26 Certain commercial entities, equipment, or materials may be identified in this document in order to describe an  
27 experimental procedure or concept adequately. Such identification is not intended to imply recommendation or  
28 endorsement by the National Institute of Standards and Technology, nor is it intended to imply that the entities,  
29 materials, or equipment are necessarily the best available for the purpose.

30 There may be references in this publication to other publications currently under development by NIST  
31 in accordance with its assigned statutory responsibilities. The information in this publication, including  
32 concepts and methodologies, may be used by federal agencies even before the completion of such companion  
33 publications. Thus, until each publication is completed, current requirements, guidelines, and procedures,  
34 where they exist, remain operative. For planning and transition purposes, federal agencies may wish to closely  
35 follow the development of these new publications by NIST.

36 Organizations are encouraged to review all draft publications during public comment periods and provide  
37 feedback to NIST. Many NIST cybersecurity publications, other than the ones noted above, are available at  
38 <https://csrc.nist.gov/publications>.

## 58 **Reports on Computer Systems Technology**

59 The Information Technology Laboratory (ITL) at the National Institute of Standards and  
60 Technology (NIST) promotes the U.S. economy and public welfare by providing technical  
61 leadership for the Nation’s measurement and standards infrastructure. ITL develops tests,  
62 test methods, reference data, proof of concept implementations, and technical analyses to  
63 advance the development and productive use of information technology. ITL’s responsi-  
64 bilities include the development of management, administrative, technical, and physical  
65 standards and guidelines for the cost-effective security and privacy of other than national  
66 security-related information in federal information systems.

## 67 **Abstract**

68 This report considers threshold signature schemes interchangeable with respect to the verifica-  
69 tion mechanism of the **Edwards-Curve Digital Signature Algorithm (EdDSA)**. Historically,  
70 EdDSA is known as a variant of Schnorr signatures, which are well-studied and suitable for  
71 efficient thresholdization, i.e., for being computed when the private signing key is secret-sha-  
72 red across multiple parties. In the threshold setting, signatures remain unforgeable even if up  
73 to some threshold number of the cosigners become compromised. The report analyzes the  
74 conventional (non-threshold) EdDSA specification from Draft FIPS 186-5, reviews important  
75 security properties, with an emphasis on strong unforgeability, and distinguishes various  
76 approaches for corresponding threshold schemes. Notably, while providing better security  
77 assurances, threshold signatures can be used as drop-in replacement for conventionally pro-  
78 duced signatures, without changing legacy code for verification of authenticity. The report  
79 identifies various challenges and questions that would benefit from more attention, are of  
80 interest for future guidance and recommendations, and may be applicable beyond EdDSA.

## 81 **Keywords**

82 Digital signatures; EdDSA; secure multi-party computation; Schnorr; threshold cryptogra-  
83 phy; threshold schemes.

84 **Preface**

85 This document is intended for: technicians engaged in the development of recommendations  
86 for threshold signature schemes; cryptography experts interested in providing constructive  
87 technical feedback, or in collaborating in the development of open reference material; and all  
88 those, including from academia, industry, government and the public in general, interested  
89 in future recommendations about threshold signatures.

90 The reference threshold approaches identified in this document are representative examples  
91 not to be construed as preferences. See NISTIR 8214A for previous context of the NIST  
92 Multi-Party Threshold Cryptography project. Feedback is welcome from the community.

93 **Acknowledgments**

94 The first author performed this work as a Foreign Guest Researcher (non-employee) at NIST,  
95 while under contract with Strativia. The authors thank Lily Chen, Dustin Moody and René  
96 Peralta for their feedback.

97 **Call for Patent Claims**

98 This public review includes a call for information on essential patent claims (claims whose  
99 use would be required for compliance with the guidance or requirements in this Information  
100 Technology Laboratory (ITL) draft publication). Such guidance and/or requirements may  
101 be directly stated in this ITL Publication or by reference to another publication. This call  
102 also includes disclosure, where known, of the existence of pending U.S. or foreign patent  
103 applications relating to this ITL draft publication and of any relevant unexpired U.S. or  
104 foreign patents.

105 ITL may require from the patent holder, or a party authorized to make assurances on its  
106 behalf, in written or electronic form, either:

- 107 a) assurance in the form of a general disclaimer to the effect that such party does not  
108 hold and does not currently intend holding any essential patent claim(s); or
- 109 b) assurance that a license to such essential patent claim(s) will be made available to ap-  
110 plicants desiring to utilize the license for the purpose of complying with the guidance  
111 or requirements in this ITL draft publication either:
  - 112 i) under reasonable terms and conditions that are demonstrably free of any unfair  
113 discrimination; or
  - 114 ii) without compensation and under reasonable terms and conditions that are demon-  
115 strably free of any unfair discrimination.

116 Such assurance shall indicate that the patent holder (or third party authorized to make  
117 assurances on its behalf) will include in any documents transferring ownership of patents  
118 subject to the assurance, provisions sufficient to ensure that the commitments in the assurance  
119 are binding on the transferee, and that the transferee will similarly include appropriate  
120 provisions in the event of future transfers with the goal of binding each successor-in-interest.

121 The assurance shall also indicate that it is intended to be binding on successors-in-interest  
122 regardless of whether such provisions are included in the relevant transfer documents.

123 Such statements should be addressed to: [nistir-8214B-comments@nist.gov](mailto:nistir-8214B-comments@nist.gov)

## 201 **Executive Summary**

202 Digital signatures, based on public-key cryptography, underpin the security of critical  
203 information systems. They support authentication and non-repudiation, and have been  
204 standardized by NIST, via the Federal Information Processing Standard (FIPS) Publication  
205 186. Its most recent version — Draft FIPS 186-5 — specifies three signature schemes, the  
206 most recent of which is the Edwards-Curve Digital Signature Algorithm (EdDSA).

207 The security of signatures relies critically on the secrecy and proper use of its private signing  
208 key. In threshold cryptography, the key is split (secret-shared) across various parties, so that  
209 a signature can be produced only if a threshold number of parties agrees. In a *threshold*  
210 *signature scheme*, the signing takes place without the parties ever recombining the key.

211 For interoperability, a threshold scheme should produce signatures that, with respect to the  
212 verification operation, are interchangeable with those produced in a non-threshold (conven-  
213 tional) manner. This allows for a drop-in replacement of the signature generation, without  
214 changing legacy code for verification. EdDSA, being a Schnorr-style scheme, has a linearity  
215 property that is very well suited for thresholdization, once the needed secrets have been  
216 secret-shared. However, there are various ways in which to distributively achieve those secret  
217 sharings. They give rise to a diversity of threshold approaches, with various tradeoffs.

218 EdDSA signatures are specified as deterministic, but their determinism is not verifiable from  
219 the signature. Thus, a variant probabilistic signature can still be interchangeable with respect  
220 to EdDSA verification. Such a variant would use a randomized or hybrid (with randomness  
221 and pseudorandomness) nonce, allowing for a simpler threshold protocols.

222 Threshold EdDSA has a high potential for adoption, as it enables distribution of trust for  
223 signing operations and higher resistance to certain attacks. Several considerations in this  
224 report are also applicable to other NIST-approved signature schemes specified in Draft  
225 FIPS 186-5. Allowing threshold EdDSA for pre-quantum security may also provide useful  
226 experience for the exploration of threshold schemes for post-quantum primitives.

227 The analysis in the present report is covered in four main sections:

- 228 • **Conventional setting:** the context of the NIST specification, and the security proper-  
229 ties of EdDSA and interchangeable Schnorr-style signature schemes.
- 230 • **Threshold approaches:** high-level summary of four types of approaches from the  
231 literature, including both deterministic and probabilistic schemes.
- 232 • **Further considerations:** various aspects of relevance in the threshold setting.
- 233 • **Conclusions:** a synthesis of the benefits of the threshold setting, with a highlight on  
234 probabilistic schemes, and a proposal for consultation with the greater community.

235 The main security property of interest for EdDSA signatures is strong *unforgeability*. This  
236 ensures that an adversarial client cannot produce any signature that has not been generated  
237 by the key holder. There are other properties, such as *binding*, which can be considered from  
238 the perspective of a malicious signer.

239 A main concern with the implementation of EdDSA is the assurance of good nonces. The  
240 inadvertent reuse of a nonce (across different messages being signed) leaks the private key.  
241 In fact, even a slight bias in the nonce allows for key-recovery, provided enough signatures  
242 are obtained. Conversely, when the nonce is pseudorandomly generated as a transformation  
243 of a persistent secret key and the message, thus avoiding a detectable bias, some side-channel  
244 attacks may enable determining the secret key. The implementation of a hybrid mode, using  
245 both randomness and pseudorandomness, has the potential to improve on each of the two  
246 non-hybrid modes. This hybrid approach can also be useful in the threshold setting, where  
247 there are more opportunities and challenges about randomness and determinism.

248 There are known solutions for threshold EdDSA/Schnorr-style schemes, including distributed  
249 key generation. Recently there has been a surge of new approaches, focused on features like  
250 low number of rounds and/or simulatability, for both deterministic and probabilistic signing.

252 For deterministic signing, a secure multi-party computation can distributively generate  
253 a secret-sharing of a pseudorandom nonce, based on the message and a secret-shared  
254 nonce-derivation key. Another approach is to let each party provide a deterministic nonce  
255 contribution, while proving correctness with a zero-knowledge proof.

256 For probabilistic signing, the distributed generation of a randomized nonce can take advan-  
257 tage of homomorphic properties already innate to the EdDSA/Schnorr scheme. Here, it is  
258 important to safeguard security under concurrent executions, where an adversary has a view  
259 of the intermediate state of many signing operations. Recent proposals have focused on  
260 protocols with reduced number of rounds of interaction, with two and three being the norm  
261 (assuming broadcast is possible in a single round), depending on the security formulation.

262 There are two main frameworks used in practice to formulate and prove threshold security:

- 263 • *simulation-based* (useful for modularity and composability): where the notion of  
264 security is incorporated into an ideal functionality.
- 265 • *game-based*: where a game defines each property of interest, e.g., unforgeability.

266 Some considerations are inherent to the threshold setting: agreement on what to sign,  
267 malicious “random” contributions, interface between requester and cosigners, authenticated  
268 channel, timing assumptions, precomputation before receiving signature requests, failure  
269 modes, good vs. bad randomness, modularity and composability. The options related to these  
270 considerations create a diverse space of solutions that should be considered.

271 This document explains the potential benefits of the threshold setting. In particular, there  
272 are various advantages for probabilistic approaches. Yet, safely realizing the promise of  
273 the threshold approach requires a thorough analysis. This can be pursued with an open  
274 consultation with the community of experts, via a public call for threshold schemes, to  
275 create a testbed, gathering security formulations, technical explanations, and reference  
276 implementations. The clarification resulting from analyzing said reference material can then  
277 be helpful to synthesize recommendations about threshold signature schemes.

278 **1. Introduction**

279 A signature scheme enables generating a “digital signature” (hereafter just “signature”)  
280 that assures the authenticity of a “message” (any digital datum). The scheme is based on  
281 a cryptographic private/public key-pair, such that only the private-key holder can produce  
282 signatures that are verifiably valid with respect to that public key [DH76]. In other words, a  
283 signature scheme is *unforgeable*. When the public key is certifiably bound to the identity of  
284 the private-key holder, a valid signature provides *non-repudiation*: the signer cannot credibly  
285 deny having produced said signature. These unforgeability and non-repudiation features  
286 underpin the security of many modern applications of information systems, including public-  
287 key infrastructures (PKI). For example, they are extensively used to prevent impersonation  
288 in cyberspace, establish authenticated channels between parties, enable contract signing  
289 with legal validity, and provide offline-verifiable authenticity of software.

290 **NIST-specified signatures.** As of August 2022, the Edwards-curve Digital Signature  
291 Algorithm (EdDSA) is the most recent signature scheme included by the National Institute  
292 of Standards and Technology (NIST) in a Federal Information Processing Standard (FIPS),  
293 albeit still in draft mode: Draft FIPS 186-5. This FIPS also specifies the Elliptic Curve Digital  
294 Signature Algorithm (ECDSA) and the Rivest–Shamir–Adleman (RSA) signature schemes.  
295 Both EdDSA and ECDSA, relying on the infeasibility of computing discrete logarithms (and  
296 related assumptions) over approved elliptic curves, allow signatures noticeably shorter than  
297 RSA, which relies on the infeasibility of integer factorization (and related assumptions). For  
298 example, at an estimated level of 128 bits of security, EdDSA and ECDSA signatures have a  
299 bit length of 512, which is one-sixth of the 3072 bits required by RSA signatures.

300 **The threshold setting.** The critical reliance on signature schemes requires a careful con-  
301 sideration of the techniques that help ensure the secrecy of the private signing key. The  
302 multi-party “threshold” setting allows for a distribution of trust of the private key, by use of  
303 *secret sharing* [Bla79; Sha79]. The key is split (i.e., “secret shared”) across multiple parties,  
304 such that no coalition of up to some *corruption threshold* number  $f$  of faulty parties is able  
305 to recover the key. Furthermore, the actual cryptographic operation of interest — in this  
306 case signing — can be performed by any quorum with a stipulated *participation threshold*.  
307 The signing takes place without reconstructing the key. Moreover, the signatures remain  
308 *unforgeable* by a coalition of up to  $f$  malicious parties, without the help of other honest  
309 parties. The study of threshold schemes has been active for over three decades [Des88;  
310 DF90]. More recently, the NIST Internal Report NISTIR 8214A proposed that a focused  
311 analysis takes place, to collect expert feedback that can be useful as a basis for developing  
312 recommendations about threshold schemes.

313 **Schnorr and thresholdizability.** EdDSA [BDLSY11; RFC 8032] is based on Schnorr  
314 signatures [Sch90], which have been subject to extensive analysis in the literature. They have  
315 the special feature of one of their components resulting from a linear combination of two  
316 secret elements: the private signing key  $s$  and the (per-message secret) nonce  $r$ . This linearity

317 allows for simple threshold schemes based on a linear secret-sharing of the two secrets. The  
318 matter becomes more elaborate when considering the nature of the nonce: pseudorandom  
319 (deterministic) vs. randomized. The essential property is that  $r$  remains indistinguishable  
320 from random. The secret-sharing of a random nonce can be easily achieved by leveraging  
321 independent contributions from each party. Conversely, the threshold production of a  
322 pseudorandom nonce based on the EdDSA specification is considerably more complex. It  
323 requires an expensive distributed (multi-party) computation of a specific hash over a secret-  
324 shared input. Fortunately, probabilistic versions of EdDSA, when properly parameterized,  
325 are interchangeable with respect to the verification algorithm of standardized EdDSA.

326 **EdDSA relevance.** In applications where succinctness matters, RSA signatures may be too  
327 long, and those based on elliptic curves may be preferred. In a threshold context, EdDSA  
328 may be preferred to ECDSA because the process for threshold generation of interchangeable  
329 signatures is far simpler. This report discusses the properties of conventional (non-threshold)  
330 and threshold schemes interchangeable with respect to (w.r.t.) EdDSA verification, paving  
331 the way to possible future recommendations or guidance about the latter.

332 **Avoiding bias.** The Draft FIPS 186-5 specification of EdDSA requires the use of a pseu-  
333 dorandom nonce (i.e., deterministic, depending on a secret key). While this avoids the  
334 catastrophic security breakdown in case of a biased “random” nonce, it raises a concern  
335 about higher vulnerability to some side-channel attacks. Fortunately, determinism is not the  
336 only solution to the mentioned problem. By properly adding a random component, as input  
337 to the pseudorandom transformation already used by deterministic schemes, it is possible  
338 to create a probabilistic scheme that minimizes the risk of bias. The EdDSA verification  
339 algorithm works interchangeably with randomized and with deterministic signatures. In  
340 fact, determinism is not a standalone verifiable property of EdDSA signatures.

341 **Toward guidance.** After summarizing the NIST Draft FIPS 186-5 requirements of the  
342 conventional EdDSA, this document puts in perspective various aspects of interest to corre-  
343 sponding Schnorr-based threshold schemes. This is intended to support possible future NIST  
344 recommendations promoting secure implementations of threshold signatures interchangeable  
345 with respect to the EdDSA verification algorithm. It is worth noting that Schnorr/EdDSA is  
346 already widely deployed and used, albeit with variations of the curves and parameters. For  
347 example, these signatures are used in Transport Layer Security (TLS), Secure Shell Protocol  
348 (SSH), Signal, The Onion Router (TOR) / Invisible Internet Project (I2P) and Domain Name  
349 Server Security Extensions (DNSSEC), as well as some cryptocurrencies.

350 **Document organization.** Section 2 explains the notation. Section 3 establishes the NIST  
351 context about the EdDSA specification, and analyzes some security properties, including  
352 its non-verifiable determinism. Section 4 compares various approaches to thresholdize Ed-  
353 DSA/Schnorr. Section 5 comprises additional considerations relevant to future guidelines and  
354 recommendations about threshold signatures. Section 6 concludes with a summary of insights  
355 and a recommendation for a public call for threshold signature schemes interchangeable w.r.t.  
356 the NIST specified EdDSA verification.

357 **2. Notation**

358 This section explains the acronyms, abbreviations and symbols used in the document.

403 **2.2. Abbreviations**

404 The report uses some abbreviations: det. (deterministic); discrete log (discrete logarithm);  
 405 e.g. (*exempli gratia* = for example); i.e. (*id est* = that is); iff (if and only if); keygen (key  
 406 generation); prob. (probabilistic); pub key (public key); vs. (versus); w.r.t. (with respect to).

