Energy Levels and Spectrum of Neutral Helium (HeI)

William C. Martin

(August 24, 1959)

A table of energy levels based on the most accurate observations now available is given for the neutral ⁴He atom. The wavelengths contained in a revised list of ⁴He I lines from 320 A to 21132 A are also based on the best measurements, over half of them having been calculated from the wavenumber separations of appropriate levels. Several previously disturbing features of the ⁴He term scheme are obviated by the revised level values. In a discussion of the experimental results for this spectrum some comparisons with theory are made.

1. Introduction

It seems important that an up-to-date helium line list and a table of revised energy levels be made generally available. The use of helium in many kinds of spectroscopic sources, in studies of electrical discharge mechanisms and of plasma conditions, and the importance of helium in astrophysics combine to make He I one of the spectra most frequently observed. The most recent essentially complete compilation of helium wavelengths, contained in A Multiplet Table of Astrophysical Interest and An Ultraviolet Multiplet Table [1], appeared in 1945 and 1950. Although these lists have advantages over earlier compilations [2, 3] in having line classifications in modern notation and containing more recent wavelength values, improved measurements of many He I lines have been made since they were published. The most notable of these are probably Herzberg's [4] recent observations, which have decreased the uncertainty in the connection between the ground state and the higher levels about one hundredfold. His measurements, combined with others made since the publication of volume 1 of Atomic Energy Levels [5], have led to the present complete revision of the He I level values. These new level values allow the calculation of helium wavelengths which, for over half the known lines, are believed to be more accurate than the available observed wavelengths.

In pointing out the need for the present revision of the He 1 level values, it may be well to emphasize the special place of two-electron atoms in atomic theory. Since these are the simplest atoms for which exact calculations in either nonrelativistic or Dirac's relativistic wave mechanics cannot at present be made, they furnish excellent testing grounds for the various approximation methods of quantum mechanics and theories of the interaction between electrons. Indeed, until the recent beautiful measurements by Herzberg [4] the theoretically predicted ground-state energy of helium was more accurate than the experimental determination. The fact that Herzberg was able to verify field theory (Lamb) effects in two two-electron atoms (4He and 3He)

illustrates the importance of maintaining as accurate data on the helium-type atoms as contemporary experimental techniques allow.

Naturally, the present discussion of experimental results will stress the more recent observations. The references are mainly to work done since the appearance of volume VII of the *Handbuch der Spectroscopie* [3]. Since the article on helium in that superb work contains a practically complete list of references through 1927, it and this paper together furnish a guide to the principal experimental energy level determinations for ⁴He I to date.

No attempt has been made in this paper to deal with the interesting and important ³He I spectrum. Because of the large percentage mass difference of ³He and ⁴He and because ³He has a nonzero nuclear magnetic moment giving rise to hyperfine structure, the ³He I spectrum differs in detail a good deal from ⁴He I. A reasonably comprehensive article on the experimental results for ³He I would be about as long as this one. Perhaps one of the investigators of that spectrum will supply such an article.

2. Spectrum

Except for a few normally very weak "forbidden" lines, table 1 contains wavelengths for all He I lines which have been observed in the laboratory. It has already been mentioned that well over half these wavelengths were calculated from newly-derived energy level values (see the following section). In the first column of the table, opposite each calculated wavelength, appears a symbol denoting the source of what is probably the most accurate measurement of the line. The symbol in the second column gives the actual source of each wavelength in the table. The meanings of the symbols are given in the appendix following the table.

The wavelengths of the vacuum ultraviolet lines were calculated from adopted level values except for the line at 320.392 A. Wu [6] has made a convincing argument for assigning this line to the transition give in the table. Edlén's [7] suggested classification, $1828 \, ^3S - 282p \, ^3P^{\circ}$, is open to objection since the upper term is subject to autoionization into the $^3P^{\circ}$ continuum above the $1s \otimes p$ series limit. A

¹ Figures in brackets indicate the literature references on pages 22 and 23.

weaker line observed by Kruger [8] at 357.507 A has been the subject of speculation by Kruger himself and by Wu [6] and Holøien [9]. These last two authors find that none of the suggested transitions satisfactorily accounts for both the position and width of the line. For this reason it is not listed here. (Both Wu and Holøien incorrectly state that Compton and Boyce observed this line.)

