protect their privacy and security

ABSTRACT

Additive manufacturing involving layer-wise selective laser melting of a powder material, or laser powder bed fusion (LPBF), is a fast-growing industry. At the Additive Manufacturing Metrology Testbed (AMMT) at the United States National Institute of Standards and Technology (NIST) an integrating hemispherical reflectometer has recently been developed to facilitate measurements of spatially resolved reflectance of the laser-melting heat affected zone (HAZ) during the LPBF process. Reflectance is then used to determine spatially resolved emissivity. The design features of the hemispherical-directional reflectometer are discussed. Then, the reflectometer performance and measurement uncertainties are detailed. A two-dimensional map of emissivity and emissivity uncertainty of the HAZ around a meltpool of high-purity nickel are presented. It is found that emissivity measurements are in good agreement with literature values at the melting point of high-purity nickel with acceptable uncertainty.

Keywords: High-temperature baffle-less reflectometer, emissivity of high-temperature metals, laser powder bed fusion

1. INTRODUCTION

Laser powder bed fusion (LPBF) is a layer-wise selective melting of the metal powder by scanning a high-power laser across the powder bed, which is located inside a process chamber with low oxygen content and laminar flow of protective gas. It is a fast-growing industry with unique fabrication capabilities compared to more traditional casting and forging [1]. Physical understanding of the processes taking place in laser-based additive manufacturing processes, such as LBPF and others, can be significantly enhanced by the knowledge of the thermodynamic surface temperature distribution [2]. The utility of thermodynamic surface temperature distribution includes, but is not limited to, the study of the rapid solidification of molten metal, which defines the metallographic structure—and associated mechanical properties—of the resulting part.

To establish traceable radiance-based temperature measurements we have selected the only first principle approach which is applicable, (1) direct measurement of spectral radiance of the heat-affected zone (HAZ) by comparison with a radiance standard, (2) indirect measurement of spectral emissivity, by illuminating the sample with a uniform hemispherical source and comparing the reflected radiant flux to that from a calibrated standard, and (3) calculation of the surface temperature distribution. This general approach has been realized and validated previously at NIST [3], and here is applied to the LPBF process, which is quite different from the one normally encountered in laboratory reflectometers. The scope of this paper is limited to the reflectometer design, performance of emissivity measurements, and evaluation of uncertainties.

The relatively small dimensions of the HAZ (with typical size of molten metal area less than 0.3 mm × 1.2 mm) and the dynamics of the process necessitate retrieval of spatially distributed data at a high spatial resolution. This comes at a cost of using a much more complicated sensor with relatively large imperfections and uncertainties as compared with a single element optical detector normally used in optical metrology [4]. In terms of requirement for reflectometry, this means using hemispherical illumination and directional (conical but within a small collection angle) imaging.

The temperatures encountered in a typical LPBF process range from room temperature to 3000 °C and above, with a special interest at the temperatures of the solidification and crystallographic phase changes (500 °C and above). Since the probing light of the reflectometer must compete with the self-emitted light from the hot scene, and in combination with

Deisenroth, David; Hanssen, Leonard; Mekhontsev, Sergey. "High temperature reflectometer for spatially resolved spectral directional emissivity of laser powder bed fusion processes." Paper presented at Reflection, Scattering, and Diffraction from Surfaces VII, San Diego, CA, US. August 24, 2020 - August 28, 2020.

the hemispherical-directional geometry (as mentioned above), this calls for an unusually high-power light sources in the reflectometer.

A further complication arises from the dynamic character of the process, in which the laser spot is scanned across the build area. Every frame of the imager is registered at a different location, which further complicates reflectance measurements due to sample spatial nonuniformity and possible defocusing of the laser. Since use of a stationary field of view will result in motion blur, it is customary to use imaging systems which share the scanning system with the process laser. This allows for avoidance of some problems with relative motion of the process and the field of view, but brings a new set of problems due to changes in focusing and optical path length for the wavelengths of the laser and reflectometry wavelength, as well as a lower collection efficiency due to the optics which are optimized for the laser wavelength to avoid damage by the high power laser. This results in additional uncertainties due to position-dependent defocusing of the laser and image.

Finally, there are some additional aspects of the process due to the presence of the process by-products (such as hot and condensed metal vapor), which require a directional flow of a shield gas which can significantly affect the process [5]. This introduces new sources of uncertainty, as well as further complicating the reflectometer design. Some of these effects have yet to be evaluated in detail, which is planned for a later date.

As stated previously, the scope of this paper is limited to the reflectometer design, the performance of emissivity measurements, and uncertainty evaluation. Section 2 describes the measurement approach, including the measurement equation, reflectometer design, and signal corrections for directional imaging. Section 3 details the uncertainty evaluation of test conditions, reflectometer illumination, and directional imaging. Finally, Section 4 describes measurement of a two-dimensional map of emissivity and emissivity uncertainty of the HAZ around a meltpool of high-purity nickel, followed with conclusions in Section 5.

2. EXPERIMENTAL SETUP AND MEASUREMENT APPROACH

The experiments were performed in the NIST Additive Manufacturing Metrology Testbed (AMMT) [6,7]. The AMMT is a custom LPBF research platform that is designed to be highly configurable for characterization of all aspects of the LPBF process. The AMMT includes a removable carriage that contains the build-well and a large metrology-well, both of which may be moved laterally within the large build chamber. The laser is an Yb-doped continuous wave (CW) fiber laser with an emission wavelength of 1070 nm. The delivered laser power can be adjusted from 20 W to about 385 W, with a 4σ diameter (D4σ, representing diameter within which about 95% of the Gaussian laser power profile is contained) spot size that is adjustable from 45 µm to more than 200 µm. The laser spot can be scanned with full control of the laser scan path/strategy at 100 kHz and laser power control at 50 kHz, with scan velocity of more than 4000 mm/s.

The core elements of the AMMT meltpool thermographic systems include (1) a high power fiber laser system emitting at 1070 nm; (2) an optical scanner (galvanometer), used to direct process laser spot; (3) beam splitter and optical components enabling co-axial meltpool imaging configuration; and (4) the sample under study, which can be accurately positioned and aligned with the object plane of the co-axial laser/imager optical path and is surrounded by an environmental enclosure with a shield gas flow. Additional thermographic equipment, which is referred to as the TEMPS system (Temperature and Emissivity of Melts, Powders, and Solids), includes an external (coaxial) imaging system, which is optically combined with the process laser and is used to measure the radiance distribution across the HAZ of the process.

An “indirect” method of emissivity measurement is employed in this work, in which the laser melting process is uniformly illuminated with uniform radiance across the hemisphere by a hemispherical reflectometer. The reflectometer uses a hemispherical-directional geometry, in which a ring of light emitting diodes (LEDs) around the equator of the hemisphere is optically integrated within the reflectometer to provide the uniform illumination. The laser melting scene is then imaged directionally through imaging optics that are coaxial with the heating laser, allowing for stationary viewing of the meltpool relative to the laser heating location. The measurement is performed once with the LED illumination on, and once with the LED illumination off. This approach facilitates spatially resolved radiance and reflectance/emissivity measurement of the meltpool. The measurement equation for emissivity will be discussed in the Section 2.1.

2.1 Measurement equation

The emissivity measurement equation for each single pixel of the focal plane array (FPA) is as follows:

$$\varepsilon_\lambda(\lambda_o, T_s) = 1 - C_\rho \rho_{ref} \frac{S_{samp}^{LED\ On}(\lambda_o,T_s) - S_{samp}^{LED\ Off}(\lambda_o,T_s)}{S_{ref}^{LED\ on}(\lambda_o) - S_{ref}^{LED\ off}(\lambda_o)} \quad (1)$$

where ε_λ is the spectral normal (or 8°) spectral emissivity of the sample, λ_o is the central wavelength of the radiometer (and the light source), T_S is the sample temperature, and ρ_{ref} is the reflectance of the calibrated reference standard. The linearized signal measured by a single pixel of the imager is denoted by *S*. The signal linearization approach and its uncertainties will be discussed in Section 2.3.1. The superscripts "LED on" and "LED off" refer to signals obtained with and without LED illumination. The subscripts "samp" and "ref" refer to the objects of measure: the sample and the calibrated reflectance standard, respectively. The term C_ρ has a nominal value of one and is used as a correction factor for systematic biases. It has an associated uncertainty, which is propagated into the uncertainty of ε_λ. The correction factor C_ρ is comprised of multiple correction factors, which are associated with each source of bias, non-ideality, and uncertainty associated with the reflectometer:

$$C_\rho = C_{TU} C_{PL} C_{LED} C_{ARM} C_{AS} C_{BRDFS} C_S \quad (2)$$

where C_{TU},C_{PL}, C_{LED}, C_{ARM}, C_{AS}, C_{BRDFS},and C_S are the factors associated with throughput uniformity, port losses and high angle losses, LED reproducibility, alignment of the reference mirror, alignment of the sample, the sample bi-directional reflectance distribution function (BRDF, discussed in Section 3.1.4), and out of field scatter, respectively. Section 2.2 will describe the important design considerations of the reflectometer used for these measurements.

2.2 Baffle-less center-mount reflectometer design features

The design of the reflectometer is constrained by the size of the build chamber, the necessary gas flow provisions for laser-metal interaction, fabrication limitations, and the likelihood of damage to the reflective coating by laser reflection from the melting process. In the current case, a hemispherical reflectometer design is used instead of a complete sphere in order to address the unique considerations of the LPBF environment, while maintaining illumination performance. Use of integrating hemispheres have been applied for compact size and other optical considerations, but have not yet been applied to emissivity measurement of the LPBF to the best of our knowledge [8].

With respect to port size ratio, use of a hemisphere instead of a complete sphere allowed for a smaller laser-entrance port size and sample port size, relative to the total integration area, while fitting within the height of the build chamber of the AMMT. An equivalent height complete integrating sphere would have had about double the port area to integration area ratio. With respect to coating damage, the hemispherical design allowed the integrating surface to have greater average distance from the process, ranging from the same distance at the entrance port to double the distance at about 22° from horizontal. At normal incidence, irradiance (radiant flux received by a surface in units of W/m^2) is proportional to the square of distance, and so the hemispherical design reduces the diffuse coating exposure to intense laser reflections on average by about a factor of two. Furthermore, the hemispherical geometry allowed for double the perimeter for LED illumination, also facilitating double the intensity of illumination which must be on the same order of magnitude of the process self-emission.

A cross-sectional view of a computer aided design model of the integrating hemisphere is shown in Figure 1. As shown, optical integration is facilitated by a diffuse, barium sulfate coating and with a specular, polished aluminum base electroplated with gold, which has excellent reflectivity at 850 nm. The reflected light from the hemispherical illumination is imaged through an elongated port on the top of the hemisphere, about 8° from the vertical. The 8° offset of the port prevents retroreflection from a specular (or nearly specular) sample into the inline optics, reducing the possibility of incomplete and/or nonuniform illumination of the sample due to the detection port. Furthermore, in the case of the current application, reduced likelihood of retroreflection from the sample into the inline optics also reduces the possibility of damage to the filters or the imager from retroreflected high-power laser light. The elongated design of the laser port and sample port enables scans to be performed within an area of about 3 mm × 20 mm with coaxial imaging of the laser-metal interaction scene.

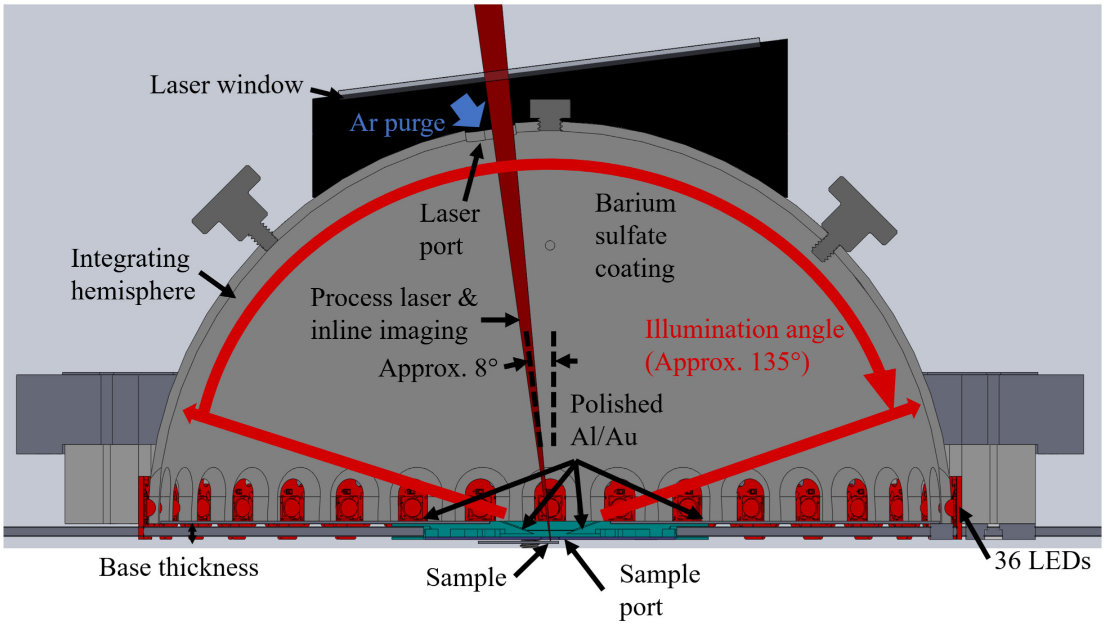

Figure 1. Cross-sectional view of a computer aided design model of the integrating hemisphere.

