Preparation and Heat of Formation of a Magnesium Oxysulfate

E. S. Newman

(June 10, 1964)

Magnesium oxysulfate, $3\text{Mg(OH)}_2\cdot\text{MgSO}_4\cdot8\text{H}_2\text{O}$, was precipitated from metastable aqueous solutions of MgO in MgSO$_4$. The compound forms in solutions containing 12 percent or more of MgSO$_4$, but at lower concentrations is converted to Mg(OH)$_2$. Magnesium hydroxide is not converted to the oxysulfate by nearly saturated MgSO$_4$ solutions in times up to three years. The solubility of the oxysulfate is given in the form of a plot of the basicity and MgSO$_4$ content of magnesium sulfate solutions. The heat of solution of the oxysulfate compound in HCl-26.61H$_2$O (2.00N normal at 25°C) is 68.94 kcal/mole with a standard deviation of 0.23 kcal/mole and its heat of formation from Mg(OH)$_2$, MgSO$_4$, 7H$_2$O, and liquid water is $\Delta H = 2.11$ kcal/mole. The corresponding heat of formation from the elements is $\Delta H_f = -1537.9$ kcal/mole.

1. Introduction

Magnesium oxychloride and magnesium oxysulfate cements have long been known and used for a variety of purposes, for example as binders in flooring or in insulating materials. In 1952 Newman, Gilrich, and Wells [1], and in 1955 Newman [2], published the results of thermochemical studies of the system MgO-MgCl$_2$-H$_2$O at 25°C. The present paper presents a similar study of the system MgO-MgSO$_4$-H$_2$O at 25°C.

In 1957 Demediuk and Cole [3] reviewed the previous work on the system MgO-MgSO$_4$-H$_2$O. In addition, they studied the reactions occurring in the system at MgSO$_4$ concentrations up to saturation and at temperatures from 30 to 120°C. Four oxysulfates, 5Mg(OH)$_2$-MgSO$_4$, 2H$_2$O, 3Mg(OH)$_2$-MgSO$_4$-8H$_2$O, Mg(OH)$_2$-MgSO$_4$-5H$_2$O, and Mg(OH)$_2$-2MgSO$_4$-3H$_2$O, were found, and a diagram was presented showing the conditions of stability of each. Only 3Mg(OH)$_2$-MgSO$_4$-8H$_2$O, hereafter referred to as the 3:1:8 compound, was found at temperatures below about 35°C. X-ray powder diffraction patterns of each of the compounds were given.

Recently Adomaviciute and coworkers [4] reported the formula $3\text{Mg(OH)}_2\cdot2\text{MgSO}_4\cdot5\text{H}_2\text{O}$ for the only oxysulfate formed at 20 ± 2°C. These workers gave x-ray patterns also and differential thermal analyses (DTA's), as well as curves showing the solubility of the compound (expressed as grams of titratable MgO per liter) in magnesium sulfate solutions of various concentrations. They found Mg(OH)$_2$ in hardened magnesian cement and, from x-ray and DTA data, suggested the possibility that the formation of oxysulfate occurs in cements only above a MgSO$_4$/MgO ratio of 0.6.

No thermochemical data for the oxysulfates have been found in the literature. In the present work, only the 3:1:8 compound was found at room temperature, and this paper is concerned with its preparation and the determination of its heat of formation. The heat of reaction of Mg(OH)$_2$, MgSO$_4$, 7H$_2$O, and H$_2$O to form the compound was determined from the heats of solution or dilution of these reactants and of the compound in HCl-26.61H$_2$O (2.00N at 25°C), and the heat of formation was calculated from this heat of reaction and heats of formation taken from the literature [5].