The original investigation of the helium spectrum in the vacuum ultraviolet was made by Lyman [11], who discovered the resonance series and the intercombination line 591 A. Suga [12] has obtained the resonance series $1s^2$ $^1S_0 - np$ $^1P^\circ_1$ to n=15, as well as the forbidden transitions $1s^2$ $^1S_0 - ns$ 1S_0 to n=7, $1s^2$ $^1S_0 - 2p$, 3p $^3P^\circ_1$, and $1s^2$ $^1S_0 - 3d$ 1D_2 . Bomke [13] had earlier found the lower members of these forbidden series. The most accurate of the older measurements of the He I spectrum in the vacuum ultraviolet were those of Hopfield [14], of Kruger (as given by Paschen [15]), and of Boyce (measurements of the lines 584 A and 537 A given by Boyce and Robinson [16]). Paschen calculated the best absolute value for $1s^2$ 1S_0 as 198307.9 cm $^{-1}$ from Kruger's measurements. From this adopted value for the ground term he then calculated wavelengths for the $1s^2 {}^{1}S_0 - np {}^{1}P^{\circ}_{1}$ series to n=12. Using this procedure, which is essentially that followed here, Boyce and Robinson [16] obtained from Boyce's measurements of the lines 584 A and 537 A what were undoubtedly the best values for the higher resonance lines previous to this paper. They are systematically below the wavelengths in table 1 by only 0.004 to 0.005 A.

The earlier wavelength measurements made in the vacuum ultraviolet region are, of course, superseded by the work of Herzberg [4] and by the values in table 1 based on his work. Herzberg conservatively estimated the uncertainty in his measurements of the lines at 584, 591, and 537 A to be 0.0005 A.

The intensities for the vacuum ultraviolet lines in table 1 are based on those given by Hopfield [14], Compton and Boyce [10], and Kruger [8]. The spectrograms published by Suga [12] were used in an attempt to put these values on a consistent scale. It should be remembered that the relative intensities of these lines are very strongly dependent on the excitation conditions. For most sources, the decreases in the intensities of the higher series members relative to the lowest member would be much sharper than is indicated in table 1. The intensities and, indeed, the appearance or nonappearance of the forbidden lines are especially affected by source conditions.

Care has been taken to assure that the wavelengths given for lines in the air region should also be the best values now available. Almost all of the 192 lines given for this region have been observed, but wavelengths calculated from adopted level differences are considered more accurate than observed values for about half of these. Most of the wavelengths which are taken directly from observation also correspond exactly to the level differences involved, since they were used to determine these differences. Besides the 100 calculated air wavelengths.

the table includes 27 other new air values; these are mostly either unpublished measurements by Shenstone [17] or weighted averages from the literature. The wavenumbers given for some of the calculated lines and for several lines which are averages from observations do not agree in the last significant figure with the wavenumbers which would be obtained by applying the Edlén conversion formula to the corresponding wavelengths in table 1. In these cases it is the wavenumber which is the primary adopted quantity, and the wavelength is taken from the Edlén formula to the number of figures regarded as significant.

Only two "forbidden" lines in the air region are given in table 1. These are measurements by Herzberg [4] of the intercombinations used to determine the relative positions of the singlet and triplet systems. In addition to other intercombination lines, numerous transitions violating the electric-dipoleradiation parity-change rule have been found near the strong allowed lines. The observations of Jacquinot [18] indicate that the forbidden lines are usually less than one-thousandth the strength of the corresponding allowed lines. If the need occurs, their wavelengths can be computed from the corresponding energy level differences.

Normally unobserved forbidden transitions in helium appear quite readily when the radiating gas is in a strong electric field. Investigations of the Stark effect in HeI probably culminated in the beautiful work of Foster [19, 20], whose papers the

reader may consult for other references.

Most investigations of the Zeeman effect in Her carried out in the last 30 years have been concerned with forbidden lines. The work of J. Brochard and P. Jacquinot [21] is rather comprehensive. A noteworthy achievement is the determination of the g_J -value for 2s 3S_1 to an accuracy of 1 ppm by Drake et al. [22] using microwave techniques.

The quantitative intensity measurements of Crosswhite and Dieke [23] show striking changes in the relative intensities of various helium lines when only the gas pressure is changed. As in the vacuum ultraviolet region, the intensities given for lines above 2615 A are not valid for all commonly occurring

excitation conditions.