407 **2.3. Symbols**

408 The symbols of some variables were chosen to match the notation used in Draft FIPS 186-5.  
 409 These often vary across the literature. The colors red, blue and green are sometimes used  
 410 to help identify private input or intermediate values, public output or intermediate values,  
 411 and public input values, respectively. However, color identification is not required for  
 412 understanding the descriptions.

413 **2.3.1. Symbols useful for the conventional setting**

414 **Table 2.** Symbols for conventional setting

415	<b>Symbol</b>	<b>Description</b>
417	$+$ , $\cdot$	Binary operators for integer addition and multiplication.

Table 2 (continued from previous page)

Symbol	Description
$\oplus, -$	Binary operators for addition and subtraction of two elliptic curve elements.
$\cdot$	Non-commutative binary operator used to multiply an elliptic curve element (on the right) by an non-negative integer (on the left), e.g., $s \cdot G$ .
$\leftarrow^{\$}$	Random sampling of a value.
$b$	Bit-length (multiple of 8) of the public key $Q$ , and the initial private key $d$ . EdDSA signatures $\sigma$ have $2b$ bits. Approved values: 256 and 456.
$c$	Binary logarithm (3 for Ed25519, 2 for Ed448) of the cofactor $2^c$ (order of small subgroup); useful to compare cofactorless vs. cofactored verification.
$\chi$	Challenge component computed in the Sign and Verify operations.
$ctx$	Context (optional parameter in some signature modes).
$d$	<i>Precursor</i> private key of the signature scheme. It is the hash pre-image used to derive the <i>signing key</i> $s$ and the <i>nonce-derivation key</i> $v$ .
$E_{i,j}$	Some encoding function (the subscripts are used to differentiate encodings).
$G$	Base point (aka generator), generator of the subgroup $\mathbb{G}$ of prime order $n$ .
$\mathbb{G}$	Subgroup generated by $G$ . It is the domain of public keys. It is the large subgroup (or order $n$ ) of the elliptic curve group (of order $2^c \cdot n$ )
$H$	Some cryptographic hash function (subscripts can be used to differentiate between hash functions).
$\kappa$	Standardized security level (estimated bits of strength, e.g., 128 or 224).
$M$	Message (string) being signed.
$\mu$	Index identifying the mode of a signature scheme.
$n$	Prime order of the elliptic curve subgroup generated by $G$ .
$Q$	Public key of the signature scheme, equal to $s \cdot G$ .
$r$	Nonce (secret).
$R$	Commitment of the nonce $r$ ; used as the first component of the signature.
$s$	<i>Signing key</i> (also called <i>hdigest1</i> in Draft FIPS 186-5): it is the 1 <sup>st</sup> half of the digest of the private key $d$ . It is used to generate the public key $Q$ , and to compute the 2 <sup>nd</sup> component ( $S$ ) of each signature.
$v$	<i>Nonce-derivation key</i> ( <i>hdigest2</i> in Draft FIPS 186-5): it is the 2 <sup>nd</sup> half of the digest of the private key $d$ ; used to pseudorandomly generate each nonce.
$S$	Second component of the signature, obtained via a linear combination of the signing key $s$ and the secret nonce $r$ , with the help of the challenge $\chi$ .
$\sigma$	Signature — a pair $(R, S)$ of elements.

451 **2.3.2. Symbols specific to the threshold setting**

452 **Table 3.** Symbols for threshold setting

453	Symbol	Description
454	$f$	Corruption threshold (smaller than $t$ ) w.r.t. unforgeability. With “mixed adversaries” one may differentiate thresholds across types of corruptions.
455		
456	$n$	Total number of “parties” (share-holders) [does not include the requester client, coordinators and others without a share of the private key].
457		
458	$\mathcal{P}$	Set of possible cosigners (aka <b>p</b> arties) — there are $n$ of them.
459	$\mathcal{P}'$	Set of cosigners agreed to participate in a particular signing execution.
460	$P_i$	One of the parties (share holders) — the index $i$ is used similarly for shares of contributions, to identify to which party they correspond.
461		
462	$sid$	<b>S</b> ession <b>i</b> dentifier (to distinguish sessions in a concurrent setting)
463	$t$	Reconstruction <b>t</b> hreshold (usually $t = f + 1$ ) of the baseline secret sharing.
464	$t'$	Participation <b>t</b> hreshold: minimum size of quorum needed to generate a signature, when the number of corrupted parties does not exceed $f$ .
465		

466 For simplicity we assume throughout the paper that  $f$  is also the corruption threshold for  
 467 key-recovery, being equal to the corruption threshold for the underlying secret-sharing of  
 468 the signing key. However, there are conceivable protocols where the corruption threshold  
 469 for unforgeability is lower than that for key-recovery.

470 **2.3.3. On the use of square brackets []**

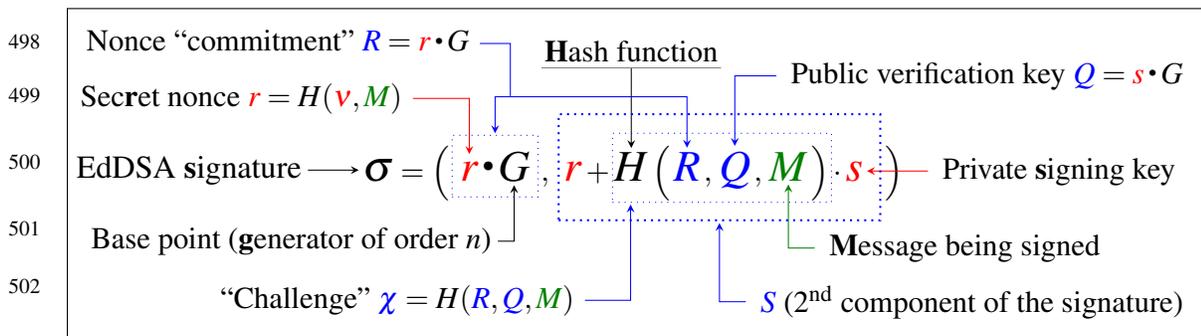

471 In the present document, square-bracketing is used for various purposes.

- 472 1. **Secret-sharing.** To represent a (linear or additive) secret-sharing of the enclosed  
 473 element, when used in some operation, to indicate that a vector of operations takes  
 474 place. For example,  $[d] \cdot G$  indicates that each secret-share  $d_i$  of  $d$  is multiplied by the  
 475 base point  $G$ , with each such operation being performed locally by a different party.  
 476 In Draft FIPS 186-5, the use of brackets in a left-side multiplier (e.g.,  $[d]$ ) is instead  
 477 used to indicate that the enclosed element is an integer, thus distinguished from the  
 478 group element (on the right side)  $\mathbb{G}$ .
- 479 2. **Optional argument.** When nested inside a parenthesis, to indicate an optional  
 480 argument of a function, e.g.,  $f(a, b[, c])$ .
- 481 3. **Predicate evaluation.** When embracing an equality with question mark, to enclose a  
 482 predicate evaluation/verification, e.g.,  $[x =? y]$ .

483 **3. The conventional EdDSA and Schnorr schemes**

484 The **Edwards-curve Digital Signature Algorithm (EdDSA)** is a signature scheme specified  
485 in the Draft FIPS 186-5 “Digital Signature Standard (DSS)”. EdDSA operates over elliptic  
486 curves, whose allowed parameters are specified in Draft SP 800-186. The NIST specification  
487 is based on RFC 8032, which in turn was based on prior work [BDLSY11; BJLSY15].  
488 EdDSA is a variant of the Schnorr signature scheme, itself a proof of knowledge of a discrete  
489 logarithm (discrete log) [Sch90].

490 The EdDSA scheme specifies a triple (*keygen*, *sign*, *verify*) of algorithms. It operates  
491 over an elliptic curve group of known order  $2^c \cdot n$ , where  $n$  is prime and  $c$  is a short integer  
492 (2 or 3). However, the actual operations (in additive notation) are performed in the cyclic  
493 subgroup  $\mathbb{G}$  of order  $n$ , with an agreed *base point*  $G$ , the generator. Fig. 1 shows a simplified  
494 version (missing some encoding details) of the formula for an EdDSA signature. Notably,  
495 the 2<sup>nd</sup> element (the  $S$ ) of the signature is a linear combination of the signing key  $s$  and the  
496 secret nonce  $r$ , once the public challenge  $\chi$  has been calculated. This linearity is a distinctive  
497 feature of Schnorr/EdDSA-style signatures, as compared to ECDSA.

503 **Figure 1.** Annotated simplified formula of an EdDSA signature

504 The secrecy of the private signing key  $s$  (which is actually a cryptographic digest of the  
505 precursor private key  $d$ ) depends on the infeasibility of computing “discrete logs” (in  
506 traditional multiplicative notation). In additive notation (as usual with elliptic curves, and as  
507 used in this document), this requires that it be infeasible to compute which integer  $s$  needs  
508 to multiply the base-point  $G$  to yield the public key  $Q = s \cdot G$ . The generation of the secret  
509 nonce  $r$  for each message requires the use of a nonce-derivation key  $v$  (which is actually  
510 another cryptographic digest of the precursor private key  $d$ ), which must also remain secret.  
511 The property of unforgeability also depends on the one-wayness (or collision resistance,  
512 depending on the signature mode) of the hash function  $H$ .

513 **EdDSA as a variant of Schnorr.** The EdDSA signature of a message  $M$  can be interpreted  
514 as a (transferable) non-interactive zero-knowledge proof of knowledge (ZKPoK) of the  
515 discrete-log (the private signing key) of the public key, with the property that  $M$  is bound to  
516 the proof. The binding is done by including  $M$  in the pre-image of the ZKPoK “challenge”

517 element  $\chi$  that is determined as a hash, according to the Fiat-Shamir heuristic [FS87]. This  
518 ZKPoK approach for a signature was devised by Schnorr in 1989 [Sch90]. While the original  
519 Schnorr scheme is probabilistic, the standardized EdDSA signature (per Draft FIPS 186-5)  
520 is deterministic, since its secret nonce  $r = H(v||M)$  is pseudorandom. The original Schnorr  
521 scheme includes the challenge  $\chi$  in the signature, whereas EdDSA replaces it with the nonce  
522 commitment  $R$ . This change of format requires a change in the verification operation, but  
523 the rationale for unforgeability is similar, since both  $R$  and  $\chi$  can be obtained from any of  
524 the signatures. More concretely:  $\chi = H(R, Q, M)$  and  $R = S \cdot G - \chi \cdot Q$ . Based on the above,  
525 EdDSA is sometimes said to be a Schnorr-style signature, or a variant of Schnorr.

526 **NIST-approved curves and modes.** The Draft FIPS 186-5 specifies two Edwards curves  
527 (with corresponding subgroups  $(\mathbb{G}, +)$ ), for two corresponding security levels: curve Ed-  
528 wards25519 for 128-bit strength; curve Edwards448 for 224-bit strength. Each of the two  
529 curves allows two signing modes, w.r.t. whether the signed message is pre-hashed or not.  
530 The Draft FIPS 186-5 specifies four allowed EdDSA modes: Ed25519, Ed25519ph, Ed448,  
531 Ed448ph. The suffix “ph” means the message is prehashed when given as input to the  
532 Sign operation, and these modes are sometimes called HashEdDSA. The preceding part  
533 “EdXXX[XX]” identifies the underlying elliptic curve. Note that RFC 8032 defines an  
534 extra mode Ed25519ctx that is not approved in Draft FIPS 186-5. Consequently, in Draft  
535 FIPS 186-5, Ed25519 is the only mode (out of four) that does not use a context field (denoted  
536 *ctx* in Fig. 3 and Table 5).

537 **Other curves and modes.** In this document, the mode is sometimes left implicit, using a  
538 “simplified” description that omits details about the used curves, the differentiated hash func-  
539 tions, encodings and/or a “context” argument. The logic of EdDSA can for the most part be  
540 modularized away from these details. Thus, when some of these details are abstracted away,  
541 some of the rationale may be applicable to non-standardized parameters. For example, while  
542 the Draft FIPS 186-5 specification requires Ed22519 or Ed448 for the curve, and SHA-512  
543 or SHAKE256 for hashing, a Schnorr variant used in Bitcoin [WNR20] specifies secp256k1  
544 for the curve and SHA-256 for hashing. Nonetheless, when actual interchangeability with  
545 Draft FIPS 186-5 EdDSA verification is required, the focus is on the concrete standardized  
546 modes summarized in Table 5.

547 **Pre-Quantum.** EdDSA is not a post-quantum secure scheme. It is plausible that a future  
548 quantum computer will be able to use any EdDSA public verification key to determine the  
549 corresponding secret signing key. Therefore, EdDSA may in the future be decommissioned  
550 in favor of post-quantum alternatives. Nevertheless, EdDSA is currently an important  
551 signature scheme with useful features. Guidance regarding how to thresholdize it can thus  
552 be useful as a way to enable distribution of trust.

### 553 3.1. Schemes interchangeable w.r.t. EdDSA verification

554 NISTIR 8214A proposed the notion of interchangeability that is relevant for this document.  
555 A secure scheme is said to be *interchangeable* w.r.t. the verification algorithm of (determin-

556 istic) EdDSA signatures if the `Verify` algorithm accepts, without distinction, the variant  
557 signatures. In particular for EdDSA, this applies to a probabilistic distribution of the nonce,  
558 such as uniformly at random from  $\mathbb{Z}_n$ .

559 Figure 2 shows a simplified description of a generic signature scheme interchangeable w.r.t.  
560 EdDSA verification. It abstracts the nonce generation to fit several possibilities and omits  
561 various details deferred to Fig. 3. A probabilistic variant of EdDSA can use a random nonce.  
562 In a hybrid mode, it can also be a hash whose pre-image includes a secret key, as well as  
563 some fresh randomness per signature. See Section 3.5 for security considerations about  
564 these variants.

- 565 • `Keygen`[ $n$ ]: { (private key)  $s \leftarrow^{\$} \mathbb{Z}_n$ ; (public key)  $Q = s \cdot G$ ; output  $(s, Q)$  }.

566 • `Sign`[ $s$ ]( $M$ ): {  $r \leftarrow \text{GenNonce}(\dots)$ ;  $R = r \cdot G$ ;  $\chi = H(R, Q, M)$ ;  
567  $S = r + \chi \cdot s \pmod n$ ; output  $\sigma = (R, S)$  }.

568 • `Verify`[ $Q$ ]( $M, \sigma$ ): {  $\chi' = H(R, Q, M)$ ; output accept iff  $S \cdot G \stackrel{?}{=} R \oplus \chi' \cdot Q$  }

569 **Legend:**  $\chi$  (challenge);  $G$  (base point, i.e., generator of  $\mathbb{G}$ ); `GenNonce`(...) (procedure used to generate  
570 the secret nonce);  $M$  (message being signed);  $n$  (order of the group generated by  $G$ );  $Q$  (public key);  
571  $r$  (secret nonce);  $R$  (nonce commitment; first component of the signature);  $s$  (private signing key; in  
572 the detailed scheme it is obtained as a digest — `hdigest1` — of a precursor private key  $d$ );  $S$  (second  
573 component of the signature);  $\sigma$  (signature);  $\leftarrow^{\$}$  (random sampling);  $+$ ,  $\cdot$  (integer sum and multiplication);  
574  $\oplus, \cdot$  (sum and multiplication-by-constant in additive group  $\mathbb{G}$ ). Extra verification details are required.

576 **Figure 2.** (Simplified) EdDSA-style scheme, with generic nonce

577 **Key-prefixing.** The inclusion of the public key  $Q$  in the hash-calculation of the challenge  $\chi$   
578 is a best practice (known as key-prefixing) that addresses concerns w.r.t. application settings  
579 with more than one public key [Ber15; BCJZ21]. It is used in EdDSA, but it is actually not  
580 considered in the original Schnorr signature scheme [Sch90]. Hereafter in this document,  
581 the reference to “Schnorr” type signatures is considered (sometimes implicitly) only within  
582 the scope of key-prefixed versions.

583 **Non-verifiable determinism.** The EdDSA signing procedure defined in Draft FIPS 186-5  
584 generates a deterministic signature, since `GenNonce` is a hash-based pseudorandom function.  
585 However, the deterministic property is not verifiable from the signature itself, without  
586 the secret signing key. This lack of verifiable determinism distinguishes EdDSA (and  
587 ECDSA) from some other schemes (see Table 4). Particularly, the RSA Signature Scheme  
588 with Appendix (SSA) — RSASSA-PKCS-v1\_5 — part of the Public Key Cryptography  
589 Standards (PKCS) incorporated in Draft FIPS 186-5 produces verifiably deterministic  
590 signatures. (Note that Draft FIPS 186-5 also specifies an RSA-based Probabilistic Signature  
591 Scheme (PSS): RSA-PSS-PKCS-v2\_1.)

599 At considerable computation cost compared to that of producing a signature, a signer could  
600 produce a ZKP that an EdDSA signature was correctly generated with the prescribed secret

592 **Table 4.** Determinism vs. verifiable determinism of signature schemes

593	Signature scheme	Is the signature algorithm deterministic?	Is the output signature verifiably deterministic?
594	RSASSA-PKCS	Yes	Yes
595	EdDSA	Yes	No
596	Deterministic ECDSA	Yes	No
597	RSA-PSS	No	No
598	(Probabilistic) ECDSA	No	No

601 nonce. Such a ZKP is outside the scope of the EdDSA specification.