Another design constraint unique to the LPBF environment is that inert gas atmosphere is required for laser melting in order to reduce detrimental oxidation [9(p3)]. Previous studies have shown that directional and inert shield gas flow is essential to facilitate continuous, consistent beam delivery by removing process biproducts that can distort, scatter, and obstruct beam delivery [10,11]. As shown in Figure 1, Ar gas is pumped into the reflectometer through the laser port. The gas flow rate is typically about 30 L/min, which results in a downward flow onto the sample of about 0.5 m/s, which provides some byproduct removal. Future tests will incorporate an improved directional gas flow provision. In the current investigation, laser scanning occurred in the direction perpendicular to the image plane of Figure 1.

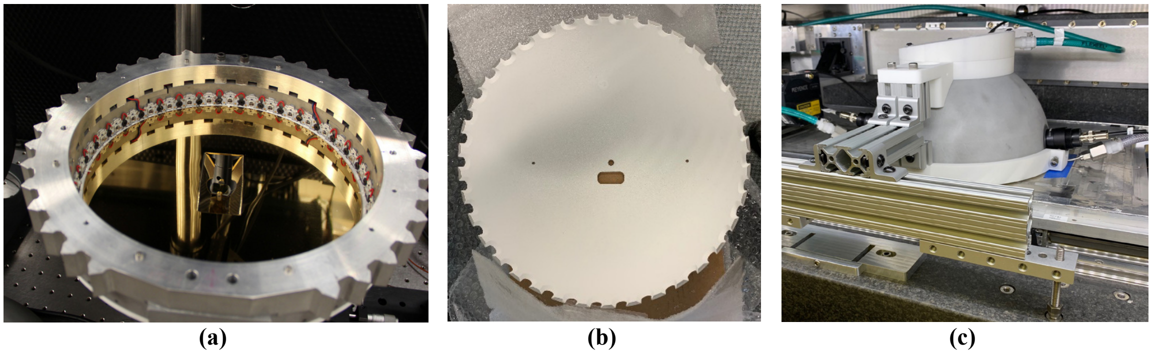

Figure 2. Images of the fabricated integrating hemisphere: (a) the specular base assembly, (b) the barium sulfate coated hemisphere interior, and (c) the assembled apparatus mounted in the build chamber.

The surfaces near the sample port are angled at about 22°, as shown in Figure 1. This creates a base thickness of about 6.7 mm. The thickness of the base of the dome acts as a baffle and results in an illumination angle of about 135°, as shown in Figure 1. The LEDs are located as close as possible to the equator of the hemisphere. At this location, the base thickness has a beneficial baffle-effect, and prevents deleterious direct illumination of the sample by the LEDs, which would lead to nonuniform illumination. The base thickness, though, causes a loss of light in the remaining 45° of the hemisphere, which does not contribute to illumination. In practice, surface features reflecting light into the directional imaging path at an angle less than 22° from the horizontal are unlikely, but possible, and the associated contribution to surface reflectance/emissivity measurement uncertainty must be evaluated. The fabricated base, hemisphere interior, and assembled integrating hemisphere within the build chamber are shown in Figure 2. Each source of error and uncertainty associated with the reflectometer-based measurement of emissivity will be described in Section 2.3.

2.3 Directional imaging signal corrections

The corrections used to condition the signal used for the measurement of spatially resolved emissivity will be described at length in a forthcoming publication, hence these items will be only briefly summarized in this section. Two primary corrections are applied to the signal: 1) the erroneous signal components due to stray light and blooming are subtracted, and 2) the images are deconvolved with a blur kernel to compensate for image distortion due to the optical blur and finite pixel size of the FPA. The corrections are applied to each image of the 30 central images of the test sequence to avoid transients due to startup and laser shutoff.

In this work, motion blur is not considered because the image is static relative to the laser motion, making the meltpool quasi-static in this reference frame. Although the meltpool undulates slightly relative to the laser motion, blur due to meltpool length changes and location variability within the reference frame within the integration time is assumed to be negligible.

2.3.1 Linearization with radiant flux

The imager signal must be linearized with respect to the object radiant flux for accurate determination of the emissivity. The imager signal is linearized by exposure to the steady, known radiance of a high temperature blackbody (HTBB). The imager is outfitted with a long working distance microscope lens body and objective lens, a band filter, and a laser cutoff filter. The measurement equation for linearization is then as follows:

$$S(T)_{cal} = C_{cal,BB} \int_{\lambda 1}^{\lambda 2} \tau_{\lambda}^{obj}(\lambda) \tau_{\lambda}^{filt}(\lambda) r_{\lambda}^{FPA}(\lambda) \frac{c_{1L}}{\lambda^5 \left[exp(c_2/(\lambda T_{rad,BB})) - 1 \right]} d\lambda \tag{3}$$

where the pixel signal $S(T)_{cal}$ is the FPA signal, $\tau_{\lambda}^{obj}(\lambda)$ is the spectral transmittance of the objective lens, $\tau_{\lambda}^{filt}(\lambda)$ is the filter spectral transmittance, and $r_{\lambda}^{FPA}(\lambda)$ is the imager spectral responsivity, c_{1L} and c_2 are the first and second radiation constants, λ is wavelength, and $T_{rad,BB}$ is the radiance temperature of the HTBB. The signal is linearized with the single-point averages of image sequences at varying HTBB temperatures. This can be done because of the relatively low noise and FPA nonuniformity, both of which are incorporated into the measurement uncertainty. Once $C_{cal,BB}$ is determined at a single point, the signal at each HTBB temperature is linearized using Equation (3) to generate a linearization function for the signal.

2.3.2 Stray light and blooming correction

Stray light is light that passes through the optical system in a manner that is not intended in the optical system. Imager blooming occurs when a pixel potential well is overfilled and the excess charge bleeds over into adjacent pixels. Both stray light and blooming tend to increase the FPA signal near high intensity regions, typically exhibiting exponential decay in erroneous signal with distance from the high intensity regions. Although the TEMPS optical system is designed using best practices to reduce stray light [12] and the imager with complementary metal–oxide–semiconductor (CMOS) is relatively impervious to blooming, these effects must be measured and compensated for high accuracy measurements. Our measurements indicate that the meltpool hotspot generates about 100 times more radiant flux than the intensity levels of interest near the melting temperature, which produces a significant potential for erroneous signal due to stray light and blooming.

Stray light and blooming are be measured simultaneously because both have similar causes and effects on the measurements. In order to quantify the combined effect of stray light and blooming, an illumination source other than the meltpool is required to eliminate the optical effects of the laser-melting process variability and byproducts. The source chosen for the application is a 6 µm diameter fiber coupled laser with divergence angle exceeding the acceptance angle of the TEMPS optics. The fiber-coupled laser is located under an aperture located at the build plane height so that the aperture is slightly overfilled. Illumination is projected onto the imager through the TEMPS optics system to replicate the meltpool hot spot. The aperture size and intensity are selected to closely mimic the area and intensity of the meltpool hotspot.

A curve fit is performed on the erroneous signal generated outside of the 100 µm aperture. The center of the hotspot is then located and the distance of the center of each pixel from the hotspot center is calculated. The erroneous signal at each pixel due to stray light and blooming is calculated from the curve fit based on the pixel distance from the hotspot. Finally, the erroneous signal is subtracted from each meltpool image of interest. The pixels in the saturated region are left at the original saturated digital level (DL). After subtraction of the signal due to stray light and blooming, a mild smoothing operation is then applied to images.

2.3.3 Image smoothing

A mild smoothing filter is applied to each test image after the stray light and blooming subtraction. Smoothing the images reduces the effects of noise on the deconvolution. The smoothing filter is based on nearest-neighbor averaging with one adjacent pixel on either side, top and bottom. We confirmed that the smoothing operation does not introduce a systematic signal bias by subtracting the original image from the smoothed image and averaging across the frame. The resulting average signal difference has been found to result in a negligible average bias of less than 1% of a digital level at each pixel.

2.3.4 Image deconvolution

Deconvolution is an image processing operation intended to reconstruct an image to its original form prior to blur induced by inevitably non-ideal optics and finite pixel size of FPAs. The multistep deconvolution approach taken here is based on that of Lane and Whitenton [13] and ISO 12233:2017 [14]. First, a knife edge measurement is taken to establish an edge spread function (ESF). The ESF is then transformed into a point spread function (PSF), which can be thought of as a "deblurring kernel." Finally, the images are deconvolved. The details of each element of the operation are discussed.

2.3.4.1 Knife-edge measurement

Use of an ESF measurement is a practical approach to the determination of the PSF, because use of a true point source is experimentally difficult, if not impossible [14]. Use of an ESF to determine the PSF reasonably assumes that the response of the optical system is rotationally symmetric.

To establish the ESF, a thin, opaque, and straight edge is placed to partially cover the aperture of the thermal integrating sphere source with 850 nm center wavelength (TISS850) set at a radiance temperature of 1600 °C at the build plane. The TISS850 is transfer source developed in the AMMT that is composed of LEDs that are thermally stabilized (by ethanol heat pipes cooled by a thermoelectric cooler and fan) to illuminate a polytetrafluoroethylene (PTFE) integrating sphere that generates uniform illumination at the waveband of interest—brightness that is calibrated against the HTBB thermal source. The edge is placed a few degrees from vertical so that it is not perfectly aligned with the pixel array [13,14]. Sampling lines are then taken perpendicular to a curve fit of the maximum image gradient to mark the edge between the high and low DLs. The image data are taken with a resolution of 6.0 µm per pixel through the TEMPS optics and the imager is set to a shutter speed of 98.3 µs, which is followed by determination of the ESF.

2.3.4.2 Edge spread function determination

The four sampling lines across the knife-edge image are found to be negligibly different, and so one of them is taken as representative of the image profile. The representative profile is then normalized to have a peak intensity of unity and is supersampled with 4 samples per pixel along the length of the array, per ISO 12233:2017 [14]. The data is then centered on zero based on the maximum gradient of the profile. In sampling with one, two, and three component error function fits, it is found that the most appropriate fit is with the two-component error function shown in Equation (4), with $R^2 = 0.998$.

$$\mathrm{ESF} = a_1 \operatorname{erf}\frac{x}{b_1} + a_2 \operatorname{erf}\frac{x}{b_2} + 0.5 \tag{4}$$

where x is distance in pixels, $b_1 = 3.184$ [pixels], $a_2 = 69.04$, and $b_2 = 3.184$ [pixels].

2.3.4.3 Point spread function determination

The PSF is determined from the ESF via differentiation followed by an Abel Transform as per Lane and Whitenton [13]. The corresponding PSF is shown in Equation (5).

$$\mathrm{PSF} = \frac{2}{\pi}\frac{a_1}{b_1^2}\exp\left(-\frac{r^2}{b_1^2}\right) + \frac{2}{\pi}\frac{a_2}{b_2^2}\exp\left(-\frac{r^2}{b_2^2}\right) \tag{5}$$

where r is the radial distance in pixels, and a_1, b_1, a_2, and b_2 are the values determined from Equation (4). The value of the PSF array is calculated at each super-sampled pixel location using Equation (4), and then averaged across the 4 × 4 super-sampled pixel to determine the PSF value at each pixel. The resulting PSF array is 25 pixels × 25 pixels in order to cover four orders of magnitude of intensity from the PSF center to the perimeter. The volume under the PSF array is finally normalized to unity.

2.3.4.4 Deconvolution

The final step is the deconvolution operation. Each image of the central 30 images of the test sequence is individually deconvolved to allow for later uncertainty analysis of the deconvolved image transient variability. Each image is first corrected for stray light and blooming, then smoothed as discussed in the preceding sections. The PSF array is then used to deconvolve each image with the MATLAB[2] 'deconvlucy' function, which is based on the iterative Richardson-Lucy method [15,16].

It is observed that the image is "sharpened" after deconvolution. The sharpening causes an apparent narrowing of the meltpool and steepening of the signal gradients on the left and right side, as well as at the nose. Toward the end of the tail, the local signal gradient becomes shallower and longer along the length of the meltpool, but steeper in the transverse direction across the tail.

2.3.5 Summary of the effects of signal corrections

The effect of each image correction operation is shown by a central cross-sectional profile along the length of the meltpool in Figure 3. Beginning with a linearized signal, the stray light and blooming subtraction operation reduces the signal at the nose of the meltpool because of its proximity to the hotspot, but has a very small effect on the signal at the tail because of its larger distance from the hotpot. The smoothing operation has very little effect on the signal levels but reduces the apparent pixel to pixel noise.

Deconvolution tends to have the most notable effect on the signal levels, both at the nose and tail of the meltpool. Deconvolution sharpens the profile, reducing the signal at areas of high curvature (large values of the second derivative), and steepening the profile at areas of high (two-dimensional) gradients. This can be observed at the nose and tail of the meltpool at pixel 10 and 48, respectively. The most significant variation in the central cross-sectional profile due to deconvolution occurs in the tail, where a "solidification plateau" appears. At this solidification plateau from pixel 59 to 63, the signal is flat, indicating an apparently isothermal solidification region as the laser heat source moves. This isothermal region is expected in the solidification process of high purity metals (99.998% Ni used here), because the fixed-point freezing temperature at which the phase change occurs is maintained as the material dissipates the latent heat of fusion at the solidification temperature. The solidification region is made significantly more apparent in the signal by deconvolution. The signal uncertainty incurred by each signal correction operation will be discussed in Section 3.

[2] Certain commercial entities, equipment, or materials may be identified in this document to describe an experimental procedure or concept adequately. Such identification is not intended to imply recommendation or endorsement by the National Institute of Standards and Technology, nor is it intended to imply that the entities, materials, or equipment are necessarily the best available for the purpose.