C. J. Humphreys [24] has very kindly furnished unpublished quantitative intensity measurements for the infrared region beyond 10912 A. His source was an electrodeless tube filled to 3.5 mm (Hg), and care was taken to obtain precise intensities. Humphreys states that the intensity of the triplet at 10830 A is 5 to 10 times that of the singlet line at 20581 A which has intensity 20850 on his scale. Since this intensity ratio would not be much different at the pressure (7.5 mm) at which Crosswhite and Dieke [23] obtained an intensity of 105,000 for the 10830 triplet, it seems that these observers have used very nearly the same scale.

It is hoped that the intensities given in table 1 for lines from 2644 to 21132 A are on this reasonably consistent scale with the relative intensities of the stronger lines being useful for most sources operating at a few millimeters (Hg) pressure of helium.

(The intensities of the weaker lines are especially dependent on excitation conditions other than pressure.) In addition to the article of Crosswhite and Dieke, almost every paper referred to here which gives intensities in the region 2644 to 10912 A has been consulted. The intensities in this region are also based in part on observations made at NBS.

3. Energy Levels

A new square array has been made for the ⁴He i spectrum. The first step in obtaining revised energy level values (based on the value 0.00 for the $1s^2$ 1S_0 ground state) was to fix the $2p^3P_1^{\circ}-2p^4P_1^{\circ}$ and $2p^4P_1^{\circ}-3p^4P_1^{\circ}$ separations. Herzberg [4] observed the vacuum ultraviolet transitions from each of these three odd levels to the ground state with an accuracy of ± 0.0005 A at 500 to 600 A. From the best values for these separations as determined by the relevant observations in the air region, and from Herzberg's wavenumbers for the vacuum ultraviolet lines, the positions of 2p $^3P_1^{\circ}$, 2p $^1P_1^{\circ}$, and 3p $^1P_1^{\circ}$ were fixed as given in table 2. With the ground state thus determined relative to the other energy levels, new values for all levels have been calculated from the best available measurements. The relative positions of the singlet and triplet systems are based primarily on Herzberg's measurements of the intercombination lines 2p 1 P $_1^{\circ}$ —3d 3 D $_2$ (6679.683 A) and 2p 3 P $_1^{\circ}$ —3d 1 D $_2$ (5874.463 A). The resulting positions give good agreement with Mlle. Pilon's measurement [25] of the 3d ³D-3d ¹D separation, and it is unlikely that the intersystem connection is in error by more than 0.02 cm⁻¹. A recent unpublished interferometric measment of $2s \, {}^{1}S_{0} - 2p \, {}^{1}P_{1}^{\circ}$ (4857.454 cm⁻¹) has been combined with the average of two recent interferometric determinations of 2s 'S°-3p 'P1' to obtain the $2p \, {}^{1}P_{1}^{\circ} - 3p \, {}^{1}P_{1}^{\circ}$ separation. Since these measurements (the sources of which are given in table 1) are much more accurate than any other pair determining this separation, its value is based entirely on them. The positions of the higher terms relative to the ground state have been taken so that subtraction of the resulting level values for 2p $^3P_1^{\circ}$, 2p $^1P_1^{\circ}$, and 3p $^1P_1^{\circ}$ from the corresponding "observed" values of Herzberg yields, respectively, -0.11, +0.04, and +0.11 cm⁻¹. Herzberg's estimated uncertainty in the wavenumbers of the observed lines is ± 0.15 ${\rm cm}^{-1}$

The measurements used here to determine the resolved fine structure intervals deserve some discussion, since all of these have been improved in the last few years. The 2p $^3P_1^{\circ}-2p$ $^3P_0^{\circ}$ splitting is taken from the paper of Brochard et al. [26], while the much smaller 2p $^3P_2^{\circ}-2p$ $^3P_1^{\circ}$ interval is a conversion to wavenumbers of the microwave frequency measurements by Wieder and Lamb [27]. (This last measurement gave the 2-1 splitting to a higher accuracy than is shown in the present table—for those who may need this accuracy the result of Wieder and Lamb is 2p $^3P_2^{\circ}-2p$ $^3P_1^{\circ}=2291.72\pm0.36$ Mc/sec.) In 1929 Houston [28] gave the 3p $^3P^{\circ}$ intervals as 2-1=0.02 cm⁻¹ and 1-0=0.27 cm⁻¹. He had not resolved the smaller separation, but guessed at it