2. Materials, Apparatus, and Procedure

2.1. Formation of the 3:1:8 Compound

The compound was prepared by precipitation from metastable solutions of MgO in concentrated solutions of MgSO$_4$, or by reaction of the latter with solid MgO. Concentrated aqueous solutions were prepared from distilled water and MgSO$_4$-7H$_2$O of reagent quality. In some cases the solutions were boiled to remove CO$_2$ and cooled, protected by a CO$_2$ absorption tube, but this procedure was found unnecessary and discontinued. Generally 4 liters of nearly saturated solution was used. Clear metastable solutions of MgO were prepared by shaking the MgSO$_4$ solutions with 30 g of reagent-grade MgO freshly heated at 500°C. After about 2 hr at room temperature the solutions were filtered and allowed to stand. Precipitation of the 3:1:8 compound began in a few hours and continued slowly for 10 days or more. These concentrated, rather viscous solutions
of MgSO₄ were slow and difficult to filter and usually retained a few milligrams of material as a hazy suspension. Consequently, and also in order to encourage the formation of larger crystals, less MgO was used (usually 4 g and occasionally as little as 1.5 g), filtration was omitted, the solution was sometimes seeded, and the suspension was stirred continuously with a magnetic stirrer for periods up to two weeks. The precipitate, which in every case gave the x-ray pattern of the 3:1:8 compound, was recovered by filtration, suspended by stirring in methanol, refiltered and washed with more methanol, and dried at room temperature at about 20 mm Hg pressure in vacuum desiccators over saturated MgCl₂·6H₂O or MgSO₄·7H₂O solution. The former solution maintains air at a relative humidity of 33 percent; the humidity over the latter solution is much higher.

Reagent-quality MgSO₄·7H₂O was recrystallized, washed briefly with methanol, crushed to pass a No. 16 sieve, and stored in 1-g quantities in weighing bottles in partial vacuum over saturated MgSO₄·7H₂O solution. When the samples reached constant weight, their heats of solution were determined in 2.000 N HCl.

### 2.2. Determination of Solubility

In order to obtain information about the solubility and stability of the 3:1:8 compound in MgSO₄ solutions at 25 °C, solubility equilibrium was sought from both super- and under-saturation. Several groups of three series of solutions of MgSO₄ of differing concentrations were prepared and kept in 1-liter polyethylene bottles as: A, clear unstable solutions of MgO; B, suspensions of 2 g of Mg(OH)₂; and C, suspensions of 3:1:8 oxysulfate. The A series was intended to approach equilibrium from supersaturation, and the B and C series, with originally zero concentration of titratable MgO, to approach from under-saturation. These bottles were shaken by hand periodically, and the tests were continued for several years. Later, the three series were prepared and kept in continuous gentle agitation for as long as two years on a 20-in. wheel rotating at about 15 rpm. From time to time the bottles were removed from the wheel and allowed to stand quiescent overnight. Samples of the clear supernatant liquid were taken for titration with standard HCl solution and phenolphthalein indicator, and the solid phases present were examined under a microscope and by x-ray patterns. The basicity obtained by titration was calculated and reported as grams of MgO per liter. When it became evident that little further change in basicity was likely to occur, the solid was recovered by filtration, washed with methanol, and dried at 33 percent rh. X-ray patterns and analysis of some of these precipitates were obtained.

### 2.3. Analyses of Precipitates

In the beginning, analyses were performed by standard methods [6, 7], SO₃ being determined by precipitating and weighing as BaSO₄ and MgO being determined gravimetrically by the pyrophosphate method. It was found that the CO₂, SiO₂, Fe₂O₃+Al₂O₃ etc., and CaO found by the usual procedures differed little from the blank determinations and were sometimes smaller. Consequently, in the later part of the work SO₃ was determined gravimetrically as before, and total MgO was determined as the residue when the sample was ignited to 1200 °C. Tests showed that the results obtained agreed with those obtained by the pyrophosphate method and that SO₃ was absent in such heated residues, confirming the work of Schnitzer, Wright, and Hoffman [8] and the results of DTA's showing decomposition of MgSO₄ at 1135 °C. The water content was determined by difference. For the later samples to be used in the calorimeter, the material to be analyzed was divided into 0.5-g, 1-g, and 2-g portions in weighing bottles. These samples were equilibrated over MgSO₄ or MgCl₂ solutions, as described earlier, and weighted periodically. When the weights became essentially constant, the two smaller sized samples were used for analysis, and heat-of-solution determinations of the 2-g samples were begun. Periodic weighing of calorimeter samples was continued until the heat of solution was measured, and the water content at that time calculated from the weight record and the analytical results. In some cases, calorimeter samples which had been held, together with the analytical samples, over one saturated solution were transferred to the in order to change the water content. Earlier calorimeter samples were simply weighed out from a stock bottle of oxysulfate that had been equilibrated at 33 percent rh and analyzed.

### 2.4. Differential Thermal Analyses

Differential thermal analyses were performed with apparatus described elsewhere [9]. Samples of about 0.5 g were used, with alumina as the inert reference material, and a heating rate of about 12 deg/min was maintained. Temperatures of about 1250 °C were reached.