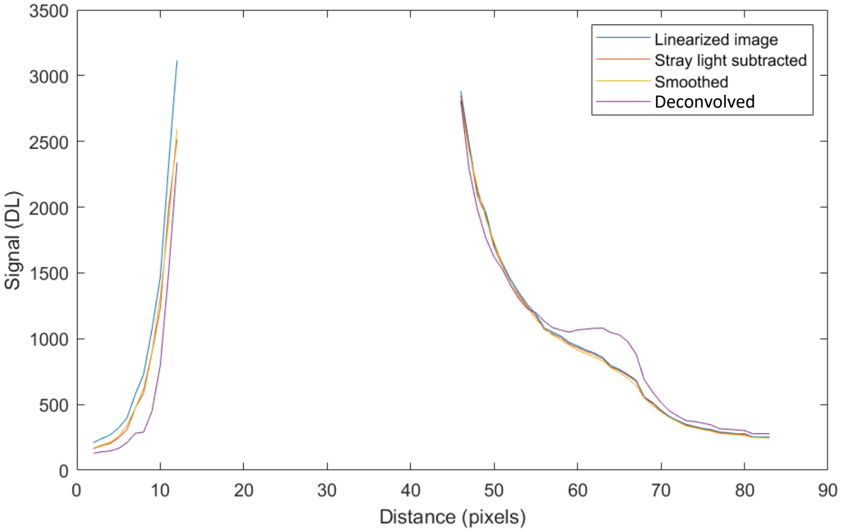

Figure 3. Central cross-sectional profile along the length of the meltpool showing the effect of each image correction. Meltpool nose is on the left and tail is on the right.

3. UNCERTAINTY

Three categories of sources of emissivity uncertainty have been identified. The first includes the nonideality, misalignment, and uncertainty in reflective character of the reference mirror and the sample. The second includes nonuniformity and incomplete hemispherical illumination, which pertains to the nonideality of the reflectometer. The third and final category of uncertainty is the nonideality of the directional imaging system, including the inline optics, imager, and image corrections.

3.1 Sample and reference uncertainties

3.1.1 Reference mirror alignment

As was discussed previously, both specular and diffuse reference samples are used in emissivity measurement and evaluation of uncertainties. The angular alignment and distance from the reflective surface to the reflectometer sample port (gap) slightly alter illumination of the reflector, as well as the reflectometer throughput (the throughput is the ratio of the flux reaching the detector to the input flux from the source). In the case of the specular mirror, misalignment or increased gap changes the location on the integrating surface from which the sample is illuminated, while also reducing throughput due to light loss from the gap. In the case of the diffuse reflectance standard, a misalignment or increased gap size changes the magnitude and location of the solid angle from which the reflector is illuminated. An experiment was performed to measure the relative change in signal when the specular reflectance standard was moved relative to the floor of the reflectometer (located at 219.3 mm from the laser window), as shown in Figure 4.

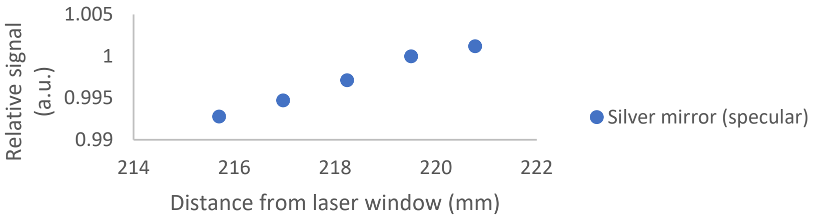

Figure 4. The relative signal measured as a function of the specular reflectance standard location relative to the laser window, with the floor of the reflectometer located at 219.3 mm

The reference mirrors are aligned with a laser displacement meter, which has an uncertainty of 1 µm (k = 1), and the reflectometer is mounted on kinematic mounts for accurate repositioning. The rotational misalignment is assumed to be negligible. It is conservatively estimated that the reflectance standard is located within ±1 mm, for which the relative range of the signal is 0.6 % (or equivalently ±0.3 % of the midpoint within the relative range). The signal has a uniform probability of being within that range, so dividing by $\sqrt{12}$, the signal uncertainty is 0.2 % [17]. Therefore, the nominal value of C_{ARM} is 1.0 with a relative standard uncertainty of 0.002.

3.1.2 Reference mirror reflectance

The reflectance standards used in these experiments are calibrated by NIST. The uncertainty in reflectance is 0.5 % [18]. Therefore, the nominal value of ρ_{ref} is 0.97 with a relative standard uncertainty of 0.005.

3.1.3 Sample gap and alignment

The effects of sample gap changes and misalignment are similar to those for the reference mirror—changes in this affects where the location from which illumination occurs on the integrating surface is, and thus the resulting throughput of the reflection. Currently, the best approximation of the effect of sample alignment is from measurements taken with a diffuse reflective standard sample (pressed polytetrafluoroethylene PTFE) and a sample with a diffuse-directional reflective character between perfectly specular and diffuse (brushed stainless steel). The results of gap change between the reflectance standards and the laser window (with the reflectometer floor located at 219.3 mm from the laser window), is shown in Figure 5.

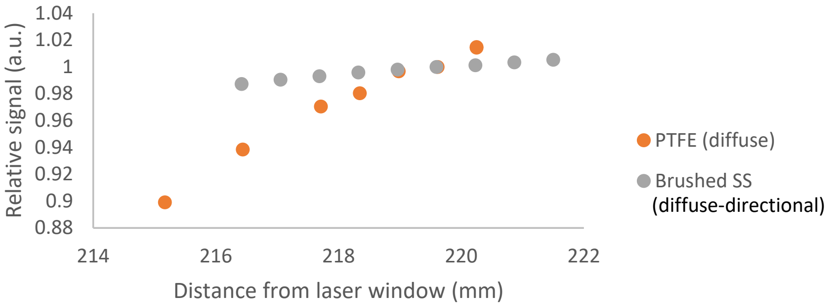

Figure 5. Relative signal measured as a function of the location of two reflectance standards relative to the laser window, with the floor of the reflectometer located at 219.3 mm

The samples of high-purity Ni for generating laser-induced meltpools are aligned with the laser focus as described above, but with a tolerance of ±20 µm (vertical misalignment is generated by surface non-flatness, general roughness, and tilt). Rotational misalignment is again assumed to be negligible. Assuming location within ±1 mm as above, and that the diffuse reflectance standard is representative of the maximum change in reflectance of a real sample (e.g., stainless steel reflectance sample, or laser-induced melt pool), the relative range of signal is about 5.0 % (or equivalently, about ±2.5 %

from midpoint of the range). Assuming a uniform distribution within this range, the relative standard uncertainty of C_{AS} becomes 1.5 %. Therefore, $C_{AS} = 1.0 \pm 0.015$.

3.1.4 Sample bidirectional reflectance distribution function

The sample BRDF is a mathematical function that describes how the hemispherical illumination of the sample is reflected and imaged by the directional imaging system. Currently, very little is known or has been measured regarding the reflective character of the laser-metal interaction scene and is an important area for future investigation. In the absence of additional information, the sample BRDF is assumed to have a similar effect to the throughput uniformity (discussed in Section 3.2.1) with no bias. Therefore, $C_{BRDFS} = 1.0 \pm 0.01$. It should be noted that under certain specific (relatively unlikely) circumstances, the sample BRDF could be a dominant uncertainty component.

3.1.5 Summary of sample and reference uncertainties

The uncertainties due to the sample and reference conditions are summarized in Table 1, where C_{ARM}, C_{AS}, C_{BRDFS}, and C_S are defined in Section 2.1. The reflectance of the reference mirror is ρ_{ref}.

Table 1: Summary of uncertainties due to sample and reference conditions

Variable	*Value*	*Units*	*Relative uncertainty (k = 1), (%)*	*Type*
C_{ARM}	1	-	0.2	A
C_{AS}	1	-	1.5	B
C_{BRDFS}	1	-	1.0	B
C_S	0.9975	-	0.5	B
ρ_{ref}	0.97	-	0.5	A

3.2 Nonuniform and incomplete hemispherical illumination

3.2.1 Throughput uniformity

Reflectometer throughput is the ratio of the flux reaching the detector to the input flux from the source. Relative throughput is measured across the integrating surface and reported in arbitrary units. Relative throughput mapping of the inside of the hemisphere quantifies the uniformity of hemispherical illumination of the reflectometer as a whole and allows estimation of the measurement uncertainty. Throughput mapping is performed by placing a photodetector at the entrance port and a gimbal-mounted mirror is located at the sample port. The mirror is aimed at a representative number of locations across the inside of the hemisphere.

As shown in Figure 6, the throughput uniformity of the surface is within ±1.0 % across from about 5° from the vertical to about 80°. Decreased radiance throughput occurs at the imaging port (5° to 15°), at the monitoring diode ports (45°), and increased high angle losses occur opposite to the port at 70° to 90°. The main features and nonidealities of the reflectometer are detected at these locations, and the uniformity around these features is taken as representative of the remainder of the reflective surface. From these results, the throughput uniformity we can assume a negligible bias in the emissivity calculation and the uncertainty is taken to be 1.0 %. Therefore, the nominal value of C_{TU} is 1.0 with a relative standard uncertainty of 0.01.

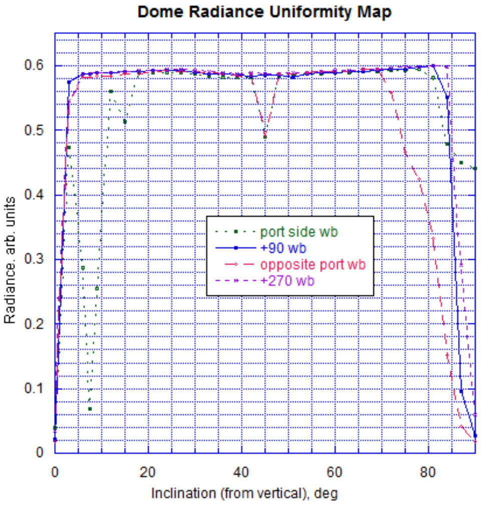

Figure 6. Relative throughput of the hemispherical integrating surface for four orthogonal cross sections. The tests are performed with the specular gold base (wb).

3.2.2 Port losses and high-angle losses

The light loss due to the laser port and base thickness on the first reflection from the sample are measured by comparing the measured signal with a specular silver standard and a diffuse gold standard. On the first reflection, a specular sample does not result in any port loss or high angle loss. In contrast, a perfectly diffuse sample results in both high angle and port losses. After accounting for the reflectivity of the samples, it is found that 2.5 % in intensity is lost for the diffuse sample as compared to the specular sample. The laser-metal interaction scene is likely better represented by a value in between the specular and diffuse cases, so the bias is assumed to be of the average of the losses for the two samples plus or minus half of the difference. Then the nominal value of C_{PL} is 1.013, with a standard uncertainty of 0.013.

The reflective character of the laser-metal interaction scene is a significant unknown and could potentially result in greater port losses and high angle losses than those considered here. Therefore, two approaches have been identified to better quantify the emissivity uncertainty component due to port losses and one approach has been identified for estimating high angle losses.

The first approach to estimating port losses is to reduce the size of the port to as small as possible, which would require a shortened laser scan distance. The relative change in signal compared with the normal port size can then be used to calculate a more representative port loss. The second approach is to add a supplementary light source via a beam splitter directed along the imaging path to add additional light from the port area, which will then be optically integrated in the reflectometer. The additional signal may then be used to better quantify port loss bias and uncertainty.

To estimate high angle losses, a small sample is moved upward through the base of the reflectometer with an adjustable cylindrical baffle surrounding it. The motion of the sample relative to the baffle and reflectometer base and the resulting change in signal intensity will be used to quantify the effect of high angle losses. The high angle losses are expected to be negligible under most circumstances, but the high-angle loss test raises concerns about scattering and absorption in the process plume and how to deconvolve those effects from high-angle loss effects, which must be addressed. Nevertheless, the combined port loss and high-angle loss estimate reported here is should be acceptable under most conditions.

3.2.3 Coating reflectance and diffuseness

Both the reflectance and the specularity of the integrating sphere coating can have an effect on the size of the potential measurement error and resulting uncertainty, with more reflective and more diffuse coatings resulting in more accurate measurements [19,20]. The barium sulfate coating used in this application has a highly diffuse reflectance with a directional-hemispherical reflectance of 0.981 at 850 nm [21]. Therefore, the coating reflectance and diffuseness is expected to have a negligible effect on the accuracy of measurements in the given application and are therefore omitted from Equation (1) and the uncertainty budget.

3.2.4 LED reproducibility

The intensity and spectrum of the illumination LEDs change as the junction temperatures increase within the semiconductor devices. According to the manufacturer's datasheet, the radiant flux output decreases by as much as 35 % when the LED case temperature changes from room temperature to 100 °C, and the peak wavelength shifts by 13 nm [22]. The absolute shift in output and wavelength are not of high importance alone, but the reproducibility of the output from the sample and the reflectance standard introduces an additional uncertainty component in the emissivity measurement. We have tested reproducibility of the LED illumination previously and estimate that it induces an uncertainty of 1.5 % in the LED correction factor C_{LED}. Stochastic non-reproducibility does not induce a bias. Hence, the nominal value of C_{LED} is 1.0 with a relative standard uncertainty of 0.015.

The uncertainty component associated with LED reproducibility can be measured with repeat tests using the reflectance standard while recording the signal received by the imager. This uncertainty component can also be reduced with combined triggering of the LEDs with triggering of the imager and laser scanning system.

3.2.5 Summary of uncertainties due to nonuniform and incomplete illumination

The uncertainties associated with nonuniform and incomplete illumination are summarized in Table 2, where C_{TU},C_{PL}, and C_{LED} are defined in Section 2.1.

Table 2: Summary of uncertainties due to nonuniform and incomplete illumination

Variable	*Value*	*Units*	*Relative uncertainty (k = 1), (%)*	*Type*
C_{TU}	1	-	1.0	A
C_{PL}	1.013	-	1.3	B
C_{LED}	1	-	1.5	B

3.3 Directional imaging

Nine sources of uncertainty in the FPA signal are considered in addition to the aforementioned measurement uncertainty components in the measurement equation (Equation (1)), as follows:

1. Out of field scatter from sample port surfaces
2. Polarization effects
3. Linearization uncertainty
4. Uncertainty due to stray light and blooming correction
5. Uncertainty due to image smoothing
6. Uncertainty due to point spread function determination
7. Uncertainty due to deconvolution operation
8. Uncertainty due to deconvolved signal variability caused by process variability and imager noise
9. FPA nonuniformity

This section describes the uncertainty of the corrections, as well as the resulting uncertainty of the measured emissivity.