from the analogy with the 2p 3 P $^{\circ}$ term and his measurement of the 3p 3 P $^{\circ}_{2,1}$ – 3 P $^{\circ}_{0}$ splitting. At the time the first volume of AEL [5] appeared, it was thought that Houston's measurements had been superseded by those of Gibbs and Kruger [29]. These latter observers found the $3p \, ^3P_2^{\circ} - 3p \, ^3P_1^{\circ}$ and $3p \, ^{3}P_{1}^{\circ} - 3p \, ^{3}P_{0}^{\circ}$ intervals to be 0.165 and 0.192 cm⁻¹, respectively. These results proved in disagreement with theoretical expectations [30], which confirmed Houston's assumption that the ratio of np $^3P_2^{\circ}$ np $^3P_1^{\circ}$ to np $^3P_1^{\circ} - np$ $^3P_0^{\circ}$ should be roughly independent of n. However, only in 1951 did Fred et al. [31] point out that the intervals of Gibbs and Kruger were spurious. The error was apparently caused by self-reversal in the strong unresolved line at 3888 A, which arises from the 2s ${}^3S_1 - 3p \, {}^3P_2^{\circ}$, transitions. Bradley and Kuhn [32] and Brochard et al. [33] also obtained results in essential agreement with the early work of Houston. Brochard et al. [33] first resolved the $3p \, ^3P_2^{\circ} - 3p \, ^3P_1^{\circ}$ splitting, and in 1957 they improved their accuracy [26]. The results of their optical measurements are in excellent agreement with the 3p ³P° intervals given in table 2, which are taken from the very accurate microwave observations by Wieder and Lamb [27]. The 2p and 3p triplet levels are given to four decimal places in table 2 in order to exhibit the accurately known term intervals. The inter-term separations are, of course, not known to this accuracy.

Note added in proof: The results of very recent high-accuracy measurements of the 2p 3 P $^{\circ}$ intervals in He I are given in reference [38].

Theoretical calculations of np $^{3}P^{\circ}$ fine structures in He I have been made by Breit [34] and Araki [30]. A more approximate, but simpler, treatment given in the article of Bethe and Salpeter [35] predicts that the splitting is independent of n except for an overall multiplying factor of n^{-3} . This result holds for any series of terms in a helium-like atom. How well this approximation is obeyed in the 2p and 3p triplets of ⁴He I may be seen from table 3. The fine structure measurements by Brochard et al. [26] yield the results shown in table 4 for the 3d 3D and 4d 3D terms. The quite small ${}^3D_3 - {}^3D_2$ intervals $(0.0030 \pm$ $0.0008~{\rm cm^{-1}}$ for 3d, and 0.0018 ± 0.001 for 4d) are not accurately enough measured to check on the constancy of the interval ratio given in the table, and the values given can only be taken as indicative. Brochard et al. [26] compare their observations of all the known 4He I fine-structure intervals with the results of various theoretical calculations

The new positions given in table 2 for the 4f ¹F° and 4f ³F° terms are based primarily on Mlle. Pilon's measurements [25] of the 4d ¹D-4f ¹F° and 4d ³D-4f ³F° separations. To a lesser extent they are also based on the measurements by C. J. Humphreys and H. J. Kostkowski [36] of the infrared transitions from the 4f terms to 3d terms. The agreement is within the expected error of Humphreys and Kostkowski, and the 5f terms positions given here are based entirely on their measurements.

In his investigations of the Stark effect in He I, J. S. Foster [19] observed transitions to the 2p ¹P° level from terms of every possible L-value belonging

to the configurations 1s 5l, 6l, and 7l. Since his measurements were made in rather strong electric fields, they cannot be used directly to obtain unperturbed energy levels. From a comparison of Foster's estimated wavelengths for certain transitions at zero field with those calculated from the 6f and 7f term values in table 2, it appears that his wavelengths are probably systematically slightly in error. However, approximate term values have been obtained from Foster's work by using his measured separations of the lines in a group $2p \, {}^{1}P_{1}^{\circ} - nl^{3,1}L$ from one of these lines whose zero-field wavenumber was known. These separations could be corrected to zero-field strength by comparing Foster's nd ¹Dnp P° separation with the known zero-field separation of these levels for each n. The term positions were also based on values found from plotting the very regular Rydberg denominators, particularly in the case of the 7*l* terms. In this manner the positions of terms belonging to the 5g, 6g, 6h, 7g, and 7h configurations have been calculated and included in table 2.