### 602 3.2. Detailed EdDSA procedures

603 The next subsections describe the three EdDSA operations: Keygen, Sign, and Verify.  
 604 In comparison with the simplified Fig. 2, the pseudo-code describing EdDSA in Fig. 3  
 605 includes: a parameter  $\mu$  to differentiate various EdDSA modes (encoding, curves, and hash  
 606 functions); details about the pseudorandom nonce generation; the use of a cofactor  $c$  in the  
 607 verification mechanism; and the differentiation between signing key  $s$  and nonce-derivation  
 608 key  $v$ . Table 5 gives further details for Hash and GenNonce.

#### 635 3.2.1. Keygen

636 As an asymmetric-key signature scheme, EdDSA requires a private signing key  $s$  for signing,  
 637 and a public verification key  $Q$  to validate signatures. As specified in Draft FIPS 186-5, the  
 638 private signing key is in fact derived from a precursor private key  $d$  of the scheme. Specif-  
 639 ically,  $d$  is hashed to yield a pair  $(s, v)$  of secret digests, which are then used separately. For  
 640 simplicity, some encoding details (explained in Draft FIPS 186-5) are being omitted here,  
 641 namely on how some bits in the extremities of the digests need to be preset, and on how the  
 642 strings are converted into integers. The first digest — the signing key  $s$  — is used in two  
 643 ways: (i) it is multiplied by the base point  $G$  to yield the public key  $Q = s \cdot G$ ; (ii) it is used  
 644 in the signing process to derive a linear form  $S$  that combines the nonce and the challenge.  
 645 The second digest — the nonce-derivation key  $v$  — is used only in the signing process, to  
 646 derive a message-specific secret nonce  $r$ . In practice, the two digests can be computed once  
 647 in the keygen phase and stored, for use thereafter in the signing phase; otherwise they can  
 648 be recomputed from  $d$  during each signing operation.

649 As described in Table 5, EdDSA has parameters approved for two security strengths (called  
 650 *requested\_security\_strength* in Draft FIPS 186-5)  $\kappa$ : 128 and 224. The private key  $d$  is  
 651 required to be obtained using an approved random bit generator (RBG) as a string with at  
 652 least  $b$  bits. The integer  $b$  must be a multiple of 8 and is at least double  $\kappa$ :  $b = 256$  for

609	Keygen[ $b$ ]: {	$S = r + \chi \cdot s \pmod n$ ;
610	(private key) $d \leftarrow \mathbb{Z}_2^b$	output $\sigma = (R, S)$ }
611	$s \parallel \mathbf{v} = \text{Hash}(d)$ ;	
612	(public key) $Q = s \cdot G$ ;	Verify[ $Q$ ]( $\mu$ [, $ctx$ ], $M$ , $\sigma$ ): {
613	output $(d, Q)$ }	$(R, S) = \sigma$ ;
614		if not $0 \leq S < n$ , then reject;
615	Sign[ $d$ ]( $\mu$ [, $ctx$ ], $M$ ): {	$\chi = \text{HashC}_\mu([ctx \parallel R \parallel Q \parallel f(M)])$ ;
616	$s \parallel \mathbf{v} = \text{HashK}_\mu(d)$ ;	$S' = 2^c \cdot S$ ; $R' = 2^c \cdot R$ ; $\chi' = 2^c \cdot \chi$ ;
617	$r = \text{GenNonce}[\mathbf{v}](\mu$ [, $ctx$ ], $M$ ) $\in \mathbb{Z}_n$ ;	if $S' \cdot G = ? R' \oplus \chi' \cdot Q$
618	$R = r \cdot G$ ;	then output accept,
619	$\chi = \text{HashC}_\mu([ctx \parallel R \parallel Q \parallel f(M)])$ ;	else output reject }
620	<b>Legend/notation:</b> $b$ (number of bits of private key, as well as of public key; it is a multiple of 8); $2^c$	
621	(cofactor — 8 for Ed25519, 2 for Ed448 — needed for cofactored verification); $\chi$ (challenge); $ctx$	
622	(optional <i>context</i> string, empty by default, only available for the Ed25519ph, Ed448 and Ed448ph	
623	modes, i.e., not available only for the Ed25519 mode; $d$ (private key of the signature scheme); $f$	
624	(transformation function applied to the message: identity for regular EdDSA; some hashing for	
625	HashEdDSA); $G$ (base point, aka generator, of a subgroup $\mathbb{G}$ of prime order $n$ ); HashK (hash function	
626	used to derive the secret keys $s$ and $\mathbf{v}$ ); HashC (hash function used to derive the challenge $\chi$ ); $\mu$	
627	(mode: Ed25519, Ed448, Ed25519ph, Ed448ph, respectively encodable as (2,0), (4,0), (2,1), (4,1)	
628	— see details in Table 5); $M$ (message being signed); $q$ (order of $\mathbb{G}$ ); $Q$ (public key, for verification);	
629	$r$ (secret nonce); $s$ (private signing key); $\mathbf{v}$ (private key for nonce generation; it is called <i>hdigest2</i> in	
630	Draft FIPS 186-5); $R$ (public commitment of nonce); $(+, \cdot)$ (integer sum and multiplication); $(\oplus, \odot)$	
631	(sum and multiplication-by-constant in additive group $\mathbb{G}$ ). $=$ (assignment); $=?$ (equality check); $\parallel$	
632	(concatenation). For simplicity, details about encodings are omitted. As secret input to the Sign	
633	algorithm, both the signing key $s$ and nonce-derivation key $\mathbf{v}$ can be used instead of the precursor key $d$ .	

634 **Figure 3.** EdDSA pseudo-code and notation

653  $\kappa = 128$ ;  $b = 456$  for  $\kappa = 224$ . Note that for  $\kappa = 224$  the private key length  $b$  is 8 beyond  
654 the double, as defined in the RFC. Hereafter,  $d$  is simply assumed to be uniformly selected  
655 from  $\mathbb{Z}_b = \{0, \dots, 2^b - 1\}$ .

673 **3.2.2. Sign**

674 The signing procedure (Sign) involves generating a pseudorandom nonce  $r$  (secret), whose  
675 procedure GenNonce varies with the signature mode, as described in Table 5. The “Prob”  
676 types (rows 6 and 7), although not FIPS-approved, are “interchangeable” in the sense of  
677 being verifiable as correct signatures by the FIPS-approved Verify algorithm. For that  
678 reason they are of interest to consider in the threshold setting, where some advantages will  
679 emerge from the use of randomness.

656

**Table 5.** EdDSA variants

657	Type	Standard	Mode $\mu$	$\kappa$	$b =  d $	$s  v$	GenNonce $r$	Challenge $\chi$
658	Det.	EdDSA	Ed25519	128	256	$H_0(d)$	$H_0(v  M)$	$H_0(R  Q  M)$
659			Ed448	224	456	$H_1(d)$	$H_1(E_{4,0}(ctx)  v  M)$	$H_1(E_{4,0}(ctx)  R  Q  M)$
660		HashEdDSA	Ed25519ph	128	256	$H_0(d)$	$H_0(E_{2,1}(ctx)  v  H_0(M))$	$H_0(E_{2,1}(ctx)  R  Q  H_0(M))$
661			Ed448ph	224	456	$H_1(d)$	$H_1(E_{4,1}(ctx)  v  H_2(M))$	$H_1(E_{4,1}(ctx)  R  Q  H_2(M))$
662	Type	Variation	Mode $\mu$	$\kappa$	$b =  d $	$s  v$	GenNonce $r$	Challenge $\chi$
663	Prob.	Random	—	—	—	—	$\leftarrow^S \mathbb{Z}_q$	—
664		Hybrid	—	—	—	—	$H(v, rand, f(M))$	—

665 **Legend:** Some symbols are better contextualized in Fig. 3. Det. (deterministic). Prob. (probabilistic).  $s, v$  (first  
666 and second halves, respectively, of  $\text{Hash}(d)$ , also denoted as 1st and 2nd digests of  $d$ ; before encoding into an integer,  
667 some bits in the left and right extremities of each of these digests is preset — see details in Draft FIPS 186-5).  $E_{i,j}(\dots)$   
668 (encoding function, defined in FIPS 186 as  $\text{dom}i(j, \dots)$ , where  $i$  is 2 or 4, corresponding to the Ed25519 or Ed448  
669 curves, and  $j$  is 1 or 0, corresponding to whether or not it is a “pre-hash” mode).  $H$  (some cryptographic hash function  
670 or extendable output function);  $H_0$  (SHA-512);  $H_1$  (SHAKE256-length-912);  $H_2$  (SHAKE256-length-512);  $rand$   
671 (secret randomness or any other secret material). The four deterministic modes (Det.) are based on Draft FIPS 186-5.  
672 The two probabilistic variants (Prob.) produce signatures interchangeable w.r.t. EdDSA verification.

680 The actual signature is a pair  $\sigma = (R, S)$ , whose first element is a “commitment”  $R$  of the  
681 secret nonce  $r$ . The second element is a linear combination  $S = r + \chi \cdot s$  of the nonce  $r$  and  
682 of the first digest  $s$  of the signing key ( $d$ ), applying as slope factor in the latter a hash-based  
683 “challenge”  $\chi$ . The challenge  $\chi$  is computed as a cryptographic hash of the commitment  $R$ ,  
684 the public key  $Q$  and the message  $M$ , as shown in Table 5. Some modes (all except Ed25519)  
685 can also use a context string  $ctx$  to determine the nonce  $r$  and the challenge  $\chi$ . The hash  
686 functions (and encodings) vary depending on the signature mode.

687 **On the meaning of “commitment” in reference to  $R$ .** The name “nonce commitment”  
688 given to  $R$  is used for convenience, but it should be understood in a sense more loose than  
689 that of a typical commitment scheme. The latter has two phases (commit and open), and  
690 needs to satisfy binding and semantic hiding properties. Conversely, the use of  $R$  as a  
691 “commitment” of the nonce  $r$  never requires an open phase, and its hiding property is only  
692 as provided by the application of a one-way permutation (which, being a bijection, does not  
693 semantically hide the input). The binding is satisfied unconditionally.

### 694 3.2.3. Verify

695 The verification procedure (`Verify`) corresponds to checking a relation between the com-  
696 ponents ( $S$  and  $R$ ) of the signature, the public parameters ( $Q$  and  $G$ ) and the message  $M$ . The  
697 operation requires recomputing the challenge  $\chi$ , which in turn also depends on the signed  
698 message  $M$ , and then performing two multiplications and one group addition. All values ( $Q$ ,  
699  $R$  and  $S$ ) are to be checked for canonical encoding. The actual verification operation specified

700 in Draft FIPS 186-5 is called *cofactored*, as it includes a cofactor adjustment (multiplication  
701 by  $2^c$ ) of  $S$ ,  $R$  and  $\chi$ .

702 Both *cofactorless* (i.e., without cofactor adjustment) and *cofactored* verifications validate  
703 signatures generated per Draft FIPS 186-5 signing specification. However, cofactored  
704 verification is less strict, also validating “signatures” outside the subgroup  $\mathbb{G}$ , i.e., with  
705 components in a subgroup different from the one generated by  $G$  [CGN20].

706 It is worth noting that an additional check (not specified in Draft FIPS 186-5) on the public  
707 key  $Q$  and the nonce commitment  $R$  — namely that their order is not smaller than the cofactor  
708  $2^c$  — can be used to protect against some key substitution attacks [BCJZ21, Table 2].

709 **Batch verification.** In Draft FIPS 186-5, the EdDSA Verify algorithm is only specified for  
710 individual signatures. However, in practice some applications amortize the cost of simultane-  
711 ous verification of multiple signatures (possibly across different messages and public keys).  
712 This can be done as a single verification using an adjusted  $S$ ,  $R$ , and  $Q$ , with each adjusted  
713 element being obtained as the same random linear combination (i.e., with random coeffi-  
714 cients) of the corresponding elements used across all signatures [CGN20]. An accepted test  
715 implies an overwhelming probability, in the size of the random linear coefficients (e.g., 128  
716 bits), that all of the individual signatures would pass their respective verifications.

### 717 3.3. Strong unforgeability

718 Unforgeability is the essential security property of a signature scheme. It considers an adver-  
719 sary not knowing the private signing key  $s$ , but being able to obtain, from a signing oracle,  
720 signatures on many chosen messages [GMR88]. A scheme is “**existentially unforgeable**  
721 against a **chosen message attack**” (EUF-CMA) if no such adversary can produce a new  
722 valid signature (denoted *forgery*)  $\sigma$  for a previously unsigned message. For simplicity, this  
723 is hereafter simply referred to as UF — the existential (“E”) and the CMA aspects remain  
724 implicit. The interest in this document is in a stronger notion: **strong UF (SUF)** [CD95,  
725 Remark 2], where the adversary cannot produce any new previously unseen message/sign-  
726 ature pair  $(M, \sigma)$  that is accepted by the Verify algorithm. (The acronym SUF should  
727 not be confused with the notion of **selective unforgeability**, which is a notion weaker than  
728 existential unforgeability, in both the regular and strong senses). That is, SUF requires,  
729 in addition to UF, that the adversary be unable to construct an alternative signature for a  
730 message that has already been signed. More formally, SUF requires the adversary to have a  
731 negligible probability (in the security parameter  $\kappa$ ) of winning the following game:

- 732 1. The keygen phase takes place as prescribed and the private key remains secret, i.e.,  
733 known only to a signing oracle.
- 734 2. The adversary can choose up to  $q$  messages —  $\{M_i : i = 1, \dots, q\}$ , for which it can  
735 obtain corresponding valid signatures  $\sigma_i$  from the oracle.
- 736 3. The adversary wins the game if it can output a previously unseen pair  $(\sigma_{q+1}, M_{q+1})$ ,  
737 for which  $\text{Verify}[Q](M_{q+1}, \sigma_{q+1})$  outputs *accept*.

738 Note that, in the SUF game (as well as in a corresponding UF game), the adversarial  
739 capability varies between deterministic and probabilistic signatures. In the latter case the  
740 adversary receives a different signature each time it repeats a query for the signing oracle to  
741 sign the same message. The UF and SUF notions for signatures are the direct analogue of  
742 the same type of properties for message authentication codes (MAC) in the symmetric key  
743 setting [BKR00; BN08].

744 Strong unforgeability implies unforgeability, i.e., if a scheme is SUF, then it is also UF.  
745 This is because the adversarial goal in the SUF game is less ambitious than in the UF game.  
746 Moreover, if a scheme is *verifiably deterministic* and UF, then it is also SUF, since it is  
747 infeasible to produce more than one valid signature for the same message (as in the case  
748 of RSASSA-PKCS-v1\_5; see Section 3.1). However, both probabilistic and non-verifiably  
749 deterministic schemes can be UF without being SUF.

750 The study of Schnorr/EdDSA unforgeability has been the subject of much research, with  
751 techniques such as the forking lemma [PS00, Theorem 4] in the programmable random oracle  
752 model, and other results ([PS96, Thm 13], [FF13; KMP16; RS21; BCJZ21]). Assuming the  
753 infeasibility of solving the “discrete log” problem in the underlying elliptic curve and the  
754 one-wayness of the hash function, the EdDSA specified in Draft FIPS 186-5 provides strong  
755 unforgeability. The HashEdDSA mode additionally requires collision resistance from the  
756 hash function.

757 Intuitively, SUF of EdDSA stems from SUF of Schnorr signatures, where the adversary has  
758 access to multiple random signatures for each message. The adversary in EdDSA can only get  
759 one signature per message which, although deterministic, is indistinguishable from random.  
760 Still, the details matter for an actual proof [BCJZ21]. Note that achieving SUF requires  
761 checking that the signature components are in a canonical representation. For EdDSA, this  
762 requires (as specified in Fig. 3) checking that  $S$  is a positive integer less than  $n$ . Otherwise,  
763 replacing  $S$  by  $S + n$  would trivially produce a valid forgery violating SUF.

764 A signature scheme that is interchangeable with Draft FIPS 186-5 EdDSA verification  
765 is not automatically unforgeable. While interchangeability only depends on the Verify  
766 function, unforgeability also depends on the space and distribution of signatures. Consider  
767 the pathological case of a signing algorithm that always uses the same nonce even when  
768 signing different messages. Such a scheme would allow extraction of the private key when  
769 the adversary queries the signing oracle on two different messages (see Section 3.5.1), and  
770 is therefore forgeable. Other pathological examples of interchangeable schemes can be  
771 devised to break strong unforgeability without breaking UF, or break UF without allowing  
772 key-recovery (see Section 5.2.4).

### 773 3.4. Binding and non-repudiation

774 The classical notion of unforgeability, where the adversary is external to the signer, does  
775 not consider all possibly desirable security properties of a signature scheme. For example,  
776 SP 800-57-P1-R5 specifies that: a “Digital Signature” is “*the result of a cryptographic*

777 *transformation of data that, when properly implemented with a supporting infrastructure*  
778 *and policy, provides the services of: 1. Source/identity authentication, 2. Data integrity*  
779 *authentication, and/or 3. Support for signer non-repudiation.”*

780 The unforgeability game considers the case of an adversary without knowledge of the private  
781 key. What happens, however, if the adversary controls the signer, i.e., knows and/or is able  
782 to generate the private key, and then tries to manipulate the signature generation against an  
783 unwary verifier? That may jeopardize the “data integrity authentication” requirement, even if  
784 maintaining “source/identity authentication”. For example, an unforgeable signature scheme  
785 may still allow a malicious signer to produce two messages (possibly under two different  
786 public keys) and one signature that validates both messages [CGN20; BCJZ21].

### 787 **3.4.1. Binding**

788 The EdDSA verification specified in Draft FIPS 186-5 provides a form of *binding* that  
789 follows trivially from the collision resistance of the hash used to calculate the challenge  $\chi$ .  
790 Considering a fixed public key  $Q$ , a malicious signer cannot find two messages  $M$  and  $M'$   
791 and a signature  $\sigma$  that validates both of them under that public key. Thus, when the signer’s  
792 identity is certifiably bound to a single public key  $Q$ , such as when relying on a PKI, then a  
793 signature  $\sigma$  binds the signer to a single message.