### 2.5. Calorimetric Measurements

Heats of solution were obtained with an isothermal-jacket platinum calorimeter described elsewhere [10]. The electrical-energy equivalent of the calorimeter was determined using instruments calibrated by the Electrical Division of the National Bureau of Standards, the time of heating being controlled by a relay activated by the standard seconds signal. Heats of solution are reported in thermochemical calories of 4.1840 absolute joules. In order to determine the effect of gross changes in the water content of the 3:1:8 oxysulfate on its heat of solution, samples were heated or otherwise dehydrated to various extents and their heats of solution determined. X-ray patterns of some of these partially dehydrated samples were obtained.
3. Results and Discussion

3.1. Formation and Solubility of the 3:1:8 Oxsulfate

Figure 1 shows, expressed as grams of MgO per liter, the basicity of metastable solutions obtained by shaking MgO for 2 hr with MgSO₄ solutions of various strengths. Two hours is about the optimum shaking time for these conditions, since the oxysulfate begins to precipitate soon thereafter. From these solutions this compound was formed in every case if the concentration equaled or exceeded 15 percent of MgSO₄. In more dilute solutions, only Mg(OH)₂ was formed.

Figure 2 shows the change of concentration of titratable MgO with time for typical solutions of the A, B, and C series. The concentrations for the A series, at first rather high, decreased as the oxysulfate was precipitated. The curves given by Adomaviciute et al. [4] are quite similar. The concentration of MgO in the B and C series rose rapidly from zero initially to a value dependent on the MgSO₄ concentration, near which it remained thereafter. These values were approximately those finally reached after longer times by the solutions of the A series.

In figure 3 are plotted the MgO concentrations obtained at 8 months for A, B, and C series kept on the wheel for the full time, plotted as a function of the MgSO₄ concentration of the solution (given as percentage MgSO₄·7H₂O). The scatter of the points was not reduced by longer times. This figure is not a true equilibrium diagram, since x-ray patterns showed that, for instance, Mg(OH)₂ remained unchanged even at MgSO₄·7H₂O concentrations up to 50 percent where the 3:1:8 compound was precipitated from the A (unstable solution) series, while the oxysulfate remained unchanged in a 20 percent solution although it would not form in solutions containing less than 25 percent.

Also plotted in figure 3 are the 6-month results obtained by Adomaviciute et al. [4], at 20±1 °C. These values are generally somewhat lower than the results found in the present work, as might be expected because of the lower temperature. The Russian work is equivalent to the A series of the present investigation. The vertical lines in figure 3 marked “A, 25 °C” and “A, 20 °C” represent the saturation limit of MgSO₄·7H₂O [11]. The Russian workers remark on the presence of crystals of this compound in their more concentrated solutions.

It must be pointed out that in the present work only the 3:1:8 oxysulfate and Mg(OH)₂ were found to form, while the Russian authors report the composition of the oxysulfate as 3Mg(OH)₂·2MgSO₄·5H₂O.

Figure 1. Basicity of magnesium sulfate solutions after 2-hr shaking with an excess of freshly calcined MgO.

Figure 2. Basicity of magnesium sulfate solutions.

Figure 3. Basicity of magnesium sulfate solutions after 8-months agitation.
The present author believes this disagreement to be due to the differing methods of recovering the precipitated oxysulfate. Adomaviciute and coworkers first dried their preparations at a temperature not exceeding 100 °C, then washed with methanol, and redried to constant weight. They comment on the incomplete removal of MgSO₄ due to incomplete washing. Demediuik and Cole [3] warn that magnesium sulfate hydrates containing less than seven molecules of water are difficultly soluble in methanol and used a procedure designed to avoid their formation.

Magnesium sulfate heptahydrate loses four molecules of water when heated to 106 °C [12], and at temperatures above 68 °C the monohydrate is the stable phase in contact with solution [11]. The 3:1:8 oxysulfate was found to lose four molecules of water at 105 °C. It would appear that the somewhat variable composition reported by the Russian workers might be formed by a suitable mixture of the probable components MgSO₄·nH₂O and 3Mg(OH)₂·2MgSO₄·nH₂O. On the other hand, the compositions of the present author's preparations, table 1, were not exactly 3:1:8 either, Mg(OH)₂ and H₂O generally being slightly below the proportions of 3 and 8 respectively. It is believed that here, also, incompletely removed magnesium sulfate is largely responsible for the low Mg(OH)₂/MgSO₄ ratios. However, a 3.5 g sample of preparation 6 with a ratio of 2.83 (table 1) was stirred with 350 ml of methanol, and the liquid analyzed periodically for SO₃. Agitation in methanol for 5 min increased the calculated ratio of the suspended solid to 2.90; no further dissolving of magnesium sulfate from the sample occurred in 6 hr. Ample methanol was present to dissolve several grams of MgSO₄·7H₂O. A small amount of magnesium sulfate may be too strongly bound to the compound for removal with methanol, the true composition may be slightly different from 3:1:8, or the inevitable errors in analysis may be responsible for most of the apparent deviations. Small differences in water content are to be expected, due to variations in attaining vapor-pressure equilibrium between the samples and the atmosphere in which they were kept.