3.3.1 Out of field scatter from sample port surfaces

The edges of the reflectometer sample port are a non-ideality that may cause out of field scatter that may be detected as erroneous signal by the directional imaging system. This effect is expected to be small, and in the absence of experimental data, it is assumed to induce an increase of signal bias of 0.25 % with a (Type B) relative standard uncertainty of 0.5 %. Therefore, $C_S = 0.9975$ with a relative standard uncertainty of 0.005. The port surfaces may be coated with absorptive (black) paint in the future to reduce the associated bias and uncertainty of out of field scatter.

3.3.2 Polarization effects

Polarization may significantly alter the throughput uniformity of integrating spheres and should be considered as a potential uncertainty component [23]. The integrating hemisphere uses 36 symmetrically distributed LED sources for illumination, which means that the illumination is very unlikely to have a preferred polarization illumination of the sample or reference mirror. The samples used for meltpool generation are randomly sanded, making the un-melted material unlikely to have preferred polarization reflectivity. The Ag reference mirror has very low polarization at 850 nm and at the 8° from normal reflection angle, making reference mirror polarization bias unlikely. Finally, nearly all practically useful data are obtained on molten or re-solidified sample surfaces, which have potential for polarizing effects, but this has not yet been measured. In the future, a series of tests will be performed with varying scan direction and rotation of the randomly sanded sample to quantify polarization effects. Currently, measurement bias and uncertainty of emissivity due to polarization is assumed to be negligible.

3.3.3 Imager signal linearization uncertainty

The primary instrument used for the emissivity measurement uses a CMOS FPA. The imager has a 1024 pixel × 1024 pixel, 12-bit dynamic range FPA. In this work, all data are obtained with a shutter speed of 98.3 µs. The transient pixel noise and nonuniformity across the FPA are sources of signal variance and therefore contribute to the measurement uncertainty. Furthermore, the nonlinearity of the signal with the incident flux requires correction by calibration to a known-flux source, which introduces an additional uncertainty component for the signal. Each of these are discussed in this section.

In order to evaluate the uncertainty due to transient pixel noise, the HTBB is used as a stable source. The imager is outfitted with an long working distance microscope lens body and an objective lens focused at the HTBB aperture to generate uniform and steady irradiance of the FPA. The majority of the signal variation is therefore due to electronic noise. The nonuniformity of the blackbody irradiation is considered to be negligible in this evaluation. The GainCal function in the imager software is used for flat-fielding (or, nonuniformity correction) to reduce the natural optical vignetting and improve the pixel uniformity across the FPA.

3.3.3.1 Pixel noise and FPA nonuniformity

Samples of 100 images are taken with varying HTBB set-point temperatures. Then the standard error (SE) of the mean DL of each pixel is determined from the 100-image sample. Use of the dynamic range is limited to between 300 DL and 3800 DL, which results in a transient pixel noise relative standard uncertainty component of the signal of 0.3 %.

Images from the linearization against the HTBB are used to measure the FPA nonuniformity. The pixel average is taken from the 100-image sample, resulting in a calibration image with the average DL of each pixel. The standard deviation across the pixel array is then determined to evaluate the nonuniformity across the FPA. The resulting frame standard deviation of the pixel average is expressed as a percentage of the DL. Use of the dynamic range is limited to between 300 DL and 3800 DL, which results in an FPA nonuniformity relative standard uncertainty component of the signal of 1.0 %. The combined transient pixel noise and FPA nonuniformity relative standard uncertainty is then 1.05 %.

3.3.3.2 Spectral variable uncertainties

In order to solve Equation (3), the lens spectral transmission $\tau_\lambda^{obj}(\lambda)$, filter spectral transmission ($\tau_\lambda^{filt}(\lambda)$), FPA spectral responsivity (r_λ^{FPA}), and HTBB temperature (T_{BB}) must be measured. Inspection of Equation (3) shows that the absolute biases of the spectral quantities will simply change the value of $C_{cal,BB}$, which does not affect its uncertainty. Therefore, deviation in the magnitude of the spectral values across the waveband of interest are used to evaluate the uncertainty of $C_{cal,BB}$.

The measured spectral responsivity of the FPA is measured with an instrument with a conservatively estimated relative standard uncertainty of 2.0 %. The worst case of the value varying from its minimum value of $0.98r_\lambda^{FPA}(\lambda)$ to $1.02r_\lambda^{FPA}(\lambda)$ from 830 nm to 870 nm is then used to evaluate the change in $C_{cal,BB}$. Because of the wide and uneven spectral spacing of the data points, interpolation of the values is used. All values of the spectral quantities used in Equation (3) are evaluated at the same uniformly gridded values of λ, and their product is integrated using trapezoidal summation.

The measured spectral transmission of the combined 850 nm ± 20 nm bandpass filter and the 1000 nm laser cutoff filter is also measured, and the spectrometer used to measure the transmission is known from previous evaluations to have a relative standard uncertainty of 0.5 %. The worst cases of the value varying from its minimum value of $0.995\tau_\lambda^{filt}(\lambda)$ to $1.005\tau_\lambda^{filt}(\lambda)$ from 830 nm to 870 nm is used to evaluate the change in $C_{cal,BB}$. Finally, the transmission of the camera lens assembly is conservatively assumed to have a relative standard uncertainty of 2.0 % across the waveband of interest.

3.3.3.3 Wavelength and radiance uncertainties

The spectrometer used to measure the transmission of the filters has a spectral resolution of 0.5 nm, which we use as the uncertainty in λ. The uncertainty of the blackbody radiance ($L_\lambda^{BB}(\lambda)$), defined in Equation (6), has been determined to be 0.6 % and which will be described in detail in a forthcoming publication.

$$L_\lambda^{BB}(\lambda) = \frac{c_{1L}}{\lambda^5\left[exp(\,c_2/(\lambda T_{rad,BB})) - 1\right]} \tag{6}$$

3.3.3.4 Combined uncertainty due to linearization

The combined uncertainty of the calibration constant is calculated by first evaluating Equation (3) with each variable in its worst case, or maximum uncertainty. This establishes the sensitivity of the calibration constant to each uncertainty component. Then, the sum-square of all the uncertainty components is taken to evaluate the combined uncertainty of the calibration constant. These results are shown in Table 3.

Table 3. Combined signal and linearity uncertainty components of the calibration constant $C_{cal,BB}$.

Variable	Uncertainty (k = 1)	Type	Change from nominal value	Change in $C_{cal,BB}$ (%)
$\tau_\lambda^{filt}(\lambda)$	0.5 %	B	Increasing with λ	-0.01
			Decreasing with λ	0.01
$\tau_\lambda^{CF1}(\lambda)$	2.0 %	B	Increasing with λ	-0.05
			Decreasing with λ	0.05
$r_\lambda^{FPA}(\lambda)$	2.0 %	B	Increasing with λ	-0.05
			Decreasing with λ	0.05
λ	0.5 nm	A	Absolute increase	-0.48
			Absolute decrease	0.48
$L_\lambda^{BB}(\lambda)$	0.6 %	A/B	Absolute increase	-0.6

			Absolute decrease	0.6
$S(T)_{cal}$	1.05 %	A	Absolute increase	1.00
			Absolute decrease	-1.00
			Combined uncertainty of $C_{cal,BB}$	**1.25**

3.3.4 Stray light and blooming

The range-normalized root mean square error (RMSE) of the curve fit applied to the erroneous signal due to stray light and blooming is 0.7 %. This is used as the uncertainty of the curve fit to the stray light and blooming signal matrix, combined with the uncertainty due to noise in the knife-edge measurements. As described in Section 3.3.3.4, the uncertainty of the signal linearization operation is 1.25 % and this is taken as an additional uncertainty. The combined uncertainty of the stray light and blooming correction is then 1.4 % of the DL of each pixel of the erroneous signal matrix, which is calculated for the uncertainty of each pixel of the stray light and blooming corrected image.

3.3.5 Image smoothing

As stated previously, it is confirmed that the smoothing operation does not introduce a systematic bias. This is demonstrated by subtracting the original image from the smoothed image and averaging across the frame, resulting in a negligible bias of less than 1% of a digital level per pixel. Therefore, the uncertainty due to image smoothing is taken to be negligible.

3.3.6 Point spread function uncertainty

Uncertainty in the PSF is due to uncertainty in establishing the ESF via curve fitting of the empirical data. The linearization operation of the data incurs an initial signal uncertainty of 1.25 %. The curve fit also incurs an uncertainty of 2.3 %, which is the RMSE normalized by the range. In order to establish a PSF at the uncertainty extremes, the function is scaled in the positive and negative direction by the combined uncertainty of 2.6 %. From this, new constants a_1, b_1, a_2, and b_2 of Equation (5) are found.

The method described in Section 2.3.4.3 is then used to establish two PSF arrays at both extremes of uncertainty due to the ESF. The images are then deconvolved using the method described in Section 2.3.4.4 with each PSF. The PSF that caused the larger average pixel signal variation from the nominal image is taken as the PSF for uncertainty evaluation, although the change in signal due to either PSF is nearly symmetric. The average deconvolved image produced by the uncertainty of the PSF is then subtracted from the nominal average deconvolved image to establish an uncertainty matrix due to error in the PSF determination.

3.3.7 Deconvolution

The Richardson-Lucy algorithm is among the most robust deconvolution algorithms, but it is an iterative process designed to converge on the most likely reconstructed signal values [24,25]. Conversely, convolution is a destructive forward process that can be done with very little error. Therefore, in order to estimate the uncertainty of the deconvolution, the deconvolved image is convolved and subtracted from the unconvolved image and the magnitude of th signal discrepancy is taken as a conservative estimate of signal uncertainty due to the deconvolution operation at each pixel.

Deconvolution error also occurs due to the saturated region of the image, in which the signal values are no longer proportional to the local radiant flux. In order to reduce the error associated with deconvolution of false signal values, a border of five pixels around the saturated region are discarded. The value of five pixels is chosen because that is the radius within which about 97 % of the PSF volume is contained, and therefore false signal values should have a negligible effect outside of that radius. In future work, signal values may be extrapolated to five pixels within the saturated region to reduce the number of discarded pixels. Or, a further improvement can be implemented by measuring the meltpool at varying shutter speeds to increase the useful dynamic range of measurement, eliminating any saturated signal values.

3.3.8 FPA nonuniformity

As described in Section 3.3.3.1, the FPA nonuniformity is measured after a digital nonuniformity correction and exposure to a uniform source. The pixel average is taken from the 100-image sample, resulting in a calibration image with the average DL of each pixel. The standard deviation across the pixel array is then taken as an evaluation of the nonuniformity across the FPA. The resulting frame standard deviation of the pixel average is expressed as a percentage of the DL. Use of the dynamic range is limited to between 300 DL and 3800 DL, which results in an FPA nonuniformity relative standard uncertainty component of signal of 1.0 %.

3.3.9 Process variability and signal noise

Each image of the central 30 images of the test is deconvolved, and an average of each pixel is taken along with the standard error of the mean of each pixel. The standard error of the mean of each deconvolved pixel is then used as an uncertainty component of the signal due to the physical process variability combined with electronic image noise.

3.3.10 Combined signal uncertainty

The measurement approach requires recording of image data in four steps. The meltpool is recorded with the inline imaging system with the LEDs off, then repeated with the LEDs on. Similarly, the reference mirror is imaged with the LEDs off, then repeated with the LEDs on. With meltpool tests, the frame rate and length of the scan produced image sets containing 80 images. The meltpool requires some "development length" at the initiation of laser melting, and similarly has a cooldown period once the laser power is turned off. Because of these considerations, the first 25 images and last 25 images are not used, and the central 30 images recorded during steady melting are used.

As described in the preceding sections, six sources of uncertainty components in the signal have been identified and quantified. The first uncertainty component is due to the signal linearization operation—it should be noted that this uncertainty is estimated based on a 1.25 % uncertainty in signal values after deconvolution, which inherently assumes that the linearization uncertainty transforms linearly through the deconvolution operation. The second component is incurred by the uncertainty of the stray light and blooming correction operation. The third component is due to the uncertainty in the calculation of the PSF for the deconvolution. The fourth component is based on the discrepancy between the re-convolved deconvolved image compared with the image prior to deconvolution. The fifth component is due to the basic FPA nonuniformity across the field of view. The sixth and final component is the combined effect of signal fluctuation

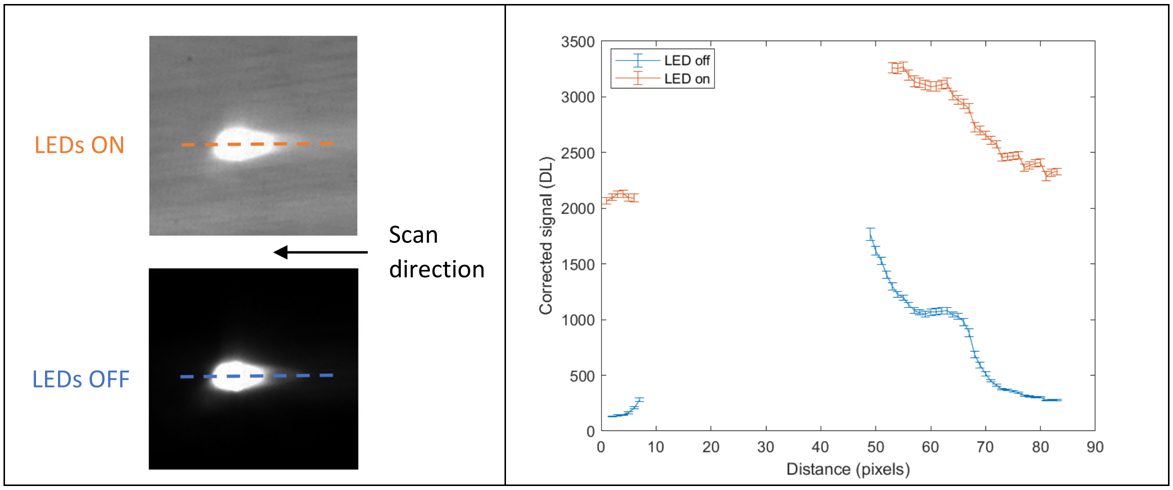

Figure 7. Image data of the meltpool generated with 99.998% Ni with the LEDs on (top left), the LEDs off (lower left), and the associated plot of the corrected signal cross-sections and uncertainties at the location of the dashed lines in the images on the left (right). The data parameters included a laser power of 250 W, scan speed of 1000 mm/s, spot size of 65 µm, image rate of 10000 Hz, and 98.3 µs shutter speed.

due to process variability combined with the electronic noise. Each of the six uncertainty components are calculated independently at each pixel to determine the local uncertainty of the signal of each pixel. The root sum-squares of the six components at each pixel is then evaluated to determine the resulting combined signal uncertainty.