794 A stronger binding notion [CGN20; BCJZ21] goes further, considering that the public key  
795 may also be manipulated: a signature scheme provides *strong binding* if no malicious signer  
796 is able to find two different pubkey–message pairs —  $(Q, M)$  and  $(Q', M')$  — and a signature  
797  $\sigma$  that is valid against both pairs. In the case of EdDSA, such a collision can be obtained by  
798 a malicious signer, by using a public-key  $Q$  that is part of the small subgroup. This allows  
799 the signer to later perform a key-substitution attack: after initially sending  $(M, \sigma)$ , w.r.t.  
800 public key  $Q$ , the signer later claims that it has actually sent  $(M', \sigma)$  w.r.t. a public key  $Q'$ .  
801 While having one of the keys being in the small subgroup is not compliant with the EdDSA  
802 keygen phase, such a key is nonetheless not caught as incorrect in the standardized EdDSA  
803 verification. As already briefly mentioned in Section 3.2.3, this can be fixed by adding a  
804 simple additional verification regarding the public key  $Q$  and the nonce commitment  $R$ .

805 Binding can even be considered in a stronger sense, across various signature schemes and  
806 parameters (e.g., approved EdDSA and ECDSA modes), which may use different hash  
807 functions  $H$ , base-points  $G$ , encodings  $E_\mu$ , moduli  $n$  and even *Verify* algorithms. For  
808 example, one can ask whether one can find a signature simultaneously valid for EdDSA and  
809 for ECDSA, each with their own parameters.

### 810 **3.4.2. Non-repudiation**

811 The colloquial expression “non-repudiation” means the inability of a signer to *repudiate*  
812 (plausibly deny) having produced a signature w.r.t. a message. However, the expression  
813 leaves some room for ambiguity, as evident by comparing the two notions explained below.

814 Such ambiguity can be resolved by expressing the needed non-repudiation features in terms  
815 of unforgeability and binding properties.

816 A (weak) notion of non-repudiation considers that the signature can be used “to support a  
817 determination by a third party of whether a message was actually signed by a given entity”  
818 [SP 800-57-P1-R5], if it can be assumed that the private key is indeed private. This property  
819 is implied by SUF, since SUF implies that any valid message–signature pair must have been  
820 created by a holder of the private key. Even if a SUF scheme is non-binding in the sense  
821 of allowing a malicious signer to produce, under the same public key, two messages and  
822 one signature that validates both messages, it still follows that both messages must indeed  
823 have been signed by the entity that knows the private key. EdDSA, being SUF, provides  
824 non-repudiation in the mentioned sense.

825 Some application settings may warrant a stronger notion of “non-repudiation”, equivalent to  
826 binding. The following is an example application setting where a false repudiation occurs  
827 despite of the use of a SUF signature scheme. Consider, hypothetically, a non-binding  
828 signature scheme used in an application where an honest signer, upon request by a server A,  
829 generates and sends to A two messages  $M_0$  and  $M_1$ , and a corresponding single signature  $\sigma$   
830 that validates both messages. Later, the signer is asked to securely send to another server  
831 B one of those messages,  $M_b$ , for some  $b$  of the client’s choice. If server B is unaware  
832 of the non-binding property, it may think that the authenticity of the message sent by the  
833 client is protected by the accompanying signature  $\sigma$ . However, if server A controls the  
834 communication channel, it could now replace the message by  $M_{1-b}$ , without the client or  
835 the server B realizing it, even though server B could check that the received signature  $\sigma$  is  
836 valid for the received message  $M_{1-b}$ . Alternatively, if server A is honest (and thus server  
837 B actually receives the original message  $M_b$ ), then a malicious client can later plausibly  
838 *repudiate* that it sent said message, and claim that the message was in fact  $M_{1-b}$ , and that,  
839 plausibly, server A may have tampered with the communication. The use of a signature  
840 scheme with strong binding would make this repudiation implausible.

### 841 3.5. Nonce implementation issues

842 Even if the unforgeability of the specified EdDSA algorithms is assumed or proven (see  
843 Section 3.3), there are still potential security issues that arise from the implementation. The  
844 security of signatures interchangeable w.r.t. EdDSA verification depends critically on the  
845 secrecy and unbiased selection of the nonce  $r$  used in any signature  $(R, S)$ . For example,  
846 should a nonce ever be known to an adversary, the signing key  $s$  can then be recovered,  
847 simply as  $s = \chi^{-1} \cdot (S - r)(\text{mod } n)$ . Other subtle issues within the GenNonce procedure can  
848 cause catastrophic security failures. The same type of issues apply to implementations of  
849 the ECDSA signature scheme, against which the mentioned attacks have been demonstrated.  
850 To summarize (also see Table 6):

- 851 • Implementations of probabilistic nonces may introduce biases, and even small biases  
852 can result in full recovery of the private signing key.

- 853 • Deterministic nonce generation prevents bias, but is more subject to side-channel and  
854 fault injection attacks that also enable key recovery.
- 855 • The upshot is that it can be more secure to generate the nonce in a *hybrid* manner, by  
856 adding some random noise to an otherwise deterministic procedure.

857 **Table 6.** Types of nonce generation

858 Nonce generation type	Bias attacks	Side-channel and fault injection attacks
859 <b>Deterministic:</b> Pseudorandom, based on a secret key	Not applicable	<u>More vulnerable</u>
860 <b>Purely random:</b> Entropy independent of secret key	Vulnerable	Less vulnerable
861 <b>Hybrid:</b> Randomness and pseudo-randomness	Not applicable	Less vulnerable

### 862 3.5.1. Nonce reuse

863 A serious nonce-related security failure occurred when the ECDSA signing key of a home  
864 video game console was recovered [bmss10]. This is due to the use of the same nonce  
865 when signing different pieces of software. A similar attack is possible if nonces are reused  
866 when EdDSA-signing different messages. In that case, from two signatures  $(R, S)$  and  
867  $(R', S')$ , one can find the secret key by solving a pair of linear equations with two unknowns.  
868 From  $S' - S = (r' - r) + s \cdot (\chi' - \chi) \pmod{n}$ , and  $r = r'$ , the secret key follows as  $s =$   
869  $(S' - S)(\chi' - \chi)^{-1} \pmod{n}$ .

870 Nonce reuse can occur when an adversary is able to perform a “rewinding” attack. For  
871 example, if the signer is running in a virtual machine and nonces are generated before  
872 the message to be signed is determined, an adversary may rewind the virtual machine in  
873 order to obtain signatures on two different messages using the same nonce and different  
874 challenges. This attack can be prevented by generating the nonce in a way that depends on  
875 the message to be signed, as happens in the pseudorandom nonce generation specified for  
876 EdDSA in Draft FIPS 186-5. Some system models may also avoid rewinding concerns based  
877 on other assumptions on fresh randomness, such as selecting the nonce via a non-rewindable  
878 hardware random-number generator that produces true fresh randomness on every call.

### 879 3.5.2. Partial knowledge of random nonce

880 Partial information about nonces can be leaked through a poorly implemented or biased  
881 random number generator [BH19], as well as various side-channel attacks, such as cache-  
882 timing side-channels [ANTTY20]. Deliberately injected faults can also induce bias in the  
883 nonce [TTA18]. This bias can be leveraged to recover the private signing key by solving  
884 the Hidden Number Problem (HNP) [BV96] using one of two known techniques. Fourier  
885 analysis [Ble00; ANTTY20] is used when there is a very small bias (potentially even less

886 than a single bit [ANTTY20]) but the adversary has access to many signatures; lattice-  
887 based techniques [HS01] can be used when the bias is more significant but the adversary  
888 has access to fewer signatures.

### 889 3.5.3. Side-channel and fault injection attacks against deterministic nonce

890 A pseudorandom (deterministic) nonce generation avoids the issues caused by bad ran-  
891 domness. However, that may result in a signing process more susceptible to side-channel  
892 [ABFJLM18] and fault injection attacks [RP17; SB18]. For example, differential power  
893 analysis on the modular addition operation within SHA-512 can enable the recovery of the  
894 nonce-derivation key  $\mathbf{v}$  being hashed. Also, a differential fault injection attack can induce  
895 a “glitch” during the computation of the challenge  $\chi$ , resulting in a faulted challenge hash  
896  $\chi'$ . Then, the computation follows with the proper formula  $S = R + \chi \cdot s$ , but using the  
897 incorrect challenge value  $\chi'$ , leading to an invalid signature component  $S'$  that is nonetheless  
898 a linear relation of the secret key and a secret nonce. Since the signature is pseudorandom,  
899 the adversary can additionally obtain a valid signature component  $S$  for the same message,  
900 using the same nonce  $r$  as before (and thus the same  $R$  as before), and necessarily having  
901 a different (correct) challenge  $\chi$ . From  $S$  and  $S'$  the adversary can recover the private key,  
902 similar to as when a nonce is reused when signing different messages (see Section 3.5.1).  
903 The exploitation of these vulnerabilities often requires physical access to the signing device.

### 904 3.5.4. Hybrid nonce generation — combined randomness and determinism

905 The security issues mentioned above can be mitigated by using a hybrid mode of nonce  
906 generation, combining both random and pseudorandom components. As with deterministic  
907 nonce generation, the nonce can be computed as the output of a pseudorandom function  
908 (using as key the nonce-derivation key), whose input is the message. However, to protect  
909 against side-channel and fault-injection attacks, the function can additionally take some  
910 random bytes as input. The actual details on how the randomness and the nonce-derivation  
911 key are possibly intertwined when used as input to the pseudorandom function may depend  
912 on the concrete side-channel protection being sought.

913 Even if there is some bias in the used randomness, the use of a PRF (dependent on the secret  
914 nonce-derivation key) will prevent the bias from being apparent in the nonce itself. The idea  
915 is not new [SBBDS18; PSSLR18]. It has also been suggested as an update [MTR22] to  
916 RFC 8032 (on which the EdDSA specified in Draft FIPS 186-5 is based), which after the  
917 encoding of the nonce derivation key  $\mathbf{v}$  would concatenate a random string (with the same  
918 length as  $\mathbf{v}$ ), used as a preimage to the hashing that computes the nonce.

919 Furthermore, as long as the “random” values contributed to this function do not repeat for the  
920 same message, there is some additional protection against side-channels and fault-injection  
921 attacks. With a single signer, if the needed entropy is unavailable at signing time, the signing  
922 simply falls back to the deterministic mode. (The threshold setting requires particular  
923 attention against insider attacks, as discussed in Section 4.3.1).

## 924 4. Threshold approaches

925 This section surveys, at a high level, several approaches for threshold signatures with  
926 potential interchangeability w.r.t. EdDSA verification. Section 4.1 provides intuition about  
927 the linear operations involved in a semi-honest probabilistic setting. Section 4.2 describes a  
928 template protocol for threshold Schnorr/EdDSA signatures, matching at a high-level many  
929 concrete protocols. Section 4.3 explains several deterministic approaches, while Section 4.4  
930 considers probabilistic approaches.

### 931 4.1. Intuition for efficiency of threshold [probabilistic] Schnorr signatures

932 The baseline building block assumed available for threshold signatures is a secret sharing  
933 (SS) scheme . From an initial secret value  $x$ , the SS scheme allows producing a vector  
934  $[x] = \langle x_1, x_2, \dots, x_n \rangle$  of shares, usually for distribution across  $n$  parties, such that any subset  
935 of  $t$  parties can reconstruct the secret  $x$ , but any subset of  $t - 1$  colluding parties learns  
936 “nothing” about the secret. For example, Shamir SS [Sha79] selects a random polynomial of  
937 degree  $t - 1$ , subject to its evaluation at zero being the secret  $x$ ; then the various shares are  
938 the evaluation of the polynomial at other points. The evaluation points across shares must  
939 not collide (which would affect the threshold guarantee) and must not be zero (which would  
940 reveal the secret).

941 For Schnorr signatures in particular, it is most useful to use a linear SS (LSS) scheme.  
942 Linearity enables local computation of the sum of shares, and multiplication-by-constant  
943 of shares. Therefore: if  $z = x + y$ , it follows that  $[z] = [x] + [y]$  (i.e., each local share  $z_i$   
944 can be obtained as  $x_i + y_i$ .); also, if  $z = a \cdot w$ , then  $[z] = [a \cdot w]$  (i.e., each local share  $z_i$   
945 can be obtained as  $a \cdot w_i$ ). The threshold properties of the secret-sharing  $[z]$  upon these linear  
946 operations remains the same (namely  $t$  shares are required to reconstruct a secret). It should  
947 be noted that different secret-sharing schemes exist and can be useful, including those with  
948 multiplicative properties.

949 Compared with ECDSA, the better efficiency of threshold Schnorr signatures comes from  
950 being able to compute the signature operations (all linear) locally at each party, once the  
951 needed shares are distributed. In particular, when the nonce is allowed to be randomized (as  
952 in regular Schnorr, although not in EdDSA), then even the distributed secret selection of the  
953 nonce and the calculation of its commitment depend only on simple linear/homomorphic  
954 operations. Conversely, ECDSA requires computing the modular inverse of a secret-shared  
955 element, which is more complicated and inefficient to perform in a distributed manner. The  
956 non-linear operation requires interaction and may be based on a different type of secret  
957 sharing (e.g., multiplicative) and a corresponding final conversion to linear secret sharing.

958 This simplicity is captured well in a semi-honest threshold implementation (i.e., where every  
959 party behaves according to the protocol specification), as summarized in Table 7. In this  
960 case, the distributed computation only involves the secret-sharing and corresponding recon-  
961 struction of secret elements, as well as simple homomorphic operations. The description

962 is for  $n$ -of- $n$  signatures. The  $k$ -out-of- $n$  case is resolved by Lagrange interpolation in the  
963 exponent, which can also be done with (homomorphically) linear operations.

964 **Table 7.** Conventional Schnorr vs. baseline semi-honest threshold Schnorr

965 Phase	Conventional	Semi-honest threshold baseline
966 <b>Key-Gen</b>	$Q = s \cdot G$	$[Q] = [s] \cdot G$ ; then open $Q$
967 <b>Commit nonce</b>	$R = r \cdot G$	$[R] = [r] \cdot G$ ; then open $R$
968 <b>Compute challenge</b>	$\chi = H(R, Q, M)$	<i>Same as in conventional</i>
969 <b>Produce signature</b>	$S = r + \chi \cdot s \pmod{n}$	$[S] = [r] + \chi \cdot [s] \pmod{n}$ ; then open $S$
970 <b>Verify signature</b>	$S \cdot G \stackrel{?}{=} R + \chi \cdot Q$	<i>Same as in conventional</i>

971 To “open” a public value ( $Q$ ,  $R$  and  $S$ ) means that every party reveals their corresponding share ( $Q_i$ ,  
972  $R_i$  and  $S_i$ , respectively), so that everyone can reconstruct the corresponding public value.

973 For each row involving secret material, the baseline threshold version simply computes  
974 the needed public element shares ( $Q_i$ ,  $R_i$  and  $S_i$ ) by homomorphic computations over  
975 the secret-shared secret values ( $s_i$  and  $r_i$ ). Some additional care is required to deal with  
976 active/malicious adversaries, which in practice leads to some variations (e.g., how the nonce,  
977 or signature shares are produced), while leaving the compute challenge and verify signature  
978 steps identical to the conventional scheme.

979 **On regular threshold signatures vs. multi-signatures.** Sometimes it is useful to clearly  
980 distinguish between two types of distributed signature schemes:

- 981 • **(Regular) Threshold Schemes:** there is a fixed public key  $Q$ , whose corresponding  
982 private signing key  $s$  is secret-shared across various parties.
- 983 • **Multi-Signature schemes:** there is a setting where each party  $P_i$  has a public key  $Q_i$ ,  
984 and a corresponding private signing key  $s_i$ , and any subset of them can come together  
985 to produce a multi-signature, which can only have been produced by a collaboration of  
986 all corresponding private keys, and whose verification is based on either (i) a list of the  
987  $Q_i$ ’s of all signatories, or (ii) an aggregate public key  $Q$  that is derived from them.

988 The case of  $n$ -out-of- $n$  (regular) threshold signatures has some similarities to a multi-sig-  
989 nature from  $n$  parties. In particular, overlooking the Keygen phase, the Sign and Verify  
990 phases of a multi-signature scheme can be transformed into those of a  $n$ -out-of- $n$  regular  
991 threshold scheme, by fixing the public key  $Q$  and the set of  $n$  parties. In both types, there  
992 is a threshold security property: an adversary must corrupt all  $n$  cosigners in order to forge  
993 a signature. Furthermore, Schnorr multi-signatures can be interchangeable w.r.t. the EdDSA  
994 verification algorithm, provided that the aggregate public key is given. For the most part,  
995 the discussion in this report considers threshold schemes in the regular sense. However,  
996 considering the above, it is sometimes useful to consider “threshold schemes” in a broad  
997 sense that also includes multi-signatures.

## 998 4.2. A template threshold Schnorr/EdDSA signature

999 A conventional signature scheme is composed of three procedures: Keygen, Sign, and  
1000 Verify. A threshold implementation of it alters only the Keygen and Sign operations,  
1001 which relate to private key. The verification operation (Verify) remains unchanged. Here-  
1002 after, the focus is on actively secure protocols (i.e., against malicious adversaries).