### 3.2. Differential Thermal Analyses

Differential-thermal-analysis curves obtained for three oxysulfate preparations are shown in figure 4. With the aid of oven-heating experiments and x-ray patterns obtained at various stages, the following conclusions were drawn:

- Peak A at 100 to 140 °C represents the loss of four molecules of water with the formation of a material giving a different x-ray pattern than does the 3:1:8 oxysulfate. The equivalent oven temperature is about 105 °C.
- Peak B at 205 to 230 °C represents the heat effect accompanying the loss of three more molecules of water and the collapse of the structure so that no lines appeared on the x-ray pattern. An oven temperature of 183 °C gave the same result.
- Peak C at 430 to 460 °C represents the loss of most of the rest of the water. The x-ray pattern of MgO with a few lines of MgSO₄ was obtained. An oven temperature of 425 °C gave the same result. This is the approximate temperature at which Mg(OH)₂ loses its water when heated alone.
- Peak D at 630 to 645 °C accompanied the loss of a small amount of water and the formation of MgSO₄ according to the x-ray pattern. It is this peak, together with x-ray data, on which Adomaviciute and coworkers based their conclusion that the oxysulfate was present in cement samples. Certain forms of magnesium carbonate also show an endothermic reaction in this range. The corresponding oven temperature was 600 °C.
- Peaks E and F represent, respectively, a reversible transition of MgSO₄ at 1020 to 1028 °C, similar to those found for CaSO₄ and BaSO₄ at higher temperatures, and the decomposition of MgSO₄ to MgO and SO₃ at 1118 to 1135 °C.

3.3 Heats of Solution

In table 1 are listed the measured heats of solutions of 11 preparations of the 3:1:8 oxytsulfate. Samples of 2 g were dissolved in 740.00 g of HCl-26.61 H₂O, and in thermochemical calculations the heats of solution of approximately equivalent weights of Mg(OH)₂ and MgSO₄·7H₂O were used. Details of electrical calibration of the calorimeter have been given elsewhere [13]. The electrical-energy equivalent of the calorimeter was 28,450.5 J/ohm with a standard error of 3.8 J/ohm.

Since the samples listed in table 1 do not conform exactly to the composition of the pure compound 3Mg(OH)₂·MgSO₄·8H₂O, a three-constant first-degree equation relating the heat of solution to the composition of the sample was fitted to the 45 determinations of table 1 by the method of least squares on an electronic computer. The heat of solution of the compound was determined mathematically from its calculated composition and the coefficients of the equation. It has been more usual to calculate the constitution of samples in terms of the probable impurities, e.g., 3Mg(OH)₂·MgSO₄·nH₂O, MgSO₄·nH₂O, and Mg(OH)₂, making assumptions of the values of m and n, and compute a corrected heat of solution for each determination in table 1. However, the calculated quantities would themselves be linear in terms of the composition of the samples, so it seemed equally correct to make the computation as described. A heat of solution of 656.22 J/g (156.84 cal/g, 68.94 kcal/mole) was obtained for the predicted value. The standard deviation of this predicted value [14] was 2.21 J/g (0.53 cal/g, 0.23 kcal/mole).

That this type of computation must not be carried too far from the composition region represented by the data is demonstrated by the data shown in figure 5. In this figure are plotted the heats of solution of partially or completely dehydrated portions of sample 2 of table 1 as a function of n, the water content in moles per mole of SO₄. A single straight line does not fit these data, either a curve or two straight lines intersecting at about n=4 giving a much better fit. This value of n would correspond to the composition of a sample constituted of 3Mg(OH)₂ and MgSO₄·nH₂O. The x-ray pattern of such a sample contained no lines, apparently the structure was insufficiently developed. The heats of solution of various mixtures calculated from the individual heats of solution of probable components are plotted as closed circles in figure 5. At n=0 and n=7 and 11, there is good agreement between the experimental and calculated values. At n=0 the agreement is good because the sample as shown by the x-ray pattern does consist of a mixture of MgO and MgSO₄ as assumed in calculating the heat of solution, at n=7 and 11 the differences are small because of the small heat of reaction of Mg(OH)₂ and MgSO₄·nH₂O to form the oxytsulfate. Heats of solution calculated from the equation used to predict the heat of solution of the 3:1:8 oxytsulfate agree with the experimental values only in the range n=10 to 11. The solid line in figure 5 represents these calculated values. The line is curved because n is not linear with percentage composition. The 11 experimental points shown individually in figure 5 were not used in determining the equation.