Image data of the reference mirror (with the LEDs on and off) do not require stray light and blooming correction or deconvolution. Therefore, the combined uncertainty of the reference mirror images only has three components: linearization uncertainty, FPA nonuniformity, and pixel noise.

Figure 7 shows meltpool images with the LEDs off, then on, as well as central cross-sectional profiles of the corrected signal and associated uncertainty. The test parameters included a laser power of 250 W, scan speed of 1000 mm/s, spot size of 65 µm, image rate of 10000 Hz, and 98.3 µs shutter speed. The meltpool is generated with 99.998% Ni. As described previously, the signal uncertainty varies with each pixel, but typical uncertainty values are in the approximately 2 %. The solidification plateau is evident from pixel 58 to pixel 64 with the LEDs on and off in Figure 7.

4. EMISSIVITY AND UNCERTAINTY OF A HIGH-PURITY NICKEL MELTPOOL

As stated previously, the test parameters included a laser power of 250 W, scan speed of 1000 mm/s, spot size of 65 µm, image rate of 10000 Hz, and 98.3 µs shutter speed, with the meltpool generated in 99.998% Ni. The resulting emissivity values are shown in Figure 8a and the associated relative standard uncertainty is shown in Figure 8b. Figure 8c shows a central cross-sectional profile of emissivity and uncertainty along the meltpool with nose on the left and tail on the right.

Starting with Figure 8a, it can be observed that the highest emissivity values of more than 0.42 occur near the hotspot. This is likely caused by the depression in the liquid metal generated by a vapor jet emanating from the laser-metal interaction area and the resulting recoil pressure on the liquid surface. The resulting depression in the molten metal becomes a trap for illumination light by multiple reflections, and therefore decreases the local reflectivity, increasing the local emissivity. Intermediate emissivity values of about 0.4 occur in front and to the left and right of the hotspot area in Figure 8. These areas have not been melted by the laser heating, and so the original surface finish of 320 grit sandpaper grinding is maintained. The lowest values of emissivity, below 0.38, occur at the tail of the meltpool where the metal is liquid or recently solidified. These areas that have transitioned to liquid (and/or back to solid) generate more reflective surfaces because surface grinding marks have been eliminated, resulting in lower emissivity. The highest relative standard uncertainty of emissivity also occurs in the tail, which is due in large part to the uncertainty associated with deconvolution in this area of high signal gradients transverse to the meltpool.

The location of the solidification plateau is evident in Figure 7 from pixel 58 to pixel 64, which corresponds to a distance of 350 µm to 385 µm in Figure 8c. The measured value of near-normal spectral emissivity near the melting temperature (1455 °C) of 99.998% Ni is 0.36 with standard relative uncertainty of about 7 %. Published data on similar material at 1491 °C resulted in normal spectral emissivity of about 0.36 at 850 nm [26]. Therefore, under the conditions of comparison, the emissivity measurement approach developed here agrees with published values.

5. CONCLUSIONS AND FUTURE WORK

A unique high temperature reflectometer has been successfully implemented and characterized. The developed reflectometer is, to our best knowledge, the first to use an integrating hemispherical illumination setup, which has proven to be a practical approach. The high-intensity hemispherical illumination (850 nm band) used in this study produces an apparent radiance temperature of the target (with emissivity of 0.5) equal to 1705 °C, which allows for reflectometry of high temperature targets that produce significant self-emission.

This high temperature reflectometer at the NIST AMMT laboratory, with support of the TEMPS optics system and imager, facilitates the measurement of the local spectral directional emissivity, which further facilitates measurement of local surface temperatures of meltpools generated by the laser powder bed fusion process. No performance degradation of the reflectometer is observed due to damage by the high-intensity reflected laser light from the laser-melting process or from contamination by laser-melting process byproducts. Spatial distributions of the emissivity and emissivity uncertainty, of

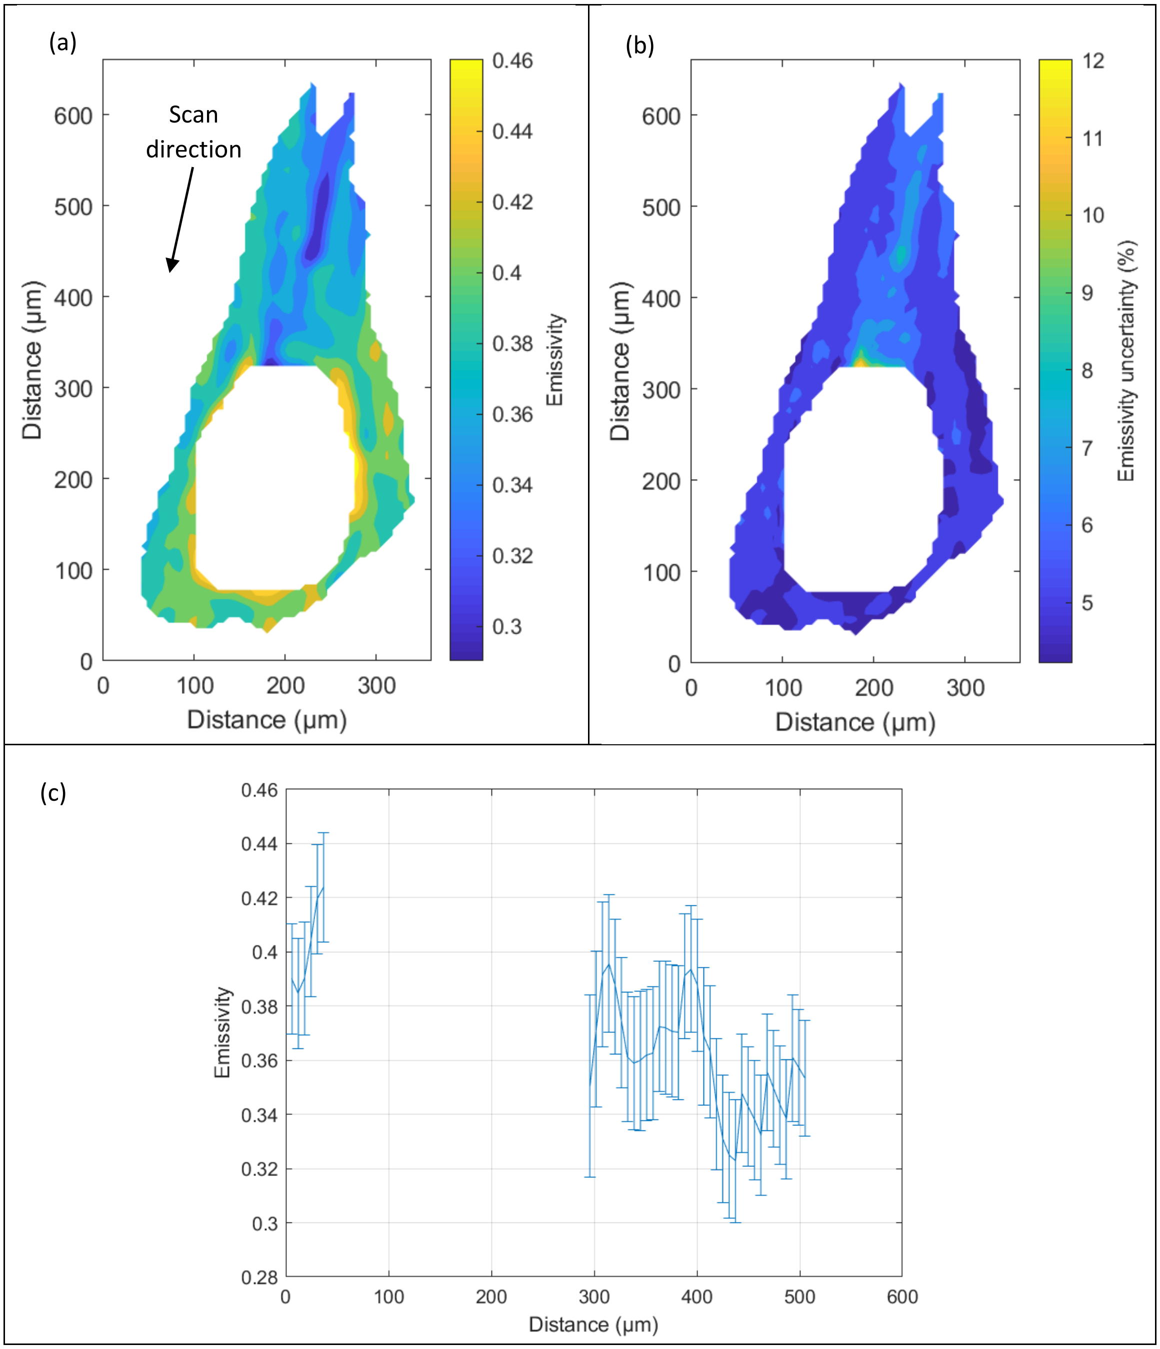

Figure 8. (a) Emissivity map of a meltpool, (b) relative standard uncertainty of the emissivity map, and (c) the central cross-sectional profile of the emissivity and the uncertainty along the meltpool with a nose on the left and a tail on the right. The data parameters included a laser power of 250 W, a scan speed of 1000 mm/s, a spot size of 65 µm, an image rate of 10000 Hz, and a 98.3 µs shutter speed with a 99.998% Ni plate.

a laser-induced meltpool of high-purity nickel, are presented. Some measurement uncertainties were estimated (Type B) in this work, but approaches are identified to better quantify the uncertainty values in the future. The measured emissivity values are found to be in good agreement with literature values at the melting point of high-purity nickel.

Due to the highly non-uniform image scene of a laser-induced meltpool, this investigation focused in part on signal processing, including signal linearization and deconvolution, and the uncertainty induced by those processing operations. Image deconvolution is found to significantly accentuate the solidification plateau of the meltpool due to the high local signal gradients, although the effect generally cancels out in the emissivity measurement equation due to an approximately equivalent effect of deconvolution with images taken with and without hemispherical illumination. Nevertheless, the current results indicate that signal processing, including deconvolution, has important ramifications for the measurement of thermodynamic surface temperatures. Approaches for estimating uncertainties associated with stray light and blooming correction, as well as deconvolution have been identified and implemented in this work.

Several hardware improvements may be implemented in the future to improve the utility of the emissivity measurement approach described here. The current reflectometer configuration uses continuous illumination by high intensity LEDs at 850 nm. The LEDs are modularized and can be changed if necessary, for measurement in other spectral bands. LEDs with shorter wavelengths will enable measurement of equivalent radiance temperatures of the probing light up to 2650 °C (for a 405 nm band illumination with a target emissivity of 0.5). Future hardware improvements also include the use of pulsed narrow band sources to increase the temperature range further, use of a thin bottom to increase the angular range of the illumination, adding the ability to translate the reflectometer, as well improvement of the shield gas arrangement to be able to work with powders. Future research also includes more detailed quantification of the port loss effects and other sources of uncertainty, especially if lower levels of uncertainty are needed. Finally, quantification of the measurement bias and uncertainty induced by laser-melting byproduct effects, such as scatter and diffraction of probing and/or reflected light by the metal vapor and condensate, will be a topic of future research.

ACKNOWLEDGEMENTS

The authors wish to thank Vladimir Khromchenko of NIST Physical Measurement Laboratory (PML) and Daniel Cardenas-Garcia of the National Metrology Center of Mexico for their work in characterizing the reflectometer. The authors also wish to thank Steve Grantham of NIST PML for his work on design and implementation of the reflectometer and LED power control. The authors further wish to thank Ivan Zhirnov formerly of NIST PML for his work in evaluation of sample/mirror alignment effects and taking of experimental data. The authors finally wish to than Brandon Lane of NIST Engineering Laboratory for his technical review of this content.

Abstract: We present our measurements of the detection efficiency of free-space and fiber-coupled single-photon detectors at wavelengths near 851 nm and 1533.6 nm. We investigate the spatial uniformity of one free-space-coupled silicon single-photon avalanche diode (SPAD) and present a comparison between fusion-spliced and connectorized fiber-coupled single-photon detectors. We find that our expanded relative uncertainty for a single measurement of the detection efficiency is as low as 0.7 % for fiber-coupled measurements at 1533.6 nm and as high as 1.8 % for our free-space characterization at 851.8 nm. © 2020 The Author(s)

Future Optical Quantum Networks will need components based on single-photon quantum technologies and those components will require characterization. We start with single-photon detectors, which in turn can be used to characterize other quantum network components such as single-photon sources, fiber losses, network switches, etc.