### 1003 4.2.1. Key Generation

1004 In the Keygen phase, each party obtains a share  $s_i$  of the private signing key  $s$ . During this  
1005 process, every party also learns all “public” keys  $Q_i$  associated to the private keys of each  
1006 other party, from which anyone can derive the global public key  $Q$ . The secret sharing  
1007 (SS) can be one from several kinds, including verifiable SS (VSS) or publicly verifiable  
1008 SS (PVSS), where each party learns additional information that enables verifying that their  
1009 share is correctly related to the global public key.

1010 The generation of these keys typically follows one of two main approaches:

- 1011 • **centralized (by a dealer):** a dealer (trusted or untrusted) determines the private  
1012 signing key  $s$ , then produces a secret sharing  $[d]$  of the private signing key, and sends  
1013 a different secret share  $d_i$  to each party  $i$ . The public key  $Q = s \cdot G$ , as well as its  
1014 shares  $Q_i = s_i \cdot G$ , are sent to every party.
- 1015 • **distributed (by the signatories):** the parties interact in a distributed key-generation  
1016 protocol, such that no party knows the global secret key  $d$ . Typically, each party  
1017 generates their own secret key share and corresponding public key share, which are  
1018 then combined to generate the global public key.

1019 Note: In the actual (deterministic) EdDSA there is also a nonce-derivation key  $v$ . In a  
1020 threshold (deterministic) EdDSA scheme, functionally equivalent to EdDSA, the parties also  
1021 obtain corresponding secret shares  $v_i$ . There is nonetheless an essential difference across  
1022 the two private keys, w.r.t. the distributed signature process: for the signing key  $s$ , there are  
1023 homomorphic properties that facilitate the group operations to be carried out in secret-shared  
1024 mode; the same does not apply for the SHA-based hash-related operations performed on  
1025  $v$ . There are other threshold schemes interchangeable w.r.t. EdDSA verification that avoid  
1026 the latter problem by deriving independent local nonce derivation keys per party, or even  
1027 simply assuming access to good randomness.

1028 **Distributed key generation (DKG) approach.** A DKG for public keys has a basic goal of  
1029 letting each party obtain a secret-share of a random private key  $s$ . For typical discrete-log  
1030 based schemes, the homomorphic properties of the group are such that an additive secret  
1031 sharing  $s_i \cdot G$  of the private key allows the calculation of (now in additive notation) a share  
1032  $Q_i = s_i \cdot G$  of the public key  $Q$ . A useful gadget for DKG is a VSS scheme [CGMA85].  
1033 In particular, Feldman’s scheme [Fel87] allows for non-interactive verifiability. After an  
1034 interactive (e.g., 2 rounds of communication) secret-sharing, each share  $s_i$  “proves its own  
1035 validity” via a verification algorithm that checks it against a commitment of the secret  $s$ . An

1036 initial DKG scheme [Ped91] based on Feldman’s VSS allowed a malicious party to bias  
1037 the public key. While such a public key may still be sufficient for some purposes, it does  
1038 not emulate the case of a random public key selected by a trusted dealer. A later protocol  
1039 [GJKR99] solves that issue, by ensuring that any party must propose their contribution  
1040 before they can learn the resulting public key. This can be achieved by adding an initial  
1041 communication round where parties commit to their contributions, e.g., using Pedersen  
1042 commitments [Ped92]. The mentioned DKG, for an honest majority setting and assuming  
1043 broadcast channels, can be used as a basis for subsequent threshold Schnorr-style signing  
1044 [SS01]. Other alternatives may be possible with a different number of rounds, depending on  
1045 the system model.

1046 **Rogue-key attack.** Some restrictions need to be enforced w.r.t. the key shares, in order to  
1047 protect against “rogue key” attacks, where a malicious party sets their public key share  $Q_i$   
1048 to some function of the honest parties’ public keys. For example, consider a 2-of-2 multi-  
1049 signature scheme intended to prove that both Alice and Bob have participated in creating  
1050 a signature. Let honest Alice have private key  $s_A$  and public key  $Q_A = s_A \cdot G$ . Bob, who is  
1051 malicious, has private key  $s_B$  and public key  $Q_B = s_B \cdot G$ . Alice says her public key is  $Q_A$ ,  
1052 while Bob says his public key is  $Q' = Q_B - Q_A$  (instead of the correct  $Q_B$ ), even though Bob  
1053 is unaware of the discrete log of  $Q'$ . The resulting shared public key is  $Q_B$ , so Bob can sign  
1054 for the group without Alice’s consent.

1055 To prevent such attacks, each party may be required to prove knowledge of their secret key  
1056 (KOSK), using a NIZKPoK of DL (base  $G$ ) of  $Q_i$ , essentially equivalent to producing a  
1057 signature with their private key. Some multi-signature schemes operate in the plain public  
1058 key model, where parties are not required to prove knowledge of their secret keys in order to  
1059 thwart rogue key attacks. This involves tweaking the procedure for generating an aggregated  
1060 public key, as well as modifying the process for generating signature shares.

#### 1061 4.2.2. Signing

1062 In each threshold signing session, the parties need to obtain *agreement* on several parameters:  
1063 the message  $M$  to be signed; the set  $\mathcal{P}'$  of cosigners actively participating in the signing  
1064 session; and a session identifier  $sid$  used to distinguish between concurrent executions.  
1065 Unless otherwise noted, the remainder of this section assumes there is a mechanism whereby  
1066 parties agree on the tuple  $(sid, \mathcal{P}', M)$ . In practice, however, threshold implementations  
1067 must explicitly consider this agreement.

1068 In an actively secure threshold Schnorr signature, some variations or extra steps are required  
1069 as compared to the semi-honest setting (Section 4.1). A simple template for threshold proba-  
1070 bilistic signing [SS01] is to perform a DKG to obtain a secret-shared secret nonce  $r$ , along  
1071 with each party receiving the nonce-contribution commitment  $R_i$  of everyone, and then let  
1072 each party locally compute and broadcast their corresponding signature share. Some tricks  
1073 can reduce the number of rounds, but special care is required to prevent the challenge  $\chi$  from  
1074 being maliciously manipulated in a way that could break unforgeability.

- 1075 1. **Nonce commit.** Each party computes a random nonce share  $r_i$  and then the corre-  
 1076 sponding commitment  $R_i = r_i \cdot G$ . The details of this computation define whether the  
 1077 overall EdDSA implementation is deterministic (see Section 4.3), or probabilistic  
 1078 (see Section 4.4). Due to homomorphism, the commitment  $R_i$  is also a share of  
 1079 the commitment  $R$  of the random secret nonce  $r$  (of which no party is aware). In  
 1080 other words, the distributed system produces secret-sharings  $[r]$  and  $[R] = [r] \cdot G$ .  
 1081 The shares of  $[R]$  are then revealed between all parties, which allows each party to  
 1082 locally reconstruct the public commitment  $R$ . Special care is required to thwart attacks  
 1083 where an adversary tries to manipulate the challenge  $\chi$  (dependent on  $M$ ,  $R$ , and  
 1084  $Q$ ), possibly in a concurrent setting with many distributed signing operations taking  
 1085 place [DEFKLNS19]. This manipulation can be prevented by having a round of  
 1086 communication where parties, when committing to their nonce contribution (e.g.,  $r_i$ ),  
 1087 do not immediately reveal a share (e.g.,  $R_i = r_i \cdot G$ ) of the nonce commitment, or with  
 1088 more advanced techniques that can eliminate a round of communication. For example,  
 1089 the nonce commitment  $R$  may be a more complex linear combination of the shares  $R_i$ ,  
 1090 using additional coefficients to avoid some malleability attacks. The revealing of the  
 1091 shares  $R_i$  of the public value  $R$  follows after a corresponding commitment phase, to  
 1092 ensure independence of values. A secret-sharing  $[r]$  of a SHA-based pseudorandom  
 1093 nonce  $r$  would require a more generic (secure) **multiparty computation** (MPC).  
 1094 2. **Compute challenge.** In the simplest (and EdDSA-interchangeable) case, the chal-  
 1095 lenge  $\chi$  is locally computed by each party, as a hash of the nonce commitment  $R$ , the  
 1096 public key  $Q$ , and the message  $M$ . Some modes also include a context component  $ctx$   
 1097 (see Table 5), or other small tweaks.  
 1098 3. **Signature shares.** Based on the linear properties of the secret-sharing scheme, each  
 1099 party can locally compute a share of the output signature This can be as simple as  
 1100  $[S] = [r] + \chi \cdot [s]$  (in  $\mathbb{Z}_n$ ). However, some protocols use sophisticated techniques where  
 1101 some of the elements may be tweaked. The final signature can then be computed by  
 1102 anyone collecting all signature shares.

1103 The above description is for  $n$ -out-of- $n$  signatures. The  $k$ -out-of- $n$  case is resolved by  
 1104 additionally using Lagrange coefficients.

### 1105 4.3. Deterministic threshold Schnorr

1106 In a deterministic threshold Schnorr signature scheme, each message leads to a single  
 1107 possible signature, once the public key and/or the subset of signatories is fixed. In particular,  
 1108 the secret nonce  $r$  (i.e., the discrete-log of the nonce commitment  $R$ ) is deterministic, even  
 1109 through never computed by a single party. It could seem that this can be trivially achieved  
 1110 by having each party provide a deterministic contribution  $R_i = r_i \cdot G$ , for a locally computed  
 1111 deterministic  $r_i$ . However, a careless protocol could result in a key-recovery vulnerability  
 1112 against internal adversaries (see §4.3.1). Therefore, a protocol needs to be carefully crafted,  
 1113 possibly using an MPC (see §4.3.2) or ZKP (see §4.3.3) that ensures correct behavior from  
 1114 the signatories. Table 8 compares various aspects of different deterministic approaches.

1115 **Table 8.** Threshold approaches for deterministic signatures

Reference	Functionally equivalent?	EdDSA Interchangeable?	Same signature per message?		Some gadgets
			Per/across quorums	Across re sharings	
1118 [BST21, §5]	Yes	Yes	Yes/ Yes	Yes	MPC gadgets
1119 [BST21, §6]	No	Yes	Yes/ Yes	Yes	MPC-friendly hash
1120 [GKMN21]	No	Yes	Yes/ No	No	ZKGC, COT
1121 [NRSW20]	No	Yes	Yes/ No	N/A	ZKP-friendly PRF

1122 Some schemes implement the HashEdDSA mode (see Table 5). The last row [NRSW20] corresponds  
 1123 to a multi-signature scheme, for which the resharing does **not** apply (N/A), since that would imply a  
 1124 change in public key. COT = committed oblivious transfer. ZKGC = **Z**KPs from **g**arbled **c**ircuits. The  
 1125 approaches also differ in efficiency, allowed thresholds, and cryptographic assumptions.

1126 **4.3.1. A key-recovery pitfall**

1127 Suppose the secret nonce  $r$  is a naive combination of “deterministic” nonce contributions  
 1128 from the various parties. Consider now two executions to sign the same message  $M$ . Since  
 1129 the determinism is not verifiable, a malicious party can provide different nonce contributions  
 1130 in both, whereas the honest participants supply the same deterministic nonce each time  
 1131 [MPSW19]. This allows the adversary to learn:

- 1132 • two different challenges  $(\chi, \chi')$ , since they respectively depend on the two different  
 1133 nonce contributions from the malicious party;
- 1134 • two different signature shares  $(S_i, S'_i)$  from each honest party, since they depend on  
 1135 the two different challenges,

1136 The above pairs from honest parties will both have been derived using the the same secret  
 1137 nonce  $r_i$  (prescribed to be deterministic) and the same secret signing share  $s_i$ . This enables  
 1138 the malicious party to obtain the secret key share of each honest party, by solving a simple  
 1139 pair of linear equations, leading to:  $s_i = (\chi - \chi')^{-1} \cdot (S_i - S'_i) \pmod n$ .

1140 Secure versions of deterministic threshold EdDSA/Schnorr need to resolve the above men-  
 1141 tioned problem. Two such approaches are described below.

1142 **4.3.2. MPC-based threshold (deterministic) EdDSA**

1143 The above described pitfall (§4.3.1) can be avoided by directly using generic MPC to ensure  
 1144 that the secret nonce  $r$  is a hash whose pre-image includes the nonce-derivation key  $v$   
 1145 [BST21], exactly as prescribed for (deterministic) EdDSA.

- 1146 1. **KeyGen:** use a dealer or a dealerless keygen, such that each party has a secret share  
 1147  $s_i$  of the signing key, and a secret share  $v_i$  of the nonce-derivation key.

- 1148 2. **Nonce commit:** use generic MPC to compute a nonce-commitment  $R = r \cdot G$ , with-  
 1149 out anyone learning the corresponding discrete-log  $r$  (the nonce), and yet be assured  
 1150 that the nonce satisfies the prescribed relation, i.e.,  $r = \text{Hash}(\mathbf{v}, \text{Hash}(M))$  in case  
 1151 of HashEdDSA. Considering the original SHA-based hash as a Boolean circuit, the  
 1152 techniques used to perform its distributed computation can be based on MPC *gadgets*,  
 1153 say, to obtain a secret-sharing  $[r]$  of the nonce, which can then be homomorphically  
 1154 converted to the corresponding commitment shares  $[R]$ . The distributed hashing can be  
 1155 based on *garbled circuits*, and using *oblivious transfer* to handle the secret inputs of the  
 1156 circuit evaluator. Alternatively, the circuit evaluation can proceed by computing over  
 1157 bits that are secret-shared using a LSS scheme and a mechanism for authentication  
 1158 of shares. To convert between shares (of the nonce-derivation key or of the nonce)  
 1159 in  $\mathbb{F}_n$ , and the bits (i.e., in  $\mathbb{F}_2$ ) used in the distributed hash computation, a modular  
 1160 conversion mechanism can also be used. In some cases it can be easier to use a Q2  
 1161 access structure, to handle multiplicative shares [BST21].
- 1162 3. **Challenge:** compute the challenge  $\chi$  as prescribed (see Table 5).
- 1163 4. **Signature shares:** locally compute the signature share  $S_i = r_i + \chi \cdot s_i \pmod{n}$  and  
 1164 send it to a *combiner* (anyone receiving all signature shares), who can then trivially  
 1165 obtain the final signature.

1166 The main challenge above is the distributed SHA-based hashing needed to obtain the secret-  
 1167 shared nonce  $r$ , depending on the secret shares  $\mathbf{v}_i$  of the nonce-derivation key  $\mathbf{v}$ . The generic  
 1168 feasibility of MPC guarantees this is possible (e.g., see [BST21] for an implementation  
 1169 in an honest majority setting), albeit contrived when compared with what is needed for  
 1170 probabilistic Schnorr.

1171 As an alternative, substantial efficiency improvements can be obtained by using an MPC-  
 1172 friendly hash (not the case of SHA-512 or SHAKE256) to distributively compute the nonce.  
 1173 This will no longer yield a *functionally equivalent* signature, but it will still be *interchange-*  
 1174 *able* w.r.t. EdDSA verification. Note that the hashing used to generate the challenge  $\chi$   
 1175 remains the original (SHA-based) one [BST21, §6].

### 1176 4.3.3. Threshold signing with local deterministic contributions

1177 An alternative solution to the key recovery pitfall (§4.3.1) is to have parties generate their  
 1178 nonce contributions deterministically and supply an accompanying proof that they were  
 1179 generated correctly [GKMN21; NRSW20].

- 1180 1. **KeyGen:** Either a dealer or dealerless keygen protocol provides to each party a  
 1181 secret share  $s_i$  of the signing key. Each party  $i$  can locally select, independently, a  
 1182 nonce-derivation key  $\mathbf{v}_i$  and send a commitment of it to all other parties. The parties  
 1183 may also generate some additional random state to be used for the proof of correct  
 1184 nonce derivation during the signing process. [GKMN21]
- 1185 2. **Nonce commit:** Each party locally derives their deterministic contribution  $r_i$  for the

1186 nonce, which depends on the secret  $v_i$  and on the public message  $M$ . Then the party  
1187 commits as usual by sending  $R_i = r_i \cdot G$  to everyone, but now also sends a ZKP that  
1188 this is correctly related to the commitment of the nonce-derivation key. If all the  
1189 proofs are valid, the honest parties combine the various contributions to obtain the  
1190 global nonce commitment  $R = \sum R_i$ ; otherwise, the parties abort. The specifics of the  
1191 ZKP and deterministic function depend on the scheme.

1192 3. **Challenge:** The challenge  $\chi$  is computed as usual (see Table 5).

1193 4. **Signature shares:** Generate, broadcast, and aggregate (partial) Schnorr signature  
1194 shares. The actual techniques may be more sophisticated, such as by masking the typi-  
1195 cal signature share such that the masks are cancelled out when combined across parties  
1196 [GKMN21], or including multiplicative coefficients that allows for key aggregation  
1197 (in case of multi-signature) [NRSW20].

1198 What distinguishes schemes with local deterministic nonces from each other is the pseudo-  
1199 random function (PRF) used to generate the nonce, and the ZKP method for proving it was  
1200 properly generated. In MuSig-DN [NRSW20] (a multi-signature scheme), the nonce is a  
1201 specially designed PRF. It is keyed with the nonce derivation key, and takes as input the  
1202 message  $M$ , the set of signers' public keys  $Q_i$ , and the commitments of the nonce derivation  
1203 keys. The corresponding ZKP is computationally heavy, but signing takes only two rounds and  
1204 is very efficient bandwidth wise. In [GKMN21], the PRF is the NIST-standardized advanced  
1205 encryption standard (AES) cipher, and the ZKP is based on garbled circuits. This is computa-  
1206 tionally lighter, at the expense of higher bandwidth and three rounds of communication.