An average value for the heat of solution of MgSO₄·7H₂O in HCl-26.61 H₂O of -151.38 J/g with a standard error of 1.83 J/g was obtained for six determinations. The corresponding ΔH of solution at 25 °C is +8.92 kcal/mole with a standard error.
of 0.11 kcal/mole. These determinations were made in the standard acid charge of 740 g (1.43 moles) of HCl/26.61H2O without prior addition of 0.82 g of Mg(OH)2 (corresponding to a 2-g sample of the 3:1:8 oxysulfate), thereby neglecting the small heat effect due to the presence of 0.014 moles of MgCl2 in the solution.

Taylor and Wells [15] give the value \(-26.64\) kcal/mole for the \(\Delta H\) of solution of brucite (Mg(OH)2) in 2.085 molal HCl and discuss the dilution corrections necessary to apply to this measurement. Using their values to adjust their result to the final concentrations 0.0185 molal in MgCl2 and 2.0444 molal in HCl used in the present work, a \(\Delta H\) of solution of \(-26.65\) kcal/mole was obtained and used in following computations.

The partial molal heat content of water in 2.09 molal HCl [16,17] was used to represent the \(\Delta H\) of solution of water. With these data the following thermochemical equation was written:

\[
3\text{Mg(OH)}_2(e, \text{brucite}) + \text{MgSO}_4\cdot7\text{H}_2\text{O(c)} + \text{H}_2\text{O(liq)} \rightarrow 3(-26.65) + 8.92 -0.02
\]

\[
3\text{Mg(OH)}_2\cdot\text{MgSO}_4\cdot8\text{H}_2\text{O} (c) -68.94 \text{ kcal/mole.}
\]

The heat of the indicated reaction is therefore 2.11 kcal/mole. The estimated uncertainty of this result, using the value \(+0.01\) kcal for brucite given by Taylor and Wells [15] and combining calibration and reaction errors as recommended by Rossini [18], is 0.57 kcal/mole.

### 3.4. Heat of Formation

Using data from the literature [5] for the heats of formation of the compounds from the elements, together with the heat of reaction calculated above, the heat of formation of the 3:1:8 oxysulfate from the elements is calculated to be \(\Delta H^0 = -1537.9\) kcal/mole. The uncertainty of this figure in addition to the 0.57 kcal/mole indicated above depends on the uncertainty of the heats of formation used in its computation. The values 221.00, 808.7, and 68.3174 kcal/mole were used for the \(\Delta H^0\) of brucite, magnesium sulfate heptahydrate, and liquid water, respectively.

### Summary

At 25 °C the magnesium oxysulfate compound 3Mg(OH)2·MgSO4·8H2O precipitates spontaneously from metastable solutions of MgO in aqueous MgSO4 solutions more concentrated than 12 percent or may be formed by the reaction of such solutions with solid MgO. The oxysulfate will remain unchanged indefinitely in aqueous solutions containing 10 percent or more of MgSO4, but at lower concentrations is converted to Mg(OH)2. Magnesium hydroxide remains unchanged by exposures to MgSO4 solutions of any concentration up to 25 percent for periods up to three years, but dissolves slightly to give alkalinity to the solutions approximating that finally reached by dissolving MgO and allowing Mg(OH)2 or the oxysulfate compound to precipitate.

The heat of solution of the oxysulfate in HCl/26.61H2O (2.000 N at 25 °C) was found to be \(\Delta H = -68.94\) kcal/mole with a standard deviation of 0.23 kcal/mole, and that of MgSO4·7H2O was found to be \(\Delta H = +8.92\) kcal/mole with a standard error of 0.11 kcal/mole. The heat of reaction of Mg(OH)2 (brucite), MgSO4·7H2O and liquid water to form the 3:1:8 compound was found to be, using data from the literature, \(\Delta H = +2.11\) kcal/mole. The corresponding heat of formation from the elements was calculated to be \(\Delta H^0 = -1537.9\) kcal/mole.