We measure detection efficiency using a calibrated attenuation stage and a calibrated optical power meter as shown in Fig. 1(a) [1]. Laser power is first roughly set using a variable fiber attenuator (VFAinput) and then sent to a splitter/attenuator unit, which has a highly attenuated output and high-light-level monitor. The ratio of the output to the monitor (Rout/mon) is about 10^{-5} and is measured using an optical power meter (PM) and monitor optical power meter (PMmon). Both, PM and PMmon, require a nonlinearity (relative) calibration, whereas only PM requires an absolute responsivity calibration. Key to the measurements are the transmittance of the splitter/attenuator unit and the output-to-monitor ratio of the splitter/attenuator unit. Both are determined from the fiber beam splitter (FBS) splitting ratio and the attenuation of VFA, using the power meter and the monitor power meter. In addition, this method relies on the stability of the splitter/attenuator unit's output-to-monitor ratio, the polarization and wavelength of the light versus time, and the independence of the output-to-monitor ratio with input optical power. We verify each of these either during the measurement or by prior characterization.

Error bars represent the extracted standard uncertainties (*k*=1) for each measurement. (c)-(d): Summary of measurements for fiber-coupled detectors (c) V23172, V23173, and PD9D at 851.8 nm and (d) NS233 at 1533.6 nm. For detector NS233, fusion splicing and FC/PC connectors were used to connect the DUT fiber to the output of the FBS as indicated. Error bars are the extracted standard uncertainties (*k*=1) of each measurement

Gerrits, Thomas; Migdall, Alan; Bienfang, Joshua; Lehman, John H.; Nam, Sae Woo; Slattery, Oliver T.; Splett, Jolene D.; Vayshenker, Igor; Wang, Chih-Ming. "Calibration of free-space and fiber-coupled single-photon detectors." Paper presented at Quantum 2.0 Conference. September 14, 2020 - September 17, 2020.

Detection efficiency results are shown (Fig. 1(b)) for a free-space-coupled silicon single-photon avalanche detector (SPAD) measured in two modes. One using a continuous wave (CW) and another using a mode-locked Ti:sapphire laser. Detection efficiency (DE) is measured at a range of detector count rates so that the DE can be determined at 1 cnt/s and 10^5 cnt/s. Setup stability and repeatability is achieved for the extracted detection efficiencies at the two rates of 1 cnt/s and 10^5 cnt/s (Fig. 1(b)).

The CW laser results show a larger variation in the extracted DE at both count rates. The spatial response of the SPAD using the CW and Ti:sapphire laser, measurements are also shown. The CW laser results show fringes in the spatial response. Thus, it will have higher sensitivity to slight spatial misalignments than for the measurements made with the Ti:sapphire laser.

Figure 1(c) shows the extracted detection efficiencies at 10^5 cnt/s of three fiber-coupled detectors, two SPADs: V23172 and V23173 and one superconducting nanowire single photon detector (SNSPD): PD9D at a wavelength of 851.8 nm. The DEs for both SPADs were determined with an FC/PC fiber connector at the output fiber of the FPC, whereas the SNSPD's DE was determined by fusion splicing the detector fiber. Good setup reproducibility is observed for all three detectors. Figure 1(d) shows the calibration results of an SNSPD optimized for 1550 nm (NS233) at a measurement wavelength of 1533.6 nm. The DE of NS233 was determined with an FC/PC fiber-to-fiber connector union and by fusion splicing the detector fiber to the output fiber of the FPC. The measured extracted DE at 10^5 cnt/s through a fusion splice is higher than that measured through an FC/PC connector, as expected. The repeatability between individual runs for both cases is comparable to the repeatability achieved for the 851.8 nm fiber-coupled measurement.

Table 1. Summary of results for all measured single photon detectors. Quoted are the photon delivery method (fiber-coupled, free-space, Ti:sapphire laser, CW laser, fusion spliced, connectorized, direct fiber connection), mean DEs at 10^5 cnt/s, the 95 % coverage intervals and the relative expanded uncertainties (k=2).

detector	CW	Ti:sapphire	Free-space	Direct fiber	connectorized	Fusion-spliced	DE at 10^5 cnt/s	95 % cov. int.	rel. exp. unc. (%)
NIST8103		x	x				0.5532	[0.5449, 0.5615]	1.5
NIST8103	x		x				0.5490	[0.5397, 0.5587]	1.8
V23172	x			x			0.5811	[0.5708, 0.5911]	1.8
V23173	x			x			0.5821	[0.5735 0.5911]	1.6
PD9D	x					x	0.9178	[0.9066, 0.9292]	1.1
NS233	x				x		0.8921	[0.8859, 0.8996]	0.73
NS233	x					x	0.9234	[0.9171, 0.9298]	0.70

Table 1 summarizes the results of this work for all detectors at a count rate of 10^5 cnt/s. The DE and 95 % coverage intervals were calculated with the NIST consensus builder [2] and linear opinion pooling for the individual measurement outcomes for each detector. Relative expanded uncertainties as low as 0.70 % are achieved in the case of a fiber-coupled SNSPD at 1533.6 nm. Whereas for the free-space measurements at 851.8 nm, the relative expanded uncertainty is 1.8 % with a CW laser. The main source of uncertainty for the free-space measurements is the uncertainty in the detector response due to laser-beam-detector alignment. For all-fiber-coupled detectors this uncertainty is not relevant but is replaced with a connector and fiber-end reflection-loss uncertainty. In this study, we were not able to compare several FC/PC connectors to establish an uncertainty associated with different commercially available fiber connectors. However, we believe that for many different FC/PC connectors the loss uncertainty will be larger than our overall uncertainty budget. For the NS233 detector, we observe a ≈3.5 % lower system DE than when splicing the fibers. In the extreme case, an FC/PC connection may have very low losses (close to 0 %). Therefore, we speculate that this measurement already reveals a variation of at least 3.5 % in the extracted DE for the FC/PC connector method.

A DEEP NEURAL NETWORK MODEL FOR LEARNING RUNTIME FREQUENCY RESPONSE FUNCTION USING SENSOR MEASUREMENTS

ABSTRACT

The frequency response function (FRF), defined as the ratio between the Fourier transform of the time-domain output and the Fourier transform of the time-domain input, is a common tool to analyze the relationships between inputs and outputs of a mechanical system. Learning the FRF for mechanical systems can facilitate system identification, condition-based health monitoring, and improve performance metrics, by providing an input-output model that describes the system dynamics. Existing FRF identification assumes there is a one-to-one mapping between each input frequency component and output frequency component. However, during dynamic operations, the FRF can present complex dependencies with frequency cross-correlations due to modulation effects, nonlinearities, and mechanical noise. Furthermore, existing FRFs assume linearity between input-output spectrums with varying mechanical loads, while in practice FRFs can depend on the operating conditions and show high nonlinearities. Outputs of existing neural networks are typically low-dimensional labels rather than real-time high-dimensional measurements. This paper proposes a vector regression method based on deep neural networks for the learning of runtime FRFs from measurement data under different operating conditions. More specifically, a neural network based on an encoder-decoder with a symmetric compression structure is proposed. The deep encoder-decoder network features simultaneous learning of the regression relationship between input and output embeddings, as well as a discriminative model for output spectrum classification under different operating conditions. The learning model is validated using experimental data from a high-pressure hydraulic test rig. The results show that the proposed model can learn the FRF between sensor measurements under different operating conditions with high accuracy and denoising capability. The learned FRF model provides an estimation for sensor measurements when a physical sensor is not feasible and can be used for operating condition recognition.

1. INTRODUCTION

Frequency response functions (FRFs), defined as the ratio between input and output spectra, describes the steady-state relationship between each possible sinusoidal input and the corresponding output under zero initial conditions for linear time-invariant (LTI) systems. Learning FRFs between system inputs and outputs is important for system identification and control. An accurate FRF can help with condition-based maintenance and system response prediction of mechanical systems as it models the system dynamics and can be used to monitor system parameters. FRFs are often estimated analytically or obtained experimentally. However, in certain dynamic operations, the FRF can be difficult to predict or obtain due to experimental difficulties, unsteady operating conditions, and mechanical noise. For example, the FRF is often measured between the dynamic force at the tool tip and the dynamic response measured on a stationary point on milling machine tools, such as the spindle headstock. Since the cutting tool is rotating, the transmission path between the tool tip and the spindle headstock involves a flexible component (the cutting tool) and a moving contact surface. The source excitation spectrum from the tool tip can be modulated by bearing ball pass frequencies and low-pass filtered by the flexible component along the transmission path. One frequency component can affect the harmonic frequency components at another measurement point due to mechanical modulation. Also, the structural resonance frequencies can serve as carrier frequencies that shift the original excitation frequency components to a new

Qu, Yongzhi; Vogl, Gregory W.; Wang, Zechao. "A Deep Neural Network Model for Learning Runtime Frequency Response Function Using Sensor Measurements." Paper presented at ASME 2021 16th International Manufacturing Science and Engineering Conference (MSEC 2021), Cincinnati, OH, US. June 21, 2021 - June 25, 2021.

frequency. Therefore, in practical systems, especially with relative movement involved between input and output points, the frequency components can affect one another.

Because the FRFs may be difficult to determine for complex systems with moving parts and varying operating conditions, this paper proposes to learn a ***runtime FRF*** from sensor measurements that would model the previously mentioned factors with a data-driven black box model. Such a method would have applications for manufacturing systems in which sensor-based systems are needed to decrease machine downtime and increase product quality and enrich the knowledge of complex manufacturing processes. For example, it is typically not possible to monitor real-time cutting forces during milling processes within machine tools. However, as a future application, by using runtime FRFs to relate force signals to on-machine sensor signals with known cutting force before cutting, on-machine sensors could be set up to monitor cutting forces during real-time machining for quality control purposes.

Note that the *generalized FRF* has been used to define FRFs for nonlinear systems under nonzero initial conditions, especially for nonlinear Volterra systems [2][3]. Generalized FRFs include the effects on the output response from previous inputs. The term of ***runtime FRF*** in this paper is ***different from*** existing definitions for *generalized FRF*. As argued in the above section, this work assumes that in general mechanical systems, one input frequency component may be related and can be used to calculate a different frequency component in the output spectrum. In the generalized runtime FRF, these cross-relationships among different frequencies can be learned.

It is generally understood that one wave frequency cannot affect another wave frequency. Hence, the system response at one frequency can only be determined by the same frequency component in the input spectrum. However, for certain mechanical and electrical systems, there are certain conditions needed for this constraint to hold in practical FRF measurements: 1.) The signals are not modulated internally between inputs and outputs; 2.) Sensors for data collection have wide-enough frequency range to capture the significant spectral amplitudes; and 3.) Nonlinearities in the system are insignificant and do not add extra frequency components to the output response. In practical systems, especially for assemblies containing multiple components, the above assumptions may not hold.

To account for all the previously mentioned factors, we propose to learn the ***generalized runtime FRF*** from sensor measurements with a data-driven black box model. The rest of the paper is organized as follows: Section 2 reviews related work for FRFs and vector regression; Section 3 introduces the basic background of encoder-decoder neural networks and presents the methodology; Section 4 provides the experimental setup for the case study; Section 5 presents the results and data analysis; and Section 6 concludes the paper.

2. RELATED WORKS

Existing research on FRF identification can be separated into several categories: physics-based FRF evaluation, experimental data-based FRF estimation, and hybrid methods for FRF identification. Theoretically, FRFs can be obtained analytically from the governing differential equations of the system [1]. Towards this direction, the effects of different factors on the FRF have been studied. For machine tools, the single-point FRF at the tool tip has been widely studied for the identification of chatter-free zones. The effects of rotational speed [5] and nonlinear behavior [6] have been considered for FRF identification. The effect of rotor rub-impact has also been modeled for the analysis of the FRF of rotor systems [7]. For nonlinear systems with fading memories, Volterra-based FRF models can be established when the system parameters are known using Volterra series [4]. However, Volterra models require the complete knowledge of the system parameters for the governing differential equations [3]. In applicable cases, system parameters can be measured offline or calculated using geometric and material parameters. However, for practical mechanical systems, the runtime boundary conditions and system parameters may change due to external loads and dynamic interactions between moving parts. Therefore, accurate estimation of system parameters are often infeasible.

With regards to experimental methods, impact hammer testing and sinusoidal function sweeping-based FRF identification are available in most commercial modal testing systems. Receptance coupling provides a hybrid approach to identify the FRF for assemblies. Several studies have tried to obtain FRFs for coupled mechanical structures with multiple components. For example, Schmitz and Duncan predicted the output frequency response of an assembly of nested components with common neutral axes using the receptance coupling approach [8].

There have been a couple of attempts towards runtime FRF determination. Kushnir proposed to estimate the runtime FRF for a lathe using the measured vibration spectrum at the top plate and spindle headstock [9]. The author took the average of the input and output spectrums under different spindle speeds, and then took the ratio between the averages to get the dynamic FRF. This ratio assumes no interaction among different frequency components in the input and output spectrums. Thenozhi and Tang used a radial basis neural network and support vector machine (SVM) to learn the frequency response function from simulation data [3]. The input space they used for the learning process was set as the system input amplitude and frequency, and learning outputs were set as the amplitudes of frequency response. They built a regression model between the learning inputs and outputs. While their input space is in the space of R^2 (i.e., two dimensions) and output space in R (i.e., one dimension), their learning model learned the output frequency response as OFR = f(a, w), where a is the amplitude and w is the frequency, and OFR is the amplitude of the corresponding output frequency response. Similar to the model in [9], the model in [3] is equivalent to finding the average ratio between input and output spectrums. Once again, this ratio assumes no interaction among different frequency components and one common average model is obtained for all operating conditions.

Therefore, all existing approaches assume that the FRF function is strictly restricted to one input frequency component affecting only the same frequency component in the output response. In this manner, the FRF is linear and cannot include nonlinearities under different operating conditions. The approach proposed in this paper is dramatically different from previous work, as this paper proposes a vector regression algorithm using neural networks in the whole frequency range, which allows the cross-relationships between different frequencies to be established. Since the model is nonlinear and includes interactions between different frequencies, it allows different ratios between input spectrums and output spectrums at different operating conditions. In other words, the model provides a regression relationship between the vector space of input spectrum and output spectrum. Also, this paper uses practical sensor measurements from mechanical systems with potentially low signal-to-noise ratios. It can provide a robust approach for real-time classification of operating conditions using a real-time input spectrum. As a general vector regression-based FRF identification approach, it can be applied to any system input and output spectrum measurements.