New level values based on recent improved series measurements and the accurate connection between the singlet and triplet systems have obviated several features of the He-atom energy level scheme which were previously disturbing. The best previous list of helium energy levels (AEL [5], vol. 1), following Paschen-Götze, had the nf singlet series members falling below the corresponding triplets from n=5on. (Indeed, Humphreys and Kostkowski [36] listed both 4f ¹F° and 5f ¹F° slightly below the corresponding 3F° terms on the basis of their improved measurements in the infrared—however, they also assumed the old Paschen-Götze singlet-triplet connection based on series limit determinations.) Similarly, the earlier data indicated that the nd ¹D series crossed over and fell below the nd ³D series at n=9. It is now clear that this puzzling behavior was not real. Shenstone's much improved measurements [17] of the nd triplet and singlet series from 8d on showed that the apparent crossing-over of those series at 9d was due to inaccurate observations. His measurements were essentially confirmed and the singlet series extended to 18d by Herzberg [4]. The new connection between the singlet and triplet systems, which raises the singlet system about 0.10 cm⁻¹ relative to the triplets, has removed the slight crossingover at 13d which remained after Shenstone's work. This accurate connection is also mainly responsible for rendering the nf series quite regular with the singlets probably slightly above the triplets. The observations are, however, not sufficiently accurate above 4f to fix the relative positions of the terms. One can say, however, that beyond 5f the Fo terms are probably not separated from the corresponding ³F° terms by more than 0.1 cm⁻¹.

The energies for members of the series np ¹P° from 11p on are taken from a series formula. Paschen and Götze apparently thought this method would give better values than any measurements available to them; since there have been no new observations, the series has been recalculated to 20p. Higher members of the ³P° series were obtained by con-

verting wavelengths from Paschen-Götze to vacuum wavenumbers according to Edlén's tables. Several numerical errors occurring in Paschen-Götze have been corrected.

Combining the limits obtained by Herzberg [4] for three separate series with energies for the three appropriate fixed terms from the new array yields the following values for the ionization energy of helium:

From the series 3d 3D —nf 3F $^\circ$:

3d $^{3}D + limit = 186101.65 \text{ cm}^{-1} + 12209.20 \text{ cm}^{-1} = 198310.85 \text{ cm}^{-1};$

from the series 2p $^3\mathrm{P}^{\circ}{}_{2,1}$ —nd $^3\mathrm{D}$:

 $2p \, {}^{3}P^{\circ}_{2,1} + \text{limit} = 169086.89 \, \text{cm}^{-1} + 29223.90 \, \text{cm}^{-1} = 198310.79 \, \text{cm}^{-1};$

from the series $2p \, {}^{1}\mathrm{P}^{\circ}_{1}$ — $nd \, {}^{1}\mathrm{D}_{2}$:

 $2p \, {}^{1}P^{\circ}{}_{1} + \text{limit} = 171135.00 \, \text{cm}^{-1} + 27175.78 \, \text{cm}^{-1} = 198310.78 \, \text{cm}^{-1}.$

The average of these values, 198310.81 cm⁻¹, is in excellent agreement with the experimental ionization energy of ⁴He adopted by Herzberg in his paper, 198310.82±0.15 cm⁻¹. The spread in the three values obtained here is reduced from that obtained by Herzberg, no doubt because the available data have already been averaged once in obtaining values for the fixed term of each series.

In conclusion, it might be mentioned that the excellent article by Bethe and Salpeter [35] on the theory of one- and two-electron atoms gives numerous references to theoretical work on helium-like atoms through 1956. The informative paper by Bengt Edlén [37] on experimental results for the He I isoelectronic sequence will also prove helpful to those interested in two-electron atoms.

Charlotte E. Moore has made available the extensive files of spectroscopic literature kept by her in this laboratory. She has also been of much assistance in deciding on matters of notation and format. The author expresses his gratitude for her support in this work.

Prof. A. G. Shenstone of Princeton, Dr. G. Herzberg of the National Research Council in Ottawa, and Dr. C. J. Humphreys of the U.S. Naval Ordnance Laboratory, Corona, Calif., have supplied unpublished data on the helium spectrum. The kindness of each is greatly appreciated.