#### 1207 4.4. Probabilistic threshold Schnorr

1208 The probabilistic approach for threshold Schnorr/EdDSA signing allows the distributed  
1209 nonce generation to take advantage of homomorphic properties innate to the signature  
1210 scheme elements. As mentioned (§4.2.1), the secret-sharing of a random secret nonce can  
1211 be performed by a DKG protocol, then to be followed by a simple local generation of  
1212 signature shares [SS01]. Some schemes can be tailored for a small number of parties, e.g.,  
1213 two [NKDM03]. More recent works have focused on a reduced number of communication  
1214 rounds (though still making use of a broadcast channel, whose real implementation may  
1215 require multiple rounds, depending on the system model). The protocol design can be  
1216 framed within a simulatable (§4.4.1) or a game-based (§4.4.2) security formulation.

##### 1217 4.4.1. Simulatable threshold Schnorr in three rounds

1218 In the ideal/real simulation paradigm of MPC, which allows for composability of ideal  
1219 components, a threshold Schnorr protocol is relatively straightforward when considering  
1220 as available gadgets an ideal commitment scheme, an ideal non-interactive zero-knowledge  
1221 proof of knowledge (NIZKPoK), and assuming authenticated communication [Lin22]. The  
1222 protocol follows from the intuitive semi-honest threshold Schnorr. A coordinator can be

1223 employed to decide the message to be signed and the signatory-subset ( $\mathcal{P}'$ ), who collab-  
1224 oratively determine a session id ( $sid$ ) for each signing execution. The signature format uses  
1225 as first component the challenge  $\chi$ , instead of the nonce commitment  $R$ , which technically  
1226 makes the scheme not interchangeable w.r.t. EdDSA. However, the scheme could be adapted  
1227 to become interchangeable.

1228 1. **Keygen:** Based on a PKI, the parties are either given shares of the secret signing key  
1229 or perform a Feldman VSS.

1230 2. **Nonce commit:** Each party is invoked with the same message  $M$  to be signed.

1231 • **Agree on session identifier ( $sid$ ).** Initially, each party  $P_i$  commits (in a hiding  
1232 manner) to a share  $R_i$  of the usual Schnorr nonce commitment  $R$  [notice the dou-  
1233 ble “commit”], at the same time that it proposes a contribution  $sid_i$  to a session id.  
1234 Essentially, the double commitment prevents the nonce commitment itself from  
1235 being biased/manipulated even by the last party to propose their contribution.  
1236 The signatory-subset  $S$  is either assumed known or proposed by the central  
1237 coordinator once hearing from the several parties. Each party calculates the  
1238 session id  $sid$  for the ongoing signature protocol based on the signatory subset.

1239 • **Reveal the nonce commitment contributions  $R_i$ .** The nonce commitment  
1240 contribution  $R_i = r_i \cdot G$  (not the actual nonce contribution  $r_i$ ) is then opened  
1241 (verifiable w.r.t. its corresponding commitment) to the coordinator, along with  
1242 a ZKPoK of the secret nonce contribution  $r_i$ , and a signature bound to the  $sid$ .  
1243 The parties then homomorphically build the global nonce commitment  $R$ , by  
1244 simple group sum of all corresponding shares.

1245 3. **Challenge:**  $\chi$  is computed as usual, based on  $R$ ,  $Q$  and  $M$  (see Table 5).

1246 4. **Signature shares:** The signature shares  $s_i$  are generated locally by each party, based  
1247 on the calculated challenge, the signing key-share and the nonce-share  $r_i$ . The central  
1248 coordinator (or anyone with access to the signature shares) can build the final signature  
1249 and check its correctness.

1250 The proof, in the static corruption model, relies on the simulation of ideal components,  
1251 which allows extracting the hidden elements (e.g., nonce shares and signing-key shares) that  
1252 enable ensuring the ideal execution is indistinguishable from a real one.

#### 1253 4.4.2. Probabilistic Two-Round Schnorr

1254 A class of two-round threshold probabilistic Schnorr schemes [KG21; NRS21; AB21;  
1255 CKM21] protects against the  $k$ -sum attack [DEFKLS19] by using multiple nonce contri-  
1256 butions per participant, and employing a “nonce binding” technique where each share of the  
1257 nonce becomes dependent on the message, the set of cosigners, and the nonce contributions  
1258 of all the cosigners.

1259 These two-round protocols can precompute the first round, deferring for later a single  
1260 round of communication for signing. The description below corresponds to FROST without  
1261 preprocessing [KG21]. Other schemes operate in a similar manner.

1262 1. **KeyGen:** Each party receives their signing key share  $s_i$  either from a dealer or via  
1263 distributed key generation.

1264 2. **Nonce commit:** The most distinctive aspect of this class of protocols is that each party  
1265 generates two or more nonce contributions  $(r_{i,1}, r_{i,2})$ , instead of just one (usually two,  
1266 but possibly more, depending on the scheme and security model). The contribution of  
1267 each party to the final nonce commitment  $R$  is “bound” to the message  $M$ , the set  $\mathcal{P}'$   
1268 of cosigners, and each of their own nonce commitments  $R_i$  supplied during a given  
1269 signing operation.

1270 Specifically, party  $P_i$  chooses two random nonces  $(r_{i,1}, r_{i,2})$ , and generates their  
1271 corresponding commitments  $(R_{i,1} = r_{i,1} \cdot G, R_{i,2} = r_{i,2} \cdot G)$ . Let  $B$  be an ordered  
1272 list of the participants involved in the signing operation,  $\mathcal{P}'$  and their commit-  
1273 ments:  $B = \{(i, R_{i,1}, R_{i,2}) : i \in \mathcal{P}'\}$ . All parties compute a set of “binding values”  
1274  $\rho_i = H(i, M, B)$ , for  $i \in \mathcal{P}'$ . The final nonce commitment  $R$ , common to all parties,  
1275 is then  $R = \sum_i R_{i,1} + \rho_i \cdot R_{i,2}$ . Given the linearity of the secret-sharing scheme, the  
1276 corresponding implied secret share of the nonce for each party  $P_i$  is  $r_i = r_{i,1} + \rho_i \cdot r_{i,2}$ .

1277 3. **Challenge:**  $\chi$  is computed as usual, based on  $R$ ,  $Q$  and  $M$  (see Table 5).

1278 4. **Signature shares:** Each party’s signature share  $S_i$  is computed as  $S_i = r_{i,1} + \rho_i \cdot r_{i,2} +$   
1279  $\chi \cdot \lambda_i \cdot s_i$ , where  $\lambda_i$  is the Lagrange coefficient for the  $i$ -th cosigner in  $\mathcal{P}'$ .

1280 The elaborate nonce commitment procedure is needed in order to thwart the  $k$ -sum attack  
1281 [DEFKLN19], which some two-round Schnorr multisignature schemes were susceptible to  
1282 when an adversary could open multiple concurrent signing sessions. The attack involves  
1283 finding a challenge value  $\chi^* = H(R^*, Q^*, M^*)$  that is the sum of several other challenge  
1284 values that differ in either the group’s nonce commitment  $R$  or the message  $M$ . The attack  
1285 is possible when the adversary has control over the nonce commitment  $R$ , by choosing the  
1286 contribution of a corrupted party adaptively after seeing the contributions of all other parties.  
1287 Exploiting the attack involves solving the Generalized Birthday Problem, which can be done  
1288 with subexponential complexity using Wagner’s algorithm [Wag02].

1289 To turn the above scheme into a single round signing protocol, parties can locally generate a  
1290 list of their nonce contributions and corresponding commitments, securely save them, and  
1291 publish a list of commitments to a common location (or provide them to a party acting as  
1292 the coordinator or signature aggregator). When a new signing session is initiated, the next  
1293 set of commitments for each party can be sent to the parties along with the message.

1294 The FROST scheme [KG21] is full threshold, meaning it can be instantiated with any secret-  
1295 sharing recovery threshold  $t$  (out of  $n$ ). MuSig2 [NRS21] and the delinearized witness  
1296 multi-signatures (DWMS) [AB21] are multisignature schemes that operate in the plain public  
1297 key model. SpeedyMuSig is similar to MuSig2 but operates in the KOSK model, which  
1298 enables faster key aggregation [CKM21].

## 1299 5. Further considerations

1300 Section 4 has described various approaches for producing threshold Schnorr-style signatures.  
1301 The present section proposes complementary aspects relevant for when preparing future  
1302 related guidance and recommendations. These considerations are also relevant for any  
1303 upcoming call for contributions and/or when analysing corresponding proposals of threshold  
1304 schemes interchangeable w.r.t. EdDSA verification.

- 1305 • Section 5.1 enumerates aspects of the threshold setting that make the case of a  
1306 corrupted signer more complex and inherently more pertinent.
- 1307 • Section 5.2 points out the diversity of security formulations, and how some security  
1308 notions (e.g., strong unforgeability) are generalized in the threshold setting.
- 1309 • Section 5.3 considers characteristics of the system model, namely assumptions about  
1310 underlying communication functionalities.
- 1311 • Section 5.4 revisits the issue of bad randomness, and how the threshold setting enabled  
1312 new ways of resolving it.
- 1313 • Section 5.5 motivates modularity and composability, and recalls useful phases (e.g.,  
1314 key-resharing, and replacement of faulty-parties).

### 1315 5.1. “Thresholdized” signer

1316 In the conventional setting, the security formulation of digital signatures is classically  
1317 established by an *unforgeability* game (Section 3.3). There, the adversary does not know  
1318 the private signing key but controls a client, who can request signatures from a signing  
1319 oracle that knows the private key. The case of a corrupted signer is typically less considered,  
1320 although it is the basis for the *message binding* property (Section 3.4). In the threshold  
1321 setting, the signer becomes distributed, due to the secret sharing of the private key across  
1322 multiple parties. The adversary can then also control some of the key-share holders. It thus  
1323 becomes relevant to consider the case of a corrupted signer (i.e., in the threshold sense). The  
1324 more complex adversarial model raises new considerations about adversarial capabilities  
1325 and goals. For example:

- 1326 1. **Corruption threshold:** the adversary can control up to a corruption threshold  $f$  of the  
1327 key-share holders. Which ranges of  $f$  are acceptable? Some functionalities/protocols  
1328 will only work for certain intervals of the proportion  $f/n$  (corruption threshold over  
1329 number of parties).
- 1330 2. **Agreement:** the decision to sign a message becomes distributed across a set of  
1331 cosigners, including corrupted parties. Whether the agreement is assumed as implicit,  
1332 or follows explicitly from a verifiable request from an external client or coordinator, it  
1333 needs to actually be implemented when the system is deployed.
- 1334 3. **Number of signatures:** if the participation threshold (i.e., the needed quorum) is not  
1335 higher than  $(n + f)/2$ , how many signatures should it be possible to create from a  
1336 single authorized request that is broadcast to all parties? Consider an adversary who  
1337 — besides compromising  $f$  parties — has some control over the network, and can

1338 partition the honest parties into two separate networks, causing them to participate in  
1339 two distinct Schnorr signings of the same message.

1340 4. **Concurrent signing:** the adversary can corrupt some of the parties and thus observe  
1341 and interfere with the intermediate steps of the concurrent generation of multiple  
1342 signatures. This is not possible in the conventional unforgeability game, where  
1343 each signature is produced by an oracle who processes each request independently.  
1344 Without proper safeguards, some protocols secure in a threshold *standalone* setting  
1345 (without concurrency) may enable forgeries in the threshold concurrent setting. For  
1346 example, if the signature scheme allows the adversary to maliciously influence the  
1347 nonce commitment  $R$ , then a forgery may be obtained upon solving a  $k$ -sum problem  
1348 [DEFKLNS19; BLLOR21].

1349 5. **Messages adapted to the nonce commitment:** depending on the threshold protocol,  
1350 an adversary may be able to select a message with a noticeable relation to  $M$  (e.g.,  
1351  $M=R$ ). This would not be possible in the conventional SUF game, since there the  
1352 oracle signer produces a (pseudo)random  $R$ . However, actual unforgeability may  
1353 follow even though the adversary is able to learn  $R$  before selecting the message  $M$ .  
1354 (Note that such capability is not considered in usual conventional proofs of security.)  
1355 Other security formulations may specifically disallow this.

1356 Being aware of the possible options and their differences is relevant to enable a security  
1357 formulation that captures the intended functionality and/or desired properties.

## 1358 5.2. Threshold security formulation

1359 There is room for nuances in security formulations for threshold signatures. For example, an  
1360 ideal threshold signature functionality — in the **universal composability** (UC) framework  
1361 — may define that a signature is produced only when all parties request the signature of a  
1362 given message  $M$ . In a security-with-abort formulation, the adversary is allowed to see the  
1363 signature first and decide whether or not the honest parties can receive it [BST21, Fig. 8].

1364 The functionality may also require that all parties agree on a proposed nonce commitment  $R$ ,  
1365 before proceeding to release the remainder ( $S$ ) of the signature [GKMN21, Func. 9.1]. The  
1366 quorum (participation threshold)  $t'$  and session identifier  $sid$  may be explicitly encoded, so  
1367 that the signature is produced once  $t'$  parties request it, with an agreeing  $sid$  [Lin22, Fig. 4.2].

1368 Security formulations can be described via an ideal functionality or via games for each  
1369 intended property. These may also encode whether or not, for example, a coordinator/aggre-  
1370 gator facilitates the communication between the remaining parties, and is responsible for  
1371 outputting the final signature upon obtaining signature shares from the other parties [KG21;  
1372 Lin22]. In the case of multi-signatures, the UF game also considers the set of public keys  
1373 used to generate a signature. Then, an adversarial win requires generating a signature for a  
1374 message  $M$  and a cosigners set  $\mathcal{P}'$  (i.e., set of their public keys) that includes at least one  
1375 honest party that never agreed to sign the message within that cosigners set ([BN06, Sec. 4];  
1376 [NRS21, Fig. 3]). This can be generalized to a SUF sense, by considering as forgery any

1377 new signature for the same pair  $(\mathcal{P}', M)$ . Various levels of unforgeability strength can be  
1378 defined based on the goal and capabilities of the adversary (see Sections 3.3 and 5.2.1),  
1379 namely what is considered a valid forgery and which contributions an adversary can obtain  
1380 from honest parties [BTZ22; BCKMTZ22]. Security formulations can also cover additional  
1381 modules/features, such as robustness [RRJSS22].

1382 The suitability of each formulation can vary with the intended system model and/or the  
1383 presence of features of interest to envisioned application settings. It is nonetheless important  
1384 to check whether the adversary in the threshold setting is prevented from gaining an ability  
1385 that exceeds that of the adversary in the conventional scheme.

1386 The simulatability setting provides a natural way of going beyond unforgeability. For  
1387 example, it inherently requires an unbiased nonce commitment, whereas in the case of a  
1388 game-based definition for UF, that property only tends to appear as a protection against a  
1389 concrete attack. Still, one can also define games for other threshold properties. As another  
1390 example, when an ideal functionality directly selects the nonce commitment, after the  
1391 message to be signed has been determined, the formulation inherently requires protects  
1392 against subliminal channels (see §5.2.4).

### 1393 **5.2.1. Strong threshold unforgeability**

1394 Since EdDSA is not verifiably deterministic, unforgeability should be considered in the  
1395 “strong” sense: SUF (see Section 3.3). This notion becomes generalized in the threshold  
1396 setting, where the adversary can corrupt up to  $f$  parties, besides possibly controlling a client  
1397 able to issue valid requests for message signing, and also possibly controlling the message  
1398 delivery in some channels. Thus, with EdDSA being SUF in the conventional setting, it is  
1399 useful that a threshold scheme interchangeable w.r.t. EdDSA considers a threshold notion of  
1400 SUF within the claimed corruption threshold.

1401 Recent work has formalized game-based definitions for various levels of strong unforge-  
1402 ability in the threshold setting [BTZ22; BCKMTZ22]. The different levels consider, for  
1403 example, the number of honest parties providing contributions (e.g., signature shares, if in a  
1404 non-interactive setting) upon receiving a signing request. Also of interest are simulatability  
1405 formulations, where an intended notion of unforgeability (as well as other properties) may  
1406 be derived from the specification of an ideal functionality.

1407 A SUF notion should clarify the conditions under which an adversary is expected to be able  
1408 to generate a new signature (see §5.2.2). Also, unforgeability should remain even when the  
1409 adversary is able to adaptively corrupt parties (see §5.2.3).

### 1410 **5.2.2. Number of signatures per request**

1411 The conventional unforgeability notion asks that an adversary be unable to obtain more  
1412 signatures than those that have been properly “requested”. In the threshold setting, the  
1413 notion of “request” can depend on the system model. For example, it can vary between (i)

1414 being any request signed by an authorized client (including one controlled by the adversary),  
1415 and (ii) being the result of an agreement (i.e, decided by an external protocol) between  
1416 the parties. There are diverse options for the threshold security formulation to encode the  
1417 meaning of valid signing request.

1418 A security formulation for a threshold signature scheme should enable a clear understanding  
1419 of what would be considered generating too many signatures, as compared to the number  
1420 of legitimate requests. It should consider that some malicious requests (say, in the model  
1421 where a client directly sends valid signed requests to each separate party) may lead to  
1422 partial executions that do not end with a valid signature. These partially fulfilled requests (a  
1423 notion not present in the conventional setting) should not give the adversary an additional  
1424 *advantage* in producing non-requested signatures. Several techniques may be considered  
1425 to protect against the generation of extra signatures. These may include, for example, a  
1426 requirement for starting with a collective agreement on which messages to sign, and in  
1427 which order, and/or the use of clocks, timestamps, counters and session identifiers.