Next, related works in deep learning for vector regression will be reviewed. An encoder-decoder neural network is a special type of neural network that features dimension reduction during the encoding process and signal reconstruction during the decoding process. The most common application of encoder-decoder networks is an autoencoder, where the training input and training output are identical. An autoencoder is often used for feature extraction as an unsupervised algorithm for dimension reduction purposes and has seen many applications [10]. Supervised and semi-supervised autoencoders have also drawn much research attention for concurrent feature extraction and classification tasks [11]. Lei *et al*. proposed that the autoencoder can be used for regression purposes if the input and output are set with different time series as regularizers [12]. Inspired by Lei's work, this paper reveals an encoder-decoder structure for multivariate vector regression. Lei *et al.* used a supervised autoencoder for the classification task, and the encoding-and-decoding network serves as a regularizer. In this paper, we consider the vectors fed to the outputs of the decoder networks as underlying labels in vector form in the target space of regression. Therefore, the encoder-decoder network will simultaneously learn the mapping relationship as well as the regression tasks for different input-output groups.

An encoder-decoder structure has also been applied to sequence-to-sequence learning for speech recognition [13]. However, the structure used for sequence-to-sequence recognition took a recurrent neural network/long short-term memory (RNN/LSTM) structure to consider time-dependent relationships with a sequential memory mechanism other than an autoencoder-like structure, which does not focus on temporal dependency. While our model shares a similar common ground with sequence-to-sequence models, the proposed approach distinguishes itself from the RNN/LSTM models. The proposed encoder-decoder network aims to learn the intra-class and inter-class spatial relationship between R^N to R^N in vector space, while sequence-to-sequence models aim to model the dependency in temporal space inside the sequence vector and then perform regression tasks in the spatial space. Our model assumes a general regression relationship between two vectors without explicitly considering temporal dependency and therefore the application scenarios are different.

3. BACKGROUND AND PROPOSED METHODS

As illustrated in the Introduction section, we formulated the identification of the generalized runtime FRF as a vector regression problem. The regression can be understood in two levels. The first level is that each frequency component in the output spectrum will be determined by a regression model that takes a vector of the whole input spectrum. The second level is that the regression relationship is learned in the vector space for inputs-outputs pairs under different operating conditions, which can be understood as regression in Hilbert space or function space. Such a regression problem can be solved by a deep encoder-decoder neural network. Next, we introduce encoder-decoder networks and propose a customized model for FRF learning.

3.1 Background Introduction and Proposed Encoder-Decoder Network

An encoder-decoder is a type of neural network that first encodes the inputs to a low dimensional space, and then decodes the data back to high dimensional space. One example of encoder-decoder network is an autoencoder, where the inputs and outputs are the same, and it works as an unsupervised dimension reduction model. A more general form of an encoder-decoder network can take different data as inputs and outputs, and serve as a vector regression model.

In this paper, a partially-tied-weight deep encoder-decoder network for vector regression between the input and output spectrums is proposed. The structure of the deep network is shown in Figure 1. In the proposed structure, tied weights are set for the embedded space learning for both the input spectrum and output spectrum, and an independent output embedding layer is added to allow different coordinates in the embedding space for the inputs and outputs, as shown in the red box in Figure 2. Then, the input and output embedding layers are fully connected to learn the mapping relationship between the input and output embeddings. The number of nodes in each layer are: 200, 100, 50, 50, 100, and 200 with a symmetric layout. Layer 1 and Layer 2 share the same weights with Layer 5 and Layer 4, respectively.

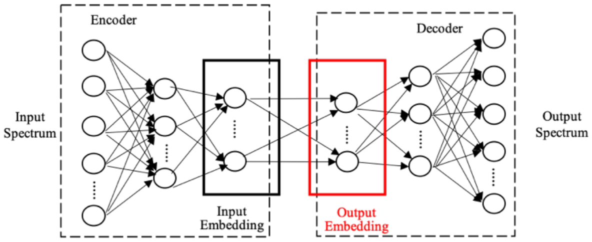

FIGURE 2. PROPOSED ENCODER-DECODER STRUCTURE FOR FRF LEARNING.

The whole network can be represented by the following equations:

$$X_{emb} = f_1(X) \tag{2}$$

$$Y_{emb} = f_2(X_{emb}) \tag{3}$$

$$Y = f_1^{-1}(Y_{emb}), or\ Y_{emb} = f_1(Y) \tag{4}$$

where X is the input of the neural network, Y is the output of the neural network, X_{emb} is the embedded coordinates for X, and Y_{emb} is the embedded coordinates for Y. The proposed encoder-decoder network includes a tied symmetric layer for the learning of input and output embeddings, as well as a fully connected layer from the input embedding to the output embedding, to enable learning of the mapping relationship between the two spectrums.

4. EXPERIMENTAL SETUP

4.1 Test Rig and Sensor Deployments

To validate the proposed FRF learning model, experiments were conducted on a high-pressure hydraulic pipeline system, as shown in Figure 3. For the given hydraulic system, the excitation force comes from the distributed dynamic pressure of the flowing liquid imposed on the inner surface of the pipeline. Measurement of such a distributed dynamic pressure would be physically infeasible. Therefore, in order to measure the excitation force on the pipeline, the dynamic strains on the outer surface of the pipeline were measured with fiber Bragg grating (FBG) sensors. The dynamic strains measured by FBG sensors serve as an indirect measurement of the dynamic pressure inside the pipeline. Using strain sensors for static pressure measurements is a common practice. Dynamic pressure measurements with strain gauges has been recently reported [14]. In this study, since the interested frequency range is about 0 Hz to 1000 Hz, which are the limits of the data collection capabilities, it can be assumed that the strain is linearly related to the dynamic pressure, which is the excitation to the pipeline. Therefore, the strain spectrum was considered to be the input spectrum of the hydraulic system and the FRF learning model, while the vibration spectrum was considered as the output spectrum.

In order to validate the proposed method for learning a generalized runtime FRF under different operating conditions, three sets of experiments were conducted under different operating pressures, namely, 4.62 MPa, 5.65 MPa, or 9.3 MPa. Vibration data and strain data over a section of straight pipeline were collected. A total of about 40 minutes of data were collected. Vibration data were collected using a tri-axial accelerometer and strain data were collected using FBG sensors. There are a total of five sensor measurements: X, Y, and Z accelerations, circumferential strain, and axial strain. For the vibration coordinates, the X axis points down to the ground, the Y axis points axially, and the Z axis points transversely, as shown in Figure 4. The sampling rate for vibration signals is 10240 Hz, and the sampling rate for FBG strains is 2000 Hz. While the sampling frequency for the FBG sensors (limited by the data acquisition system) falls a little short to cover 0 Hz to 1000 Hz, it would not significantly affect our validation process, due to the lower spectral amplitudes near 1000 Hz.

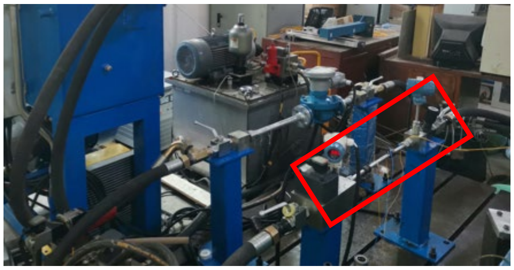

FIGURE 3. EXPERIMENTAL HYDRAULIC SYSTEM.

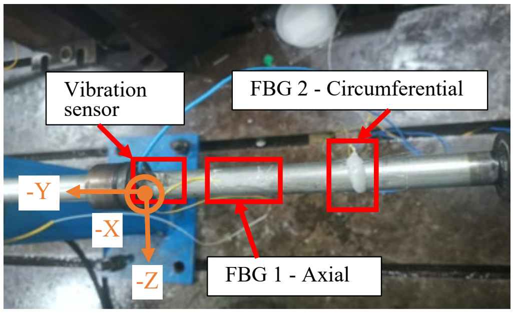

FIGURE 4. SENSOR LOCATIONS.

Based on experimental research under different pressures and quantitative calibration, it was found that the circumferential FBG is more sensitive to the pressure of the pipeline and presents a nearly linear relationship to the hydraulic pressure. Therefore, the FBG 2 sensor was selected for the FRF learning. For vibration, the Z-axis acceleration, which represents the transverse vibration in the horizonal plane and perpendicular to the axial direction of the pipeline, is chosen as the output corresponding to the FBG input.

4.2 Data Preparation

In order to provide rich enough data for FRF learning, each signal collected over about 40 minutes was segmented into multiple samples and then the Fast Fourier Transform (FFT) was used to yield the frequency spectrum of each segment. Since our vibration data and strain data were collected separately with different hardware and software systems asynchronously (misaligned by 10 s of seconds to a few minutes), in order to overcome the synchronization error and obtain more spectrums for training, the original data under the same operating condition was segmented with 50 percent overlap, which means adjacent data segments overlap by 50 percent with each other. Each data segment contains signals collected over 0.2 s, corresponding to 2024 data points for acceleration data and 400 data points for the FBG strain data, in the time domain. Both FFTs for acceleration and strain have a frequency resolution of 5 Hz, which provides 201 spectral data points for the frequency range of 0 Hz to

Qu, Yongzhi; Vogl, Gregory W.; Wang, Zechao. "A Deep Neural Network Model for Learning Runtime Frequency Response Function Using Sensor Measurements." Paper presented at ASME 2021 16th International Manufacturing Science and Engineering Conference (MSEC 2021), Cincinnati, OH, US. June 21, 2021 - June 25, 2021.

1000 Hz. The first FFT point, which is for 0 Hz, is removed, which yields 200 frequencies for learning purposes. A total of 23 254 pairs of sample segments for the training and test is obtained, where a strain spectrum and an acceleration spectrum form one pair of sample segments. The whole data sets are summarized in Table 1, in which each sample is a sample segment, a group of sequential data points, collected over 0.2 s.

TABLE 1. NUMBER OF SAMPLES FOR FRF LEARNING.

No. of samples	4.62 MPa	5.65 MPa	9.3 MPa	Total No.
FBG Strain	5242	12 011	6001	23 254
Vibration	5242	12 011	6001	23 254

During the model learning and testing process, about 85 percent of data was used for training and 15 percent was used for testing. Since the samples include overlap, which may help the testing processing if a similar sample with overlap has been seen in the training datasets, a random pool of datasets was not selected for training. Instead, for each of the operating conditions in Table 1, the first 85 percent of the data collected over time was used as training data and the latter 15 percent of data was used for testing. For example, for 4.62 MPa, the first 4500 samples out of the total 5242 samples were utilized for training. The rest of the samples served as testing datasets. A total of 20 000 samples from three different operating conditions were used for training and 3254 samples were used for testing.

4.3 Model Setting

This section provides the setting of our models for the deep encoder-decoder network. Since there exists a hybrid setting for the weight parameter, the total number of parameters for the network is 22 840. This is compared to 44 840 parameters if an un-tied encoder-decoder would have been used. Therefore, the partially-tied weights significantly reduced the number of parameters in the model. A batch optimization algorithm was adopted with a batch size of 100 samples, and the learning rate was set as 0.008. Twenty (20) epochs were performed to have the training process converge when the training loss and validation loss stopped decreasing. A quick overfit check with a 20% validation dataset over 50 epochs indicated that more epochs do not introduce overfitting since the accuracy on the validation set did not change, while the validation loss stayed relatively low after about 20 epochs.

The learning process was conducted on a MacBook Air computer with a 1.8 GHz Intel i5 processor and 8 GB of memory. On average, learning took about 11.8 s for 20 epochs, which is about 0.59 s for each epoch. Therefore, the training process is quite efficient.

5. RESULTS AND DISCUSSION

5.1 Results with the Proposed Model

In this section, the entire learning process is visualized, starting with the raw data and ending with the predicted output response from the learned FRF model. Figure 5 shows plots of the raw acceleration and FBG strain signals, and Figure 6 shows examples of FFTs of sample segments used for model learning. Note that many of the amplitudes in the strain spectrum are about 25% of the peak amplitude shown around 250 Hz. In contrast, the noise floor in the vibration spectrum is about 1% or less of its peak amplitude around 250 Hz; the vibration sensor has a much higher signal-to-noise ratio. Also, there is one dominant frequency component, which is suspected to be the first natural frequency of the pipeline structure that should capture the majority of vibrational displacements. The strain spectrum contains more noise and is flatter compared with the vibration spectrum. Yet, both spectrums share the same dominant frequency.

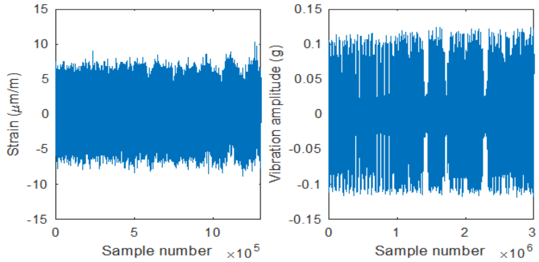

FIGURE 5. SAMPLE STRAIN AND VIBRATION SIGNALS.

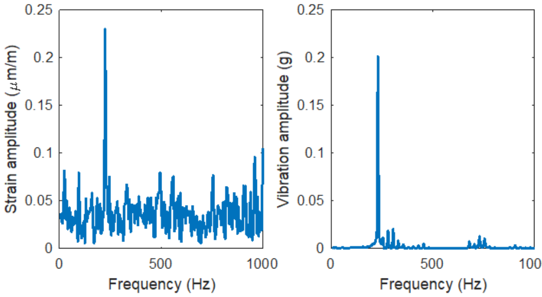

FIGURE 6. EXAMPLE FFTS OF STRAIN AND VIBRATION SIGNALS.