^{*}From 10912 A on, the intensities are measurements by C. J. Humphreys [24].

Explanation of Symbols

- C—Wavelength calculated from vacuum wavenumber difference of relevant energy levels from table 2.
- CS—Same as C, the upper energy level being obtained from a series formula.
- B-Rs—J. C. Boyce and H. A. Robinson, J. Opt. Soc. Am. **26**, 133 (1936). Hp—J. J. Hopfield, Astrophys. J. **72**, 133 (1930).

 - Hu-C. J. Humphreys, unpublished wavelength, privately
- communicated to author, August 1959. Hu-Ko—C. J. Humphreys and H. J. Kostkowski, J. Research NBS 49, 73 (1952)
- Hu-Pl-C. J. Humphreys and E. Paul, Jr., NAVORD Report 4589, 25 (1956); J. Opt. Soc. Am. 46, 999 1956)
 - Hz-G. Herzberg, Proc. Roy. Soc. (London) [A] 248, 309 (1958)
 - Hz*—The air wavelength given for this line by Herzberg (above) is incorrect; the wavelength in his paper is actually the vacuum wavelength.
 - Hz†—Unpublished observations by Herzberg, privately communicated to the author. Of these lines, only 8776 A has been previously recorded (P-Rt) Herzberg's observed value of 8776.725 ± 0.02 A is in good agreement with the calculated wavelength. The value 8518.040 ± 0.02 A from Herzberg figured in determining the position of $8p^{-1}P_{1}^{\circ}$, and his measurement of 8444 A is the same as the calculated value.

 - Kg—P. G. Kruger, Phys. Rev. **36**, 855 (1930). Mt—W. C. Martin, J. Opt. Soc. Am. (to be published). The vacuum wavelengths given in table 2 of this reference have been converted to air values according to the formula of Edlén. These wavelengths were further decreased by 0.0002 A for inclusion here because such a correction to the values assumed by Martin for the mercury-198 standards at 5462 A and 4359 A appeared probable at the time the new array was worked out. It now appears the correction should at most have been -0.0001 A; except for 5015 A, either correction is insignificant compared to the
 - probable errors. Me—P. W. Merrill, Bul. BS **14,** 159 (1917); Astrophys. J. 46, 357 (1917). Merrill's wavelengths have all been increased by 0.002 A because of a systematic difference found to exist throughout the visible range between his measurements and those of Martin (above).

^{*}Although it is not possible to give the unperturbed position of these terms, Foster [19] found transitions from them to $2p \cdot P^{\circ}$ in the spectrum emitted by helium atoms in a strong electric field.
b Level value found by plotting the Rydberg denominators of the $ns \cdot \mathbb{I}S$ series.
c The $np \cdot \mathbb{I}P^{\circ}$ levels were obtained from a series formula from $\mathbb{I}1p$ on.
d An incorrect value was given for this term by Paschen-Götze. The wavelength listed there for the transition $2p \cdot \mathbb{I}P_1^* - 13s \cdot \mathbb{I}S_0$ is in error.

Table 3. Fine-structure regularities observed for the 2p and 3p triplets in He i.

np	$\frac{{}^{3}P_{2}^{\circ}-{}^{3}P_{0}^{\circ}}{{}^{3}P_{2}^{\circ}-{}^{3}P_{1}^{\circ}}$	n ³ (³ P ₂ ° - ³ P ₀ °)
$\frac{2p}{3p}$	13. 9 13. 3	8. 523 cm ⁻¹ 7. 90

 $^{\circ}$ The value given for this term in Paschen-Götze is incorrect. f The energy for this term was calculated from a series formula. The values of Paschen-Götze for 18d, 19d, $^{3}\mathrm{D}$ are in disagreement with those of Herzberg by about 0.5 cm $^{-1}$.

Table 4. Observed fine-structure ratios and n^{-3} dependence for the 3d and 4d triplets of He I.

nd	$\frac{{}^{3}\mathrm{D}_{3} - {}^{3}\mathrm{D}_{1}}{{}^{3}\mathrm{D}_{3} - {}^{3}\mathrm{D}_{2}}$	$n^3(^3\mathrm{D}_3 - ^3\mathrm{D}_1)$