1428 The notion of a *participation threshold*  $t'$  is also relevant. Consider a protocol with a  
1429 small *corruption threshold*  $f$  (with  $f < \lfloor n/2 \rfloor$ ), and an underlying secret-sharing whose  
1430 *reconstruction* threshold  $t$  is equal to just one more party (i.e.,  $t = f + 1$ ). If a request does  
1431 not identify the cosigner subset  $\mathcal{P}'$ , then an adversary controlling the network channels  
1432 can partition the set of parties into two independent quorums. Could this lead the same  
1433 request to generate two different signatures? Despite the low *corruption* threshold  $f$ , by  
1434 requiring that the *participation* threshold  $t'$  is higher than  $n/2 + f$  (the exact minimum may  
1435 vary with the type of synchrony and other assumptions), then any two signing executions  
1436 will have at least one common honest party. Note that this is exemplifying a *participation*  
1437 threshold  $t'$  higher than the *reconstruction* threshold  $t$ . Alternatively, a protocol may require  
1438 that each signing request explicitly identifies the subset  $\mathcal{P}'$  of allowed cosigners, to prevent  
1439 non-included honest parties from giving a contribution to the adversary.

1440 **Example of multiple uncontextualized requests.** Consider an application that composes a  
1441 threshold signature scheme with an external decision algorithm used by each honest party  
1442 to decide whether (i) to participate honestly in the signing, or (ii) to declare not being  
1443 available to participate. What happens then if a request to sign the same message appears  
1444 several times, while the parties' participation decisions (whether or not to sign that message)  
1445 alternate across requests and across parties?

1446 Consider a threshold scheme with participation threshold  $t = 3$ , and only  $n = 3$  parties:  
1447 A and B are honest; C is malicious. Suppose there are two certified requests to sign the  
1448 same message  $M$ . Suppose that upon the first request only parties A and C are willing to  
1449 participate, and upon the second request only parties B and C are willing to participate.  
1450 Suppose the adversary is able to replay messages, judiciously selecting which messages to  
1451 send to which honest parties. Can the adversary induce the creation of a signature, even  
1452 though the number of "honest" parties available to participate for each request has never  
1453 reached the participation threshold?

1454 A proposed security formulation and system model for a threshold signature scheme should  
1455 include details that enable answering this type of question. Special care is required for  
1456 the case of concurrent signing requests, where parties may receive requests in inconsistent  
1457 orderings, or even with inconsistent content produced by malicious participants. The use of  
1458 (and agreement on) session identifiers is often a necessary element to handle concurrency.

### 1459 **5.2.3. Safety against adaptive corruptions**

1460 *Unforgeability* should be guaranteed against adversaries that can *adaptively* choose, based  
1461 on an observation of the protocol execution, which parties to corrupt (up to the threshold  $f$ ).  
1462 As compared to static corruptions, which must occur at the onset of a protocol execution,  
1463 adaptive corruptions introduce a new degree of freedom.

1464 The following is a classical example (slightly adapted in the parameters) of a statically-secure  
1465 but adaptively-insecure protocol [CFG96], w.r.t. confidentiality for secret storage: an  
1466 incorruptible dealer distributes secret-shares of a key across a relatively small random subset  
1467 with  $f$  parties ( $f \approx \sqrt{n}$ ), using an  $f$ -out-of- $f$  secret-sharing scheme, and then advertises  
1468 the subset. A static adversary has a negligible probability — asymptotically in  $n$  — of  
1469 having corrupted the needed subset of  $f$  parties before said set is advertised. Concretely,  
1470 the probability is the inverse of the number (“ $n$  choose  $f$ ”) of possible subsets of  $f$  parties  
1471 from within the set of  $n$  parties. Conversely, an adaptive adversary can wait to hear the  
1472 advertisement and only then corrupt exactly the  $f$  key-share holders, thereby finding the  
1473 secret. The example can be adapted to other safety properties, such as unforgeability.

1474 Despite the gap between static and adaptive security, many protocols that in practice are  
1475 proven statically-secure also retain some desirable properties (though not necessarily all) in  
1476 the adaptive corruption setting. W.r.t. a game-based security property, a proof of security  
1477 for a given protocol may happen to be independent of the difference between static vs.  
1478 adaptive corruptions, and imply security against both types of adversaries. In the UC  
1479 simulatability setting (ideal/real simulation paradigm) [Can01], security against adaptive-  
1480 active corruptions is in general more challenging to achieve, compared to the case of  
1481 static-active corruptions [CDDIM01]. However, this difficulty is often because the security  
1482 formulation comprises not just one safety property (such as unforgeability), but rather defines  
1483 a whole functionality encompassing properties of a different nature, such as deniability of  
1484 execution and composability (which are not captured by the unforgeability game).

1485 Because of the technical difficulties with adaptive security in a simulatability setting in the  
1486 UC framework, it is common to see protocols proven secure only in the static setting, often  
1487 with an implicit understanding that the lack of adaptive security does not mean a complete  
1488 breakdown of safety properties in case of adaptive corruptions. In fact, a loss of deniability  
1489 of execution and/or of some types of composability is something that may already happen  
1490 when a protocol deployed in practice uses real (non-ideal) components to instantiate ideal  
1491 components used in the proof of security (e.g., replacing a programmable random oracle by  
1492 a cryptographic hash function).

1493 Given the possibility of adaptive corruptions in the real world, it is important to consider for  
1494 any proposed threshold signature scheme whether the major safety properties of interest (such  
1495 as unforgeability) are safeguarded against such an adversary. It is acceptable that this comes  
1496 at the expense of some adjustment of the ideal functionality. It can also come in the form of a  
1497 different argument, such as the case of adaptive security in the constructive cryptography (CC)  
1498 setting [HLM21]. The latter provides an approach to explore another flavor of simulatable  
1499 adaptive security, while avoiding the mentioned difficulties.

#### 1500 **5.2.4. Preventing subliminal exfiltration**

1501 A (stateless) probabilistic signature scheme provides an avenue for exfiltration of secret  
1502 information, using the randomized component (e.g., a nonce commitment) as a subliminal  
1503 channel [Sim94; AMV15]. This also applies to deterministic signatures (such as EdDSA and  
1504 deterministic ECDSA) that can be undetectably made probabilistic by a malicious signer. For  
1505 example, consider the case of a client who requests EdDSA signatures from a cryptographic  
1506 security module (CSM) that holds the signing key. If the CSM has been corrupted, then it  
1507 can maliciously influence the nonce commitment  $R$  to exfiltrate secrets via signatures.

1508 The threat of subliminal channels can be mitigated with suitable threshold schemes, for both  
1509 probabilistic and deterministic schemes. Suppose the administrator establishes a threshold  
1510 signature scheme across various CSMs. A protocol can be such that no isolated CSM (nor  
1511 any coalition up to the corruption threshold) is able to bias the bits in the final signature. A  
1512 limitation exists in the case of security-with-abort formulations, where the the adversary has  
1513 a chance to prevent undesired outputs, which provides a low capacity channel.

1514 Since unforgeability does not imply unbiased signatures, the threshold assurance of the latter  
1515 in Schnorr/EdDSA signatures depends on the actual threshold scheme / security formulation.  
1516 In particular, the malicious manipulation is allowed in some 2-round protocols (§4.4.2) where  
1517 a malicious party (possibly the coordinator) is able to wait to be the last to propose a nonce  
1518 commitment contribution, while already knowing the nonce commitment contributions of the  
1519 other parties. Conversely, threshold schemes arising from a simulatability formulation tend to  
1520 automatically ensure an unbiased nonce commitment. This is because their ideal functionality,  
1521 which the protocol needs to emulate, selects the nonce  $r$  (uniformly or pseudorandomly) and  
1522 calculates the nonce commitment  $R$  without interference from any party. This applies to both  
1523 probabilistic (§4.4.1) and deterministic cases (§4.3). Naturally, this is also possible from  
1524 protocols proven unforgeable with respect to a game-based definition, such as usual in those  
1525 with three or more rounds [SS01; MPSW19].

#### 1526 **5.3. System model**

1527 Several elements of the system model affect the suitability of protocols, approaches and  
1528 realizable functionalities for threshold signatures. The following are relevant considerations:  
1529 how *authenticated channels* are implemented (§5.3.2); whether parties have access to a *reli-*  
1530 *able broadcast* channel (§5.3.3); which *timing assumptions* the protocol can rely on (§5.3.4);

1531 whether the deployment allows for a *precomputation* (offline) phase, before learning the  
1532 message to sign (§5.3.5); what happens when system model assumptions are broken (§5.3.6).

### 1533 **5.3.1. Interface for signature request and delivery**

1534 **Use of a coordinator or aggregator.** Important safety properties, such as unforgeability,  
1535 must hold even if the coordinator is malicious and sends inconsistent messages across  
1536 different cosigners, so long as the number of corrupted cosigners is within the corruption  
1537 threshold. As a tradeoff, some availability properties may be sacrificed, as happens with  
1538 security-with-abort formulations, where an adversary can decide to not let the protocol  
1539 produce a valid signature.

1540 **Shared-I/O modes.** In a threshold scheme where the operation request comes from an  
1541 external party, it is possible to have none of the internal parties (i.e., the key-share holders,  
1542 including corrupted ones) see the final signature value. This shared-output (shared-O) mode  
1543 can result from a formulation where the ideal functionality sends the signature (or set of  
1544 signature shares) only to the client that requested it. The ideal functionality also interacts  
1545 with the various parties to ask their agreement about signing the message. However, besides  
1546 seeing the message, each party sees at most a few shares of the signature (not enough to  
1547 reconstruct it). A shared-Input (shared-I) mode is also conceivable, with the input arriving  
1548 secret-shared (e.g., possibly with a VSS to enable verifying consistency of the shares). This  
1549 is less practical since it requires a distributed computation of the SHA-based challenge  $\chi$ .  
1550 The shared-I/O modes [NISTIR 8214A, §2.3] are not meant to include the special case of an  
1551 MPC where the message remains secret for the entire threshold entity (even if all parties  
1552 collude). The current scope is to consider an outsourced signature, performed by a threshold  
1553 entity, where the client (the signature requester) may at most perform secret-sharing and/or  
1554 reconstruction. Naturally, one can combine both shared-O and shared-I features into a  
1555 shared-IO mode.

1556 **Threshold auditability.** Threshold schemes may have additional features beyond their  
1557 functional output. For example, public auditability may be useful for some applications. This  
1558 verifiability can be embedded into secret sharing [Sch99] as well as into more general MPC  
1559 [BDO14]. Besides the original intended output, a publicly auditable MPC would produce  
1560 a proof of correct execution. For a threshold signature scheme this could mean a proof  
1561 that a signature was produced via a threshold interaction ([NISTIR 8214A, §2.5]), with the  
1562 agreement and collaboration of a particular subset of parties. This makes sense if the client  
1563 or the public has access to a PKI with the public keys of the cosigners, or to something that  
1564 verifies the underlying secret sharing. To be clear, an auditability transcript would not be  
1565 considered part of the signature to be parsed by the client, but rather an auxiliary output of  
1566 the protocol execution, to possibly be consumed by a separate audit application.

1567 **5.3.2. Authenticated channels**

1568 It is customary in MPC protocols to assume the existence of authenticated channels. In  
1569 a practical deployment, the channels have to somehow be instantiated. In the real world,  
1570 authentication may depend on physical assumptions (such as a communication wire con-  
1571 necting two parties) and/or cryptography. Such a setup may be prepared by an administrator  
1572 (e.g., if all parties belong to the same administrative domain), or in some ad-hoc manner  
1573 (perhaps based on a PKI, a distributed protocol, or other means). Practical implementations  
1574 can, for example, be based on:

- 1575 • public-key cryptography: e.g., based on digital signatures with one public-key associ-  
1576 ated to each party; or
- 1577 • symmetric-key cryptography: e.g., using a **hash-based message authentication code**  
1578 (**HMAC**), with a different key for each pair of parties.

1579 The type of authentication affects the security and capabilities of protocols. For example, a  
1580 PKI can support transferable authentication based on signatures, so that party A can prove  
1581 to party B that party C sent something to A. Conversely, an HMAC-based authentication  
1582 is typically non-transferable (deniable). Typical ideal authenticated channels are deniable.  
1583 A transferable instantiation may be considered a feature or a handicap, depending on the  
1584 context. Authentication is also relevant between a client that requests a message and the  
1585 parties that receive such request.

1586 The actual (real) authenticated channels available in the signing phase may be different  
1587 from those in a preceding distributed keygen. In fact, the state obtained from a keygen  
1588 (distributed or dealer-based) may be designed to enable new authenticated channels (even  
1589 private, if need be, to support secrecy of transmitted content) in the subsequent signing  
1590 phase. This requires proper care, or else possibly result in a security failure. In practice,  
1591 a popular instantiation of authenticated and/or private channels is based on the transport  
1592 layer security (TLS) protocol. However, its composability with (i.e., replacing the ideal  
1593 authenticated channels of) a threshold scheme should be carefully considered. For example,  
1594 a careless instantiation of authenticated channels by using the actual key-shares obtained in  
1595 the keygen phase could help the adversary produce a forgery. Conversely, it is an interesting  
1596 consideration to think how to enable, in the signing phase of a threshold signature scheme,  
1597 an instantiation of authenticated channels based on the material obtained during the keygen  
1598 phase. Conceivably, this may be based on signatures that rely on the actual key-shares of the  
1599 signing key, or derived therefrom.

1600 As part of the communication setup, a threshold scheme specification can assume that every  
1601 party knows the set of possible cosigners (and each other's public key, or pairwise symmetric-  
1602 key). In practice this may be bootstrapped by an administrator, or by an ad-hoc agreement  
1603 between parties with the help of a PKI. Some system models may allow a dynamic set of  
1604 participants, establishing rules for deciding when and how to onboard new cosigners (and  
1605 their keys), and/or remove old cosigners.

### 1606 5.3.3. Broadcast

1607 As a primitive to facilitate obtaining agreement, some protocols make use of *reliable broad-*  
1608 *cast*, where an honest receiving party is ensured that other honest parties have also received  
1609 the same message. In some cases, reliable broadcast may be woven into the communication  
1610 steps of the signing protocol, to reduce the overall number of communication rounds. Its  
1611 realization depends on the communication model, e.g., whether or not there is a PKI to enable  
1612 transferable authentication of messages (i.e., party A can prove to party B that party C has  
1613 signed a message), a coordinator facilitating the message delivery (possibly also signing the  
1614 delivered messages) vs. only point-to-point channels. The notion of reliable broadcast is  
1615 stronger than a simple multicast where a party sends a message to every other party. In other  
1616 words, it matters that each receiving party gains assurance that a particular message claimed  
1617 to have been broadcast/multicast has also been received by every other honest party.

### 1618 5.3.4. Timing assumptions

1619 The performance and security of threshold signature schemes depends on the underlying  
1620 communication model, particularly the timing for message delivery across participants. In  
1621 the synchronous model, there is a known upper bound on the delay before messages are  
1622 delivered. The asynchronous model, on the other hand, has no upper bound on the message  
1623 delay, only requiring that messages be delivered eventually. A variety of other models  
1624 exist, such as partial synchrony, where a period of asynchrony is followed by a period of  
1625 synchronous communication.

1626 More conservative timing assumptions can make a protocol more resilient to problems with  
1627 the underlying communication network. However, this can come at the cost of stricter re-  
1628 quirements on the protocol's design, performance penalties, and lower corruption thresholds.  
1629 For example, the asynchronous setting does not allow parties to distinguish between the  
1630 following scenarios: (i) a malicious party did not send a message, and (ii) an honest party  
1631 sent a message, but is experiencing delays in its delivery over the network. As a result, more  
1632 honest parties may be required to achieve the protocol's security goals.

### 1633 5.3.5. Offline/online phases

1634 Efficiency goals usually aim for low latency (low round-complexity), low communication  
1635 complexity (number of communicated bytes) and/or high throughput (number of signatures  
1636 per unit of time). In threshold settings, there are so-called offline/online models that allow pre-  
1637 processing a significant amount of computation and communication in an *offline* phase, before  
1638 the actual arrival of a message signing request. This allows for a subsequent lighter/faster  
1639 *online* phase. For example, the selection of elements necessary for a later determination  
1640 of the nonce commitment  $R$  and the nonce secret-sharing  $[r]$  can be performed before the  
1641 message is known. (Note that even the contributions  $R_i$  to the “nonce commitment”  $R$  may  
1642 be initially “committed”, when a security formulation requires preventing the adversary from  
1643 maliciously affecting  $R$ .) The generation of correlated randomness (and pseudorandomness)

1644 can be particularly useful [Bea96; IKMOP13; BCGIKS19]. An offline phase may also  
1645 prepare some aspects of agreement, such as possibly a coordinator.

### 1646 **5.3.6. Beyond covered assumptions**

1647 A threshold scheme may be designed and have provable security for a particular system  
1648 model and adversarial capabilities. What happens, however, if those assumptions are not  
1649 met? For example, what happens if (i) an assumed synchronous communication network  
1650 turns out to be asynchronous (see §5.3.4), or if (ii) an assumed reliable broadcast channel  
1651 (see §5.3.3) does not actually reach every party, or if (iii) the number of corrupted parties  
1652 (see Section 5.1) exceeds the corruption threshold by 1 or more? It is useful that the security  
1653 analysis of a threshold scheme considers these questions, identifying possible ranges of  
1654 graceful degradation, vs. others of complete security breakdown. In the case of a signature  
1655 scheme, allowing forgeries would be a complete security breakdown, whereas losing fairness  
1656 could be acceptable. Thus, if a protocol enables a given security formulation with up to  $f$   
1657 corruptions, it may still enable another security formulation with up to  $f + \epsilon$  corruptions,  
1658 possibly with mixed types of corruptions (some active, others fail-stop, others semi-honest)  
1659 [FHM98; HM20; DER21]. Graceful degradation w.r.t. to continued corruptions can also be  
1660 promoted by abort-recovery subprotocols, for example if identifying the parties that have  
1661 misbehaved and then being able to remove them.