Without further processing of the data before use in the neural network, the peak frequency components would dominate over all other frequency components with regards to training errors. During the training process to map strain (the input) to vibration (the output), the low-amplitude spectral components would be neglected, since the error contributions from smaller amplitudes are much lower than those for higher amplitudes. Thus, the natural log of vibration FFT amplitude is set as the output for the neural network, which enables network learning to be influenced by all frequency content. A similar approach has been used in another method to allow all frequency content to influence the FRF-based solution [15]. Figure 7 shows the same sample spectrum as in Figure 6, except that the vibration spectrum is the natural log of its original spectrum. As one can see from Figure 7, the vibration spectrum is flattened by the log operation and shows more details for the lower-amplitude frequency components. The spectrums are then normalized to [0, 1] to eliminate scalings and were fed into the deep neural

Paper presented at ASME 2021 16th International Manufacturing Science and Engineering Conference (MSEC 2021), Cincinnati, OH, US. June 21, 2021 - June 25, 2021.

network model. The normalization process rescales the data to a common range. Also, since Sigmoid is used as the activation function in this work, output of the neural networks needs to be normalized to [0,1].

Next, the learning results with the proposed encoder-decoder regression model are discussed. Figure 8 shows an example of the predicted outputted acceleration spectrum tested with the inputted strain spectrum for a sample segment. It can be seen that the predicted vibration spectrum closely follows the actual vibration spectrum corresponding to the testing data. However, the actual spectrum has more fluctuations, while the predicted spectrum is smoother. While it can be expected that the predicted spectrum presents an 'averaging' effect, it is surprising to find that output spectrums calculated for all test samples under the same operating condition are almost identical. This indicates that the trained deep encoder-decoder networks have excellent denoising capability. We are further interested in evaluating whether the predicted spectrums correctly reflect and separate with different operating conditions, which can help us evaluate the generalization capability of the trained deep neural network.

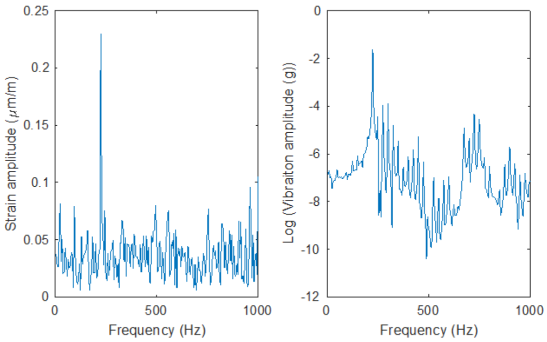

FIGURE 7. STRAIN SPECTRUM AND LOG-OF-VIBRATION SPECTRUM.

Since there are three different operating conditions, it is shown next whether the predicted output response correctly reflects the changing operating conditions, which represent the regression performance in the vector space. Figure 9 shows the predicted spectrums for three different operating conditions, a.k.a. 4.62 MPa, 5.65 MPa, and 9.3 MPa. Again, extensive examinations reveal that all predicted spectrums for one particular operating condition are almost identical even if different sample segments are used as the testing input. However, as Figure 9 shows, the learned generalized FRF captured the real difference between different operating conditions. Figure 9 shows that the predicted spectrum of 9.3 MPa clearly separates itself from those for 4.62 MPa and 5.65 MPa. The results for 4.62 MPa and 5.65 MPa can hardly be separated from each other. The reason is explained in that the data for 4.62 MPa and 5.65 MPa were collected from the same hydraulic system with a setting of 5 MPa. On the other hand, for 9.3 MPa, the control parameter was actually set to 10 MPa.

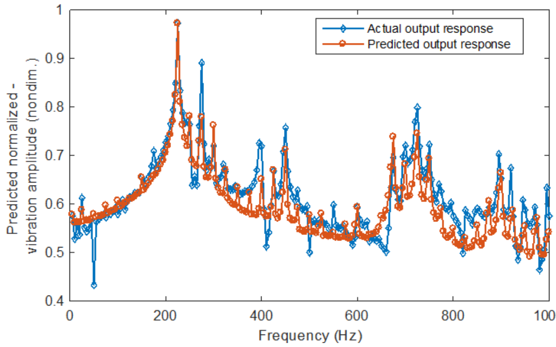

FIGURE 8. EXAMPLE OUTPUT SAMPLE SPECTRUM AND ITS PREDICTED SPECTRUM.

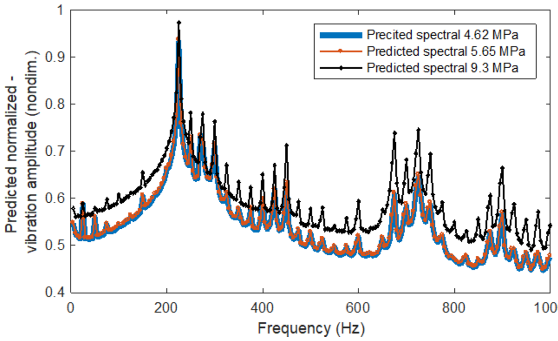

FIGURE 9. PREDICTED VIBRATION SPECTRUMS FOR THREE OPERATING CONDITIONS.

To further validate the results, the averaged spectrum for each of the three operating conditions are shown in Figure 10. The averaged spectrum is the average over all training and testing data. It is perhaps surprising to see that the learned spectrums approximate the average spectrums. Note that the amplitude of the averaged spectrum is slightly lowered due to the averaging effect over non-strictly aligned data, which is typical for averaging of FRFs with noise. Once again, the actual spectrums of 4.62 MPa and 5.65 MPa are very close to each other. Considering that the strain FRFs (the inputs) are extremely noisy with minor differences in the training targets fed to the model, the model cannot learn discriminative outputs for 4.62 MPa and 5.65 MPa. To better explain the averaging and denoising effects of the proposed model for FRF learning, examples of testing input spectrums and the corresponding output spectrums are plotted in Figure 11.

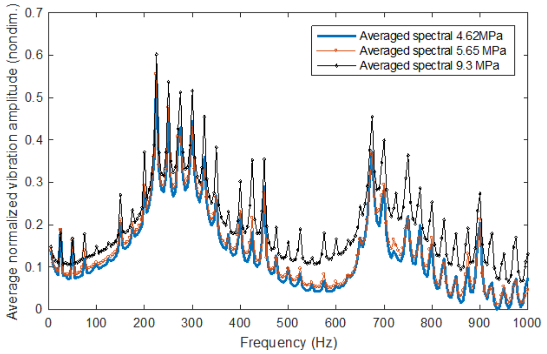

FIGURE 10. AVERAGE SPECTRUM FOR EACH OF THE THREE SEPARATE OPERATING CONDITIONS.

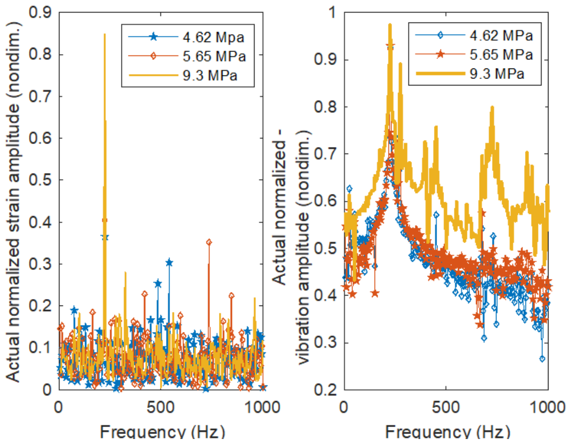

FIGURE 11. SPECTRUMS FOR AN ACTUAL SAMPLE USED FOR TESTING.

It can be seen from Figure 11 that the input spectrums are extremely noisy and the actual corresponding vibration spectrums are relatively noisy, as well. Furthermore, the vibration FFT amplitudes for 4.62 MPa are slightly lower than those for 5.65 MPa, and both are clearly separated from the FFT for 9.3 MPa. Note the differences of the average predicted spectrums in Figure 10 with the actual vibration spectrums in Figure 11; the noise-related fluctuations are filtered during the learning process, which justify the robustness of the proposed deep encoder-decoder network.

5.2 Comparison with Shallow Neural Networks

Next, the accuracy of the generalized runtime FRF is quantified. For various samples, the intra-group predictions under the same operating condition should be very close to each other, since they are sampled from the same process. In contrast, the inter-group predictions should be distinguishable in order to separate responses due to different operating conditions. Therefore, it is expected that the learned model could correctly predict discriminative results under different operating conditions.

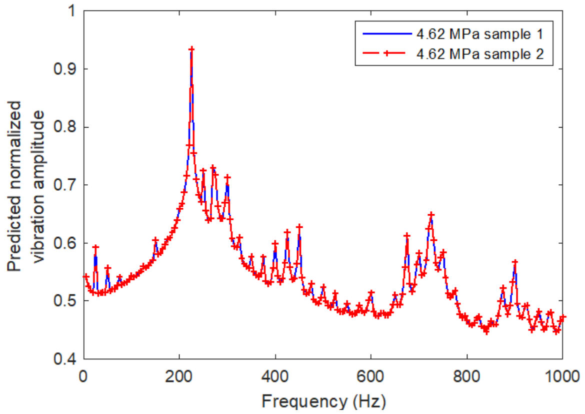

FIGURE 12. RESULTS COMPARISON FOR DIFFERENT TEST SAMPLES UNDER THE SAME OPERATING CONDITIONS FOR THE PROPOSED DEEP MODEL.

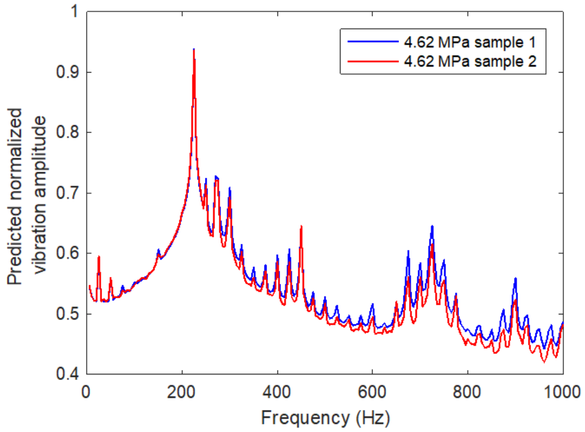

FIGURE 13. RESULTS COMPARISON FOR DIFFERENT TEST SAMPLES UNDER THE SAME OPERATING CONDITIONS FOR THE SHALLOW NEURAL NETWORK.

Figure 12 and 13 present the prediction results for the same two samples from the same operating conditions using the proposed deep neural network and a shallow neural network, respectively. It can be seen from Figure 12 and Figure 13 that the deep neural network performs much more robustly to produce almost identical results for the same process with noise filtering capability. However, the results from the shallow neural network present more fluctuations even if they come from the same process. For the prediction results of 9.3 MPa, the results from both the proposed deep model and the shallow network show fluctuations. However, the deep model still presents more robustness.

Also, Figure 9 shows that the deep neural network can predict clearly separable results for different operating processes. In order to quantify the performance of the proposed deep neural network and shallow neural network, we calculated and summarized the in-class fluctuations in terms of standard deviation. Since the standard deviation (STD) is calculated over multiple vectors, the largest STD over all dimensions is used to indicate the fluctuation, as shown in Table 2. Similar results can be obtained for the average standard deviation as well.

TABLE 2. ROBUSTNESS OF PREDICTION INDICATED BY IN-CLASS STD.

In-class STD	Class – 1 (4.62 MPa)	Class – 2 (5.65 MPa)	Class - 3 (9.3 MPa)
Proposed deep NN	0.0083	0.0069	0.0238
Shallow NN	0.0200	0.0145	0.0310

Next, we show the separation capability of predicted results from the proposed deep and shallow neural networks. The estimated FRFs using trained neural networks serve as underlying labels to each operating condition. However, since there are no true labels for them, a k-mean clustering task is performed over both networks to see whether the predicted results are discriminative with regards to the operating process or not. Therefore, we can evaluate whether the predicted results can detect a pressure change in the pipeline.

The k-mean clustering results are shown for all conditions in Table 3, but because Class – 3 corresponds to the 9.3 MPa operating condition and has more noise in the test data, Table 4 shows the separation accuracy for only Class – 3. It can be seen in Table 3 and Table 4 that the proposed deep regression model based on encoder-decoder networks clearly outperforms the shallow neural network with both FRF prediction robustness and discriminative capability.

TABLE 3. GROUPING ACCURACY FROM CLUSTERING RESULTS (ALL).

Comparison of FRF prediction accuracy, All	Deep Encoder-decoder NN	Shallow NN
k-means clustering accuracy	98.59%	97.79%

Comparison of FRF prediction accuracy, Class - 3	Deep Encoder-decoder NN	Shallow NN
k-means clustering accuracy	95.51%	92.91%

6. CONCLUSION

In this paper, identification of a generalized runtime FRF under multiple operating conditions was proposed as a supervised vector regression problem. The proposed model was tested for regression performance in the vector space to classify different inputs under changed operating conditions. A deep encoder-decoder-based model was proposed for the learning task. The model features partially-tied weights for the encoding and decoding process. An added layer for the output embedding was proposed to store different coordinates under the embedded space. The output embedding is fully connected with the input embeddings, which creates the mapping/regression relationship between them in the embedded space.

The model was validated using experimental measurement data from a hydraulic system, in which the relationship to be learned is between the vibration response (measured by an accelerometer) and the pressure (measured by an FBG strain sensor). The results showed that the proposed model can effectively learn the FRF function between the input and output spectrums under different operating conditions. The learned model also demonstrated excellent denoising capability, which was not shown by other FRF approaches. The presented work was for learning and classification of a system under very controlled conditions, and as such, is the first step of a longer process that will result in the generalized runtime FRF for prediction purposes.