### 1662 **5.4. Good vs. bad randomness**

1663 The issue of good vs. bad randomness is central to implementation security, as already  
1664 discussed in Section 3.5. In the threshold setting, each party may be subject to the causes  
1665 of bad randomness that affect the conventional (non-threshold) setting, such as insufficient  
1666 entropy, or rewinding/snapshot susceptibility (see §3.5.1). In the conventional setting, these  
1667 concerns have motivated the use of pseudorandomness when generating the secret nonce in  
1668 EdDSA. The use of randomness is more complex in the threshold setting, with both more  
1669 opportunities and challenges for security.

1670 A naive recourse to a purely pseudorandom mode may be vulnerable to the malicious  
1671 introduction of randomness (see §4.3.1). Conversely, the threshold setting can provide  
1672 some protection against bad randomness in probabilistic signature schemes. For example, a  
1673 threshold protocol can combine various random contributions in such a way that the good  
1674 randomness from a single honest party results in a signature without bias. Probabilistic  
1675 threshold signature schemes nevertheless have various randomness-related concerns, such as:  
1676 inadvertent correlated randomness across parties (§5.4.1), attempts to maliciously influence  
1677 the value of the secret nonce  $r$  or its commitment  $R$  (§5.4.2), and internal attacks against  
1678 internal “well behaved” parties that have bad randomness (§5.4.3).

1679 Issues of bad randomness can affect even threshold protocols for deterministic signing.  
1680 This is because multi-party protocols often resort to randomness for internal gadgets (e.g.,  
1681 garbled circuits and oblivious transfer). In fact, even secret sharing of a key most often

1682 relies on randomness. Therefore, the issue of good vs. bad randomness needs to be carefully  
1683 considered in the specification of a threshold scheme, including the phases of keygen and  
1684 signing (both deterministic and probabilistic).

#### 1685 **5.4.1. Inadvertent correlated randomness**

1686 The threshold setting brings in the issue of inadvertent “correlated randomness”. When  
1687 various signers operate in a similar environment (e.g., same software bootstrapped in equal  
1688 conditions, and/or using a common pool of entropy), their resulting local randomness may  
1689 be inadvertently correlated.

1690 One mitigation to address this unwanted correlation is to have each party transform their  
1691 randomness by applying a pseudorandom transformation relying on a local secret. This  
1692 ensures that the randomness of each party is unpredictable, as long as their secret remains  
1693 unpredictable to the other parties. For better resistance against side-channel attacks that may  
1694 try to exfiltrate such a secret, the secret can be updated in each use (to the extent that that  
1695 party is able to maintain that extra state).

1696 The issue of inadvertent “correlated randomness” discussed here should not be confused  
1697 with the use of securely generated “correlated randomness” in MPC [IKMOP13], which can  
1698 be useful to reduce communication complexity.

#### 1699 **5.4.2. Manipulating the nonce commitment**

1700 It is well known that the biasing of the secret nonce  $r$  used to produce an EdDSA signature  
1701 allows extracting the signing key (§3.5.2). More subtly, the possibility of malicious influence  
1702 of the nonce commitment  $R$  is also problematic. If a cosigner is able to present their  
1703 contribution  $R_i$  once already able to compute the final nonce commitment  $R$ , then it can  
1704 use the nonce commitment as a subliminal channel to exfiltrate information. Perhaps more  
1705 importantly, in the threshold setting, the manipulation of the nonce commitment can in some  
1706 cases enable forgeries, in the case of concurrent signing [DEFKLNS19]. The malicious  
1707 influence can be avoided by requiring that every participant commits to their contribution  
1708 before anyone reveals it [SS01; MPSW19] (see also §5.2.4). These challenges should be  
1709 limited within the indicated corruption threshold (see Section 5.2.4), since the  $R$  is supposed  
1710 to be indistinguishable from random.

#### 1711 **5.4.3. “Well-behaved” parties with bad randomness**

1712 The threshold setting can easily leverage the local good randomness from a single participant  
1713 to ensure an unbiased secret nonce  $r$ , and thus mitigate the risk of leaking information about  
1714 the signing key. The tolerance to malicious corruptions already handles the case of (up to a  
1715 threshold  $f$ ) parties with bad randomness. Yet, there is benefit in focusing attention in the  
1716 specific case of “well-behaved but with bad local randomness” (WBBR) parties.

1717 **Corruption escalation.** The key-recovery pitfall described earlier (§4.3.1), for a (careless)

1718 threshold deterministic scheme can be reconsidered for a probabilistic scheme. The former  
1719 had an honest deterministic party interacting with a maliciously randomized party. By  
1720 analogy, the same issue may occur in a (careless) probabilistic scheme where a well-behaved  
1721 (colloquially called “honest”) party only has access to “bad randomness” (such as from  
1722 a repeating seed). Then, the well-behaved party may leak their secret key-share to an  
1723 internal malicious party, becoming itself corrupted to a higher degree. A threshold protocol  
1724 should protect WBBR parties from having their corruption escalate to an exfiltration of their  
1725 key-shares when interacting with (other) malicious parties.

1726 **Tolerance to more corruptions.** If handled properly, the attention to the WBBR case allows  
1727 for a possible increase in the tolerance to corruptions. Once fixing the main corruption  
1728 threshold  $f$  for malicious compromises, the requirement for “good randomness” may be  
1729 sufficient to apply to a threshold of the remaining honest parties, rather than to all of them.  
1730 This can mean more suitability for deployment in settings where some “bad randomness” is  
1731 expected. The WBBR parties would then leverage good randomness from the other honest  
1732 parties. The advantage is resistance to not only up to  $f$  (the original threshold of) arbitrarily  
1733 malicious parties, but potentially to the participation of additional WBBR parties. The  
1734 presence of at least one honest party (with good randomness) requires the number of WBBR  
1735 parties to not be higher than  $t' - f - 1$ , where  $t'$  is the quorum required by for signing. In the  
1736 optimistic case where every party follows the protocol specification, the good randomness  
1737 from a single honest party, is sufficient to ensure an unbiased nonce, despite the possible  
1738 presence of up to  $t' - 1$  WBBR parties. Lower thresholds for WBBR may be required,  
1739 depending on the approach, and a formal security claim requires careful analysis.

## 1740 **5.5. Modularity and composability**

1741 A threshold scheme proposal can benefit from a modular description and implementation.  
1742 This applies both to protocol phases and to building blocks (gadgets).

### 1743 **5.5.1. Phases**

1744 Some modularity naturally follows from the structure of a signature scheme. The keygen  
1745 and the signing phases should be defined separately, albeit in an interoperable manner. That  
1746 is, the signing protocol should make sense regardless of whether the keygen is achieved via  
1747 a dealer or a distributed protocol (§4.2.1).

1748 Modularity also makes sense w.r.t. possible additional sub-protocols, such as:

- 1749 • secret-resharing, for proactive security, to render useless any key-share that may have  
1750 already leaked to the adversary (assuming fewer than  $f$  shares have leaked since the  
1751 most recent resharing);
- 1752 • dynamic change of participants, such as altering the set of potential cosigners (and thus,  
1753 when applicable, their keys) and possibly the change of corruption and participation  
1754 thresholds.

1755 The above examples require deletion of old shares, in order to retain security in the face of  
1756 mobile adversaries that continue corrupting parties after a resharing phase.

1757 Some phases may be the result of a certified administrative request built in to the implemen-  
1758 tation, such as to increase  $n$  and  $f$ , requiring a resharing of the private key. Some phases may  
1759 be activated when special internal conditions are met, such as those foreseen in threshold  
1760 schemes with *identifiable abort*, where a party may be identified as malicious. A protocol  
1761 may have a special provision to retry a signing operation after getting rid of an identified  
1762 malicious party, in order to provide *robustness*, i.e., successfully producing a signature  
1763 despite the malicious parties.

1764 Each phase may come with tradeoffs, such as possibly imposing a more restrictive set of  
1765 security parameters (e.g., thresholds) or setup conditions (e.g., communication network).  
1766 For example, the phases may be more difficult to complete in an asynchronous network or  
1767 against adaptive adversaries, and may bring other operational concerns related to agreement.  
1768 Some changes in the system need to be agreed upon by all (or a qualified majority of the)  
1769 honest parties, to avoid a partitioning where a qualified set of parties (able to produce  
1770 signatures) retains a vision of the past shares.

1771 Even within the signing phase, there may be a partition between precomputation and online  
1772 sub-phases. There may also be a modular description of possible consensus mechanisms  
1773 used to decide which message is to be signed, the session identifier *sid* and the subset of  
1774 cosigners to participate in the session. Despite modular descriptions of some aspects of the  
1775 signing phase, it may be possible to superpose them in order to reduce the number of rounds  
1776 of communication. For example, the parties may both commit to their nonces and agree on  
1777 an *sid* in the same round.

### 1778 **5.5.2. Gadgets**

1779 Ideally, various building blocks (gadgets) can be identified and used in a way that allows  
1780 replacement with other instantiations, and/or which can be reused in other threshold schemes.  
1781 This document has mentioned several examples of gadgets: secret sharing, garbled circuits,  
1782 oblivious transfer, commitment schemes, secret resharing, Lagrange interpolation, zero-  
1783 knowledge proofs, etc. The security upon replacement of a gadget instantiation by another  
1784 one may depend on the composability of the scheme, as well as variations in the setup  
1785 assumptions. Some replacements are safeguarded by some type of security proof (e.g.,  
1786 universal composability, where an ideal component can be replaced by a corresponding  
1787 UC-secure one), while others may require a closer look (e.g., because of a somewhat distinct  
1788 interface) but still provide a conceptual simplification that eases the analysis.

1789 **6. Conclusions**

1790 This document has discussed threshold signature schemes interchangeable w.r.t. the Ed-  
1791 DSA verification specified in Draft FIPS 186-5. These threshold signatures allow for a  
1792 drop-in replacement of conventional (non-threshold) EdDSA signatures, being compatible  
1793 with legacy code for signature verification. Compared to conventional implementations, a  
1794 threshold signature scheme enables a distribution of trust regarding the secrecy of the private  
1795 signing key. The threshold setting additionally allows for better implementation security  
1796 w.r.t. concerns of bad randomness and side-channel attacks (see Table 9).

1797 **Table 9.** Types of signature vs. concern — informal assessment

Signature mode	Nonce generation	Attack of Concern	Informal assessment	
			Conventional	Threshold
Deterministic	Pseudorandom	Bias	Not applicable	Not applicable
		Side channel	More vulnerable	Safer
Probabilistic	Randomized	Bias	Vulnerable	Safer
		Side channel	Less vulnerable	Safer
	Hybrid	Bias	Not applicable	Not applicable
		Side channel	Less vulnerable	Safer

1806 The use of “Less” and “More” preceding “vulnerable” is only for comparison within the side-channel attack  
1807 concern. Each “Safer” is meant in comparison with the assessment of the conventional setting in the same row.  
1808 In the threshold setting, the assessment does not relate to the corruptibility of individual parties, but rather to  
1809 unforgeability property when assumed that the number of corrupted parties is within the allowed threshold. This  
1810 informal table is meant only to provide intuition; more context is needed for formal conclusions about each  
1811 concrete signature scheme.

1812 **6.1. Comparing probabilistic and deterministic threshold EdDSA**

1813 There is a wide design space for threshold signature schemes interchangeable w.r.t. FIPS-  
1814 specified EdDSA verification. This includes schemes that produce deterministic signatures  
1815 (though not verifiably-deterministic) and also probabilistic schemes. Considering the di-  
1816 versity of approaches and tradeoffs, it would be beneficial to devise recommendations or  
1817 guidance, to facilitate the secure deployment of threshold signatures. This should involve  
1818 a more thorough analysis and refined characterization of the potential space, aided by the  
1819 broader community of cryptography experts.

1820 Threshold deterministic EdDSA signatures may be useful in some niche cases, but they tend  
1821 to be considerably less efficient than threshold probabilistic schemes. If an application re-  
1822 quires ECC-based deterministic signatures interchangeable w.r.t. FIPS-specified verification,

1823 then the threshold setting provides an interesting mitigation against the lack of verifiable  
1824 determinism. A protocol can be devised so that determinism stems from the coverage of the  
1825 threshold corruption assumption, though this determinism remains unverifiable.

1826 Deterministic threshold schemes that require a distributed SHA-based nonce computation  
1827 are prone to an inefficient protocol. Other approaches that calculate a deterministic secret  
1828 nonce using MPC/ZKP-friendly hashes can reduce the cost. In the setting of threshold  
1829 signature schemes interchangeable w.r.t. EdDSA-verification, the probabilistic approach  
1830 enables schemes that may be simpler and more efficient than deterministic ones. Intuitively,  
1831 the probabilistic approach is natural for threshold Schnorr-style schemes, taking advantage  
1832 of homomorphic properties already innate to the signature scheme elements.

1833 Compared to probabilistic Schnorr/EdDSA schemes in the conventional setting, the threshold  
1834 setting enables schemes that may be less vulnerable to biased random number generators.  
1835 Additional assurance can come from utilizing a hybrid mode of nonce generation (see  
1836 Section 3.5), which is possible in both conventional and threshold settings. It can be  
1837 straightforwardly employed to enhance a prior use of pure randomness, by additionally  
1838 applying a pseudorandom transformation, while retaining high efficiency.

1839 The comparison between probabilistic and deterministic approaches can further depend  
1840 on the application setting and intended features. For example, the resharing of a secret-  
1841 shared private nonce-derivation key (only needed for the deterministic approach) may be  
1842 substantially more difficult than that of the private signing key.

1843 The mentioned features make probabilistic EdDSA well aligned for consideration by NIST,  
1844 as framed in Draft FIPS 186-5 when expressing (page 5, end of item 3) that “additional digital  
1845 signature schemes may be specified and approved in FIPS publications or in NIST Special  
1846 Publications.” Interestingly, Draft FIPS 186-5 already specifies probabilistic ECC-based  
1847 signatures in the form of probabilistic ECDSA (which is more difficult to thresholdize). The  
1848 consideration of probabilistic EdDSA for the threshold setting warrants a thorough analysis,  
1849 as can take place based on a public call for threshold signature schemes interchangeable  
1850 with EdDSA verification. The resulting analysis may clarify the potential and feasibility for  
1851 adoption of threshold schemes for EdDSA.

## 1852 **6.2. State of the art and beyond**

1853 The state of the art in threshold schemes has come a long way, including progress in recent  
1854 years with newly proposed schemes, and a better understanding of security (namely in the  
1855 concurrent setting). At the same time, there remain worthwhile directions for future work.  
1856 The following list summarizes possible features that could benefit from further attention  
1857 from the community. While these are not necessary in order to have useful threshold  
1858 signatures, they may have utility for some applications.

- 1859 **1. Leveraging good randomness.** Schemes that leverage the good randomness from  
1860 some participating honest parties, being secure even if other “well behaved” parties

- 1861 (beyond the corruption threshold) have bad randomness (see §5.4).
- 1862 2. **Authenticated channels with real keys.** A threshold scheme whose authenticated  
1863 channels during the signing phase are based on signatures (possibly EdDSA/Schnorr)  
1864 whose keys are determined in the (possibly augmented) keygen phase (see §5.3.2).  
1865 Such a composition requires careful security analysis.
- 1866 3. **Shared I/O.** Threshold signing where the parties do not get to learn the message  
1867 being signed or/nor the produced signature (see §5.3.1).
- 1868 4. **Adaptive simulatability.** An efficient/practical simulatable threshold scheme with  
1869 proven strong unforgeability against adaptive corruptions, possibly in the constructive  
1870 cryptography sense (see §5.2.3).
- 1871 5. **Auditability.** Protocols that generate an auditable proof that the signature was indeed  
1872 produced by a valid threshold interaction (see §5.3.1).

### 1873 6.3. Recommendation for a public call for threshold EdDSA schemes

1874 A public call for threshold signature schemes interchangeable with the standardized Draft  
1875 FIPS 186-5 EdDSA verification could be of great benefit. It would seek to collect reference  
1876 implementations, accompanied by technical explanation and security analysis. The scope  
1877 would include threshold schemes for probabilistic signatures, as well as those with pseudoran-  
1878 dom nonce generation. Such a call would need to provide baseline criteria [Call2021a], such  
1879 as requiring a proof of active security with a minimum requirement of strong unforgeability.  
1880 It should also be flexible to allow submissions across various ranges of number of parties  
1881 and thresholds, security formulations (see Section 5.2), and system models (see Section 5.3).  
1882 Ideally, the distributed computation would be based on cryptographic assumptions close to  
1883 those required for EdDSA security, such as discrete-log and hash-related assumptions. Natu-  
1884 rally, the interest on threshold schemes includes those for other NIST-approved key-based  
1885 cryptographic primitives, including RSA, ECDSA and AES.

1886 Besides the keygen and signing phases, it is useful to consider secret-resharing for proactive  
1887 security, possibly also allowing *dynamic* change of the threshold parameters and number  
1888 of parties. The envisioned call should recommend submissions to be described and imple-  
1889 mented with modularity w.r.t. building blocks (gadgets) that are likely reusable by other  
1890 schemes, or that can have different internal instantiations while having a similar interface.  
1891 The security analysis should describe the security fall-back guarantees or breakdown when  
1892 some of the operational requirements are not met (e.g., exceeded corruption threshold,  
1893 asynchrony or non-reliable message transmission).
